In order to extend the computation power and efficiency of the population protocol model, various extensions were suggested. Our contribution is an extension of the population protocol model that introduces the notion of “speed”, in order to capture the fact that the mobile agents move at different speeds and/or have different communication ranges and/or move according to different patterns and/or visit different places with different frequencies. Intuitively, fast agents which carry sensors with big communication ranges communicate with other agents more frequently than other agents do. This notion is formalized by allocating a cover time, cv, to each mobile agent v. cv is the minimum number of events in the whole system that occur before agent v meets every other agent at least once. As a fundamental example, we have considered the basic problem of gathering information that is distributed among anonymous mobile agents and where the number of agents is unknown. Each mobile agent owns a sensed input value and the goal is to communicate the values (as a multi-set, one value per mobile agent) to a fixed non-mobile base station (BS), with no duplicates or losses.

Gathering is a building block for many monitoring applications in networks of mobile agents. For example, a solution to this problem can solve a transaction commit/abort task in MANETs, if the input values of agents are votes (and the number of agents is known to BS). Moreover, the gathering problem can be viewed as a formulation of the routing problem in Disruption Tolerant Networks.

We gave different solutions to the gathering in the model of mobile agents with speed and we proved that one of them is optimal.

6.10. Making Population Protocols Self-stabilizing

Participants: Joffroy Beauquier, Janna Burman, Shay Kutten, Brigitte Rozoy.

As stated in the previous paragraph, the application domains of the population protocol model are asynchronous large scale networks, in which failures are possible and must be taken into account. This work concerns failures and namely the technique of self-stabilization for tolerating them.

Developing self-stabilizing solutions (and proving them) is considered to be more challenging and complicated than developing classical solutions, where a proper initialization of the variables can be assumed. This remark holds for a large variety of models and hence, to ease the task of the developers, some automatic techniques have been proposed to transform programs into self-stabilizing ones.

We have proposed such a transformer for algorithms in the population protocol model introduced for dealing with resource-limited mobile agents. The model we consider is a variation of the original one in that there is a non mobile agent, the base station, and that the communication characteristics (e.g. moving speed, communication radius) of the agents are considered through the notion of cover time.

The automatic transformer takes as an input an algorithm solving a static problem and outputs a self-stabilizing solution for the same problem. To the best of our knowledge, it is the first time that such a transformer for self-stabilization is presented in the framework of population protocols. We prove that the transformer we propose is correct and we make the complexity analysis of the stabilization time.
6.11. Self-stabilizing synchronization in population protocols with cover times

**Participants:** Joffroy Beauquier, Janna Burman, Shay Kutten, Brigitte Rozoy.

Synchronization is widely considered as an important service in distributed systems which may simplify protocol design. Phase clock is a general synchronization tool that provides a form of a logical time. We have developed a self-stabilizing phase clock algorithm suited to the model of population protocols with cover time. We have shown that a phase clock is impossible in the model with only constant-state agents. Hence, we assumed an existence of resource unlimited agent - the base station. The clock size and duration of each phase of the proposed phase clock tool are adjustable by the user. We provided application examples of this tool and demonstrate how it can simplify the design of protocols. In particular, it yields a solution to Group Mutual Exclusion problem.

6.12. Impossibility of consensus for population protocol with cover times

**Participants:** Joffroy Beauquier, Janna Burman.

We have extended the impossibility result for asynchronous consensus of Fischer, Lynch and Paterson (FLP) to the asynchronous model of population protocols with cover times. We noted that the proof of FLP does not apply. Indeed, the key lemma stating that two successive factors in an execution, involving disjoint subsets of agents, commute, is no longer true, because of the cover time property. Then we developed a completely different approach and we proved that there is no general solution to consensus for population protocols with cover times, even if there is a single possible crash. We noted that this impossibility result also applies to randomized asynchronous consensus, contrary to what happens in the classical message-passing or shared memory communication models, in which the problem is solvable inside some bounds on the number of faulty processes. Then, for circumventing these impossibility results, we introduced the phase clock oracle and the S oracle, and we shown how they allow to design solutions.

6.13. Routing and synchronization in large scale networks of very cheap mobile sensors

**Participants:** Joffroy Beauquier, Brigitte Rozoy.

In a next future, large networks of very cheap mobile sensors will be deployed for various applications, going from wild life preserving or environmental monitoring up to medical or industrial system control. Each sensor will cost only a few euros, allowing a large scale deployment. They will have only a few bit of memory, no identifier, weak capacities of computation and communication, no real time clock and will be prone to failures. Moreover such networks will be fundamentally dynamic. The goal of this subject is to develop the basic protocols and algorithms for rudimentary distributed systems for such networks. The studied problems are basic ones, like data collection, synchronization (phase clock, mutual exclusion, group mutual exclusion), fault tolerance (consensus), automatic transformers, always in a context of possible failures. A well known model has already been proposed for such networks, the population protocol model. In this model, each sensor is represented by a finite state machine. Sensors are anonymous and move in an asynchronous way. When two sensors come into range of each other ("meet"), they can exchange information. One of the vast variety of motivating examples for this model is ZebraNet. ZebraNet is a habitat monitoring application in which sensors are attached to zebras in order to collect biometric data (e.g., heart rate, body temperature) and information about their behavior and migration patterns. Each pair of zebras meets from time to time. During such meetings (events), ZebraNet’s agents (zebras’ attached sensors) exchange data. Each agent stores its own sensor data as well as data of other sensors that were in range in the past. They upload data to a base station whenever it is nearby. It was shown that the set of applications that can be solved in the original model of population protocols is rather limited. Other models (such as some models of Delay/Disruption-Tolerant Networks - DTNs), where each node maintains links and connections even to nodes it may interact with only intermittently, do not seem to suit networks with small memory agents and a very large (and unknown) set of anonymous agents. That is why we enhance the model of population protocols by introducing a notion
of "speed". We try to capture the fact that the mobile agents move at different speeds and/or have different communication ranges and/or move according to different patterns and/or visit different places with different frequencies. Intuitively, fast agents which carry sensors with large communication ranges communicate with other agents more frequently than other agents do. This notion is formalized by the notion of cover time for each agent. The cover time of an agent is the unknown number of events (pairwise meetings) in the whole system that occur (during any execution interval) before agent $v$ meets every other agent at least once. The model we propose is somehow validated by some recent statistical results, obtained from empirical data sets regarding human or animal mobility. An important consequence of our approach is that the analytic complexity of the protocols designed in this model is possible, independently of any simulation or experimentation. For instance, we consider the fundamental problem of gathering different pieces of information, each sensed by a different anonymous mobile agent, and where the number of agents is unknown. The goal is to communicate the sensed values (as a multi-set, one value per mobile agent) to a base station, with no duplicates or losses. Gathering is a building block for many monitoring applications in networks of mobile agents. Moreover, the gathering problem can be viewed as a special case of the routing problem in DTNs, in which there is only one destination, the base station. Then we are able to compute the complexity of solutions we propose, as well as those of solutions used in experimental projects (like ZebraNet), and to compare them. The algorithms we present are self-stabilizing. Such algorithms have the important property of operating correctly regardless of their initial state (except for some bounded period). In practice, self-stabilizing algorithms adjust themselves automatically to any changes or corruptions of the network components (excluding the algorithm’s code). These changes are assumed to cease for some sufficiently long period. Self-stabilization is considered for two reasons. First, mobile agents are generally fragile, subject to failures and hard to initialize. Second, systems of mobile agents are by essence dynamic, some agents leave the system while new ones are introduced. Self-stabilization is a well adapted framework for dealing with such situations.

6.14. Self-Stabilizing Control Infrastructure for HPC

Participants: Thomas Hérault, Camille Coti.

High performance computing platforms are becoming larger, leading to scalability and fault-tolerance issues for both applications and runtime environments (RTE) dedicated to run on such machines. After being deployed, usually following a spanning tree, a RTE needs to build its own communication infrastructure to manage and monitor the tasks of parallel applications. Previous works have demonstrated that the Binomial Graph topology (BMG) is a good candidate as a communication infrastructure for supporting scalable and fault-tolerant RTE.

In this work, we presented and analyzed a self-stabilizing algorithm to transform the underlying communication infrastructure provided by the launching service (usually a tree, due to its scalability during launch time) into a BMG, and maintain it in spite of failures. We demonstrated that this algorithm is scalable, tolerates transient failures, and adapts itself to topology changes.

The algorithms are scalable, in the sense that all process memory, number of established communication links, and size of messages are logarithmic with the number of elements in the system. The number of synchronous rounds to build the system is also logarithmic, and the number of asynchronous rounds in the worst case is square logarithmic with the number of elements in the system. Moreover, the self-stabilizing property of the algorithms presented induce fault-tolerance and self-adaptivity. Performance evaluation based on simulations predicts a fast convergence time (1/33s for 64K nodes), exhibiting the promising properties of such self-stabilizing approach.

We pursue this work by implementing and evaluating the algorithms in the STCI runtime environment to validate the theoretical results.

6.15. Large Scale Peer to Peer Performance Evaluations

Participant: Serge Petiton.
6.15.1. Large Scale Grid Computing

Recent progress has made possible to construct high performance distributed computing environments, such as computational grids and cluster of clusters, which provide access to large scale heterogeneous computational resources. Exploration of novel algorithms and evaluation of performance is a strategic research for the future of computational grid scientific computing for many important applications [88]. We adapted [68] an explicit restarted Lanczos algorithm on a world-wide heterogeneous grid platform. This method computes one or few eigenpairs of a large sparse real symmetric matrix. We take the specificities of computational resources into account and deal with communications over the Internet by means of techniques such as out-of-core and data persistence. We also show that a restarted algorithm and the combination of several paradigms of parallelism are interesting in this context. We perform many experimentations using several parameters related to the Lanczos method and the configuration of the platform. Depending on the number of computed Ritz eigenpairs, the results underline how critical the choice of the dimension of the working subspace is. Moreover, the size of platform has to be scaled to the order of the eigenproblem because of communications over the Internet.

6.15.2. High Performance Cluster Computing

Grid computing focuses on making use of a very large amount of resources from a large-scale computing environment. It intends to deliver high-performance computing over distributed platforms for computation and data-intensive applications. We propose [99] an effective parallel hybrid asynchronous method to solve large sparse linear systems by the use of a Grid Computing platform Grid5000. This hybrid method combines a parallel GMRES(m) (Generalized Minimum RESidual) algorithm with the Least Square method that needs some eigenvalues obtained from a parallel Arnoldi algorithm. All of these algorithms run on the different processors of the platform Grid5000. Grid5000, a 5000 CPUs nation-wide infrastructure for research in Grid computing, is designed to provide a scientific tool for computing. We discuss the performances of this hybrid method deployed on Grid5000, and compare these performances with those on the IBM SP series supercomputers.

6.15.3. Large Scale Power aware Computing

Energy conservation is a dynamic topic of research in High Performance Computing and Cluster Computing. Power-aware computing for heterogeneous world-wide Grid is a new track of research. We have studied and evaluated the impact of the heterogeneity of the computing nodes of a Grid platform on the energy consumption. We propose to take advantage of the slack-time caused by the heterogeneity in order to save energy with no significant loss of performance by using Dynamic Voltage Scaling (DVS) in a distributed eigensolver [69]. We show that using DVS only during the slack-time does not penalize the performances but it does not provide significant energy savings. If DVS is applied to all the execution, we get important global and local energy savings (respectively up to 9% and 20%) without a significant rise of the wall-clock times.

6.16. High Performance Linear Algebra on the Grid

Participants: Thomas Hérault, Camille Coti.

Previous studies have reported that common dense linear algebra operations do not achieve speed up by using multiple geographical sites of a computational grid. Because such operations are the building blocks of most scientific applications, conventional supercomputers are still strongly predominant in high-performance computing and the use of grids for speeding up large-scale scientific problems is limited to applications exhibiting parallelism at a higher level.

In this work, we have identified two performance bottlenecks in the distributed memory algorithms implemented in ScalAPACK, a state-of-the-art dense linear algebra library. First, because ScalAPACK assumes a homogeneous communication network, the implementations of ScalAPACK algorithms lack locality in their communication pattern. Second, the number of messages sent in the ScalAPACK algorithms is significantly greater than other algorithms that trade flops for communication.
This year, we presented a new approach for computing a QR factorization one of the main dense linear algebra kernels of tall and skinny matrices in a grid computing environment that overcomes these two bottlenecks. Our contribution is to articulate a recently proposed algorithm (Communication Avoiding QR) with a topology-aware middleware (QCG-OMPI) in order to confine intensive communications (ScaLAPACK calls) within the different geographical sites.

An experimental study conducted on the Grid5000 platform shows that the resulting performance increases linearly with the number of geographical sites on large-scale problems (and is in particular consistently higher than ScaLAPACKs).

6.17. Emulation of Volatile Systems

Participants: Thomas Largillier, Benjamin Quetier, Sylvain Peyronnet, Thomas Hérault, Franck Cappello.

In the process of developing grid applications, people need to often evaluate the robustness of their work. Two common approaches are simulation, where one can evaluate his software and predict behaviors under conditions usually unachievable in a laboratory experiment, and experimentation, where the actual application is launched on an actual grid. However simulation could ignore unpredictable behaviors due to the abstraction done and experimentation does not guarantee a controlled and reproducible environment, and simulation often introduces a high level of abstraction that make the discovery and study of unexpected, but real, behaviors a rare event.

In this work, we proposed an emulation platform for parallel and distributed systems including grids where both the machines and the network are virtualized at a low level. The use of virtual machines allows us to test highly accurate failure injection since we can destroy virtual machines, and network virtualization provides low-level network emulation. Failure accuracy is a criteria that evaluates how realistic a fault is. The accuracy of our framework has been evaluated through a set of micro benchmarks and a very stable P2P system called Pastry.

We are in the process of developing a fault injection tool to work with the platform. It will be an extension of the work started in the tool Fail. The interest of this work is that using Xen virtual machines will allow to model strong adversaries since it is possible to have virtual machines with shared memory. These adversaries will be stronger since they will be able to use global fault injection strategies.

6.18. Exascale Systems

Participant: Franck Cappello.

Over the last 20 years, the open-source community has provided more and more software on which the world’s high-performance computing systems depend for performance and productivity. The community has invested millions of dollars and years of effort to build key components. Although the investments in these separate software elements have been tremendously valuable, a great deal of productivity has also been lost because of the lack of planning, coordination, and key integration of technologies necessary to make them work together smoothly and efficiently, both within individual petascale systems and between different systems. A repository gatekeeper and an email discussion list can coordinate open-source development within a single project, but there is no global mechanism working across the community to identify critical holes in the overall software environment, spot opportunities for beneficial integration, or specify requirements for more careful coordination. It seems clear that this completely uncoordinated development model will not provide the software needed to support the unprecedented parallelism required for peta/exascale computation on millions of cores, or the flexibility required to exploit new hardware models and features, such as transactional memory, speculative execution, and GPUs. We presented a rational promoting that the community must work together to prepare for the challenges of exascale computing, ultimately combing their efforts in a coordinated International Exascale Software Project.
Over the past few years resilience has become a major issue for high-performance computing (HPC) systems, in particular in the perspective of large petascale systems and future exascale systems. These systems will typically gather from half a million to several millions of central processing unit (CPU) cores running up to a billion threads. From the current knowledge and observations of existing large systems, it is anticipated that exascale systems will experience various kinds of faults many times per day. It is also anticipated that the current approach for resilience, which relies on automatic or application level checkpoint/restart, will not work because the time for checkpointing and restarting will exceed the mean time to failure of a full system. This set of projections leaves the community of fault tolerance for HPC systems with a difficult challenge: finding new approaches, which are possibly radically disruptive, to run applications until their normal termination, despite the essentially unstable nature of exascale systems. Yet, the community has only five to six years to solve the problem. In order to start addressing this challenge, we synthesized the motivations, observations and research issues considered as determinant of several complimentary experts of HPC in applications, programming models, distributed systems and system management.

As a first step to address the resilience challenge, we conducted a comprehensive study of the state of the art. The emergence of petascale systems and the promise of future exascale systems have reinvigorated the community interest in how to manage failures in such systems and ensure that large applications, lasting several hours or tens of hours, are completed successfully. Most of the existing results for several key mechanisms associated with fault tolerance in high-performance computing (HPC) platforms follow the rollback-recovery approach. Over the last decade, these mechanisms have received a lot of attention from the community with different levels of success. Unfortunately, despite their high degree of optimization, existing approaches do not fit well with the challenging evolutions of large-scale systems. There is room and even a need for new approaches. Opportunities may come from different origins: diskless checkpointing, algorithmic-based fault tolerance, proactive operation, speculative execution, software transactional memory, forward recovery, etc.

We provided the following contributions: (1) we summarize and analyze the existing results concerning the failures in large-scale computers and point out the urgent need for drastic improvements or disruptive approaches for fault tolerance in these systems; (2) we sketch most of the known opportunities and analyze their associated limitations; (3) we extract and express the challenges that the HPC community will have to face for addressing the stringent issue of failures in HPC systems.
6. New Results

6.1. Note

Note that we do not include here the results from Souhila Kaci and Tjitze Rienstra since they joined the team in September 2011.

6.2. Ontological Query Answering with Rules

Participants: Jean-François Baget, Marie-Laure Mugnier, Michaël Thomazo, Michel Leclère, Eric Salvat, Mélanie König.

In collaboration with: Sebastian Rudolph (Karlsruhe Institute of Technology)

We have developed a framework based on rules that have the ability of generating unknown individuals, an ability sometimes called value invention in databases. These rules are of the form $\text{body} \rightarrow \text{head}$, where the body and the head are conjunctions of atoms (without function symbols except constants) and variables that occur only in the head are existentially quantified, hence their name existential rules hereafter. E.g., $\forall x (\text{Human}(x) \rightarrow \exists y (\text{isParent}(y,x) \land \text{Human}(y)))$. These rules can be seen as the logical translation of conceptual graph rules, historically a main focus of the team [70] [55]. Existential rules have the same logical form as the well-known Tuple-Generating Dependencies (TGDs) in databases [45]. TGDs have been extensively used as a high-level generalization of different kinds of constraints, e.g., for data exchange [57]. Recently, there has been renewed interest for TGDs seen as rules in the context of ontological query answering. Indeed, the value invention feature has been recognized as crucial in an open-world perspective, where it cannot be assumed that all individuals are known in advance. The deductive database language Datalog allows to express some ontological knowledge but it does not allow for value invention. This motivated the recent extension of Datalog to TGDs (i.e., existential rules), which gave rise to the Datalog +/- family [52], [53], [54]. In KRR and in the Semantic Web, ontological knowledge is often represented with formalisms based on description logics (DLs). However, DLs traditionally focused on reasoning tasks about the ontology itself (the so-called TBox), for instance classifying concepts; querying tasks were restricted to ground atom entailment. Conjunctive query answering with classical DLs has appeared to be extremely complex, hence less expressive DLs more adapted to conjunctive query answering on large amounts of data have been designed recently, namely DL-Lite [51], EL [41], [63], and more generally Horn DLs (see e.g., [60]), cf. also the tractable profiles of the Semantic Web language OWL2. Existential rules cover the core of lightweight DLs dedicated to query answering, while being more powerful and flexible [53], [44],[21]. In particular, they have unrestricted predicate arity (while DLs consider unary and binary predicates only), which allows for a natural coupling with database schemas, in which relations may have any arity; moreover, adding pieces of information, for instance to take contextual knowledge into account, is made easy by the unrestricted predicate arity, since these pieces can be added as new predicate arguments.

Building on our previous work on conceptual graphs, while meeting this new trend, we have developed a knowledge representation framework centered on existential rules, which can be seen both as logic-based and graph-based.

Entailment, hence query answering, with existential rules is not decidable, thus finding decidable classes of rules as expressive as possible is a crucial issue. We have pursued our previous work on better understanding the border between decidability and undecidability. We have also extended rule dependency to k-dependency, which takes into account sequences of rule applications.

Results published in Artificial Intelligence Journal [13] (extending the work in [3],[44]); keynote talk synthesizing this work at RR’2011 [20]; extension to k-dependency at RR’2011 [22]
For newly exhibited decidable classes (namely, “frontier-one”, “frontier-guarded” and “weakly-frontier-guarded” rules), the problem complexity was unknown, moreover there was no algorithm for computing entailment. First, we have classified these classes with respect to combined complexity (i.e., usual complexity) with both unbounded and bounded predicate arity, and data complexity (i.e., restricting the input of the decision problem to the facts). An interesting result is that some of the new classes (namely frontier-one and frontier-guarded rules) have a polynomial time data complexity. Secondly, we have provided a generic algorithm for query entailment with a large class of rules including these classes, which is worst-case optimal for combined complexity (with or without bounded predicate arity) as well as for data complexity.

Results partially published at IJCAI’2011 [21]. Long paper in preparation with extended complexity results and all proofs, for submission to a major artificial intelligence journal.

6.3. Processing Conjunctive Queries with Negation

Participants: Marie-Laure Mugnier, Michel Leclère, Khalil Ben Mohamed, Michaël Thomazo.

 Conjunctive queries have long been recognized as the basic queries in database and knowledge-based systems. The fundamental decision problems on these queries, namely query inclusion checking (given two queries $q_1$ and $q_2$, is $q_1$ included in $q_2$, i.e., is the set of answers to $q_1$ included in the set of answers to $q_2$ for all databases) and query entailment (is a given query entailed by the database) are NP-complete. When atomic negation is added to queries and databases, these problems become $\Pi^P_2$-complete (with the open world assumption for the query entailment problem). Note that these problems can be recast as entailment in the FOL fragment of existentially closed conjunction of literals (without function symbols except constants). On the one hand, we have led a theoretical complexity study: we have investigated the role of pairs of literals called “exchangeable” (which generalizes the notion of unifiable literals) in the complexity increase. The main results are that when the number of exchangeable pairs is bounded, say by $k$, then the complexity falls from $\Pi^P_2$-complete to $P^{NP}_1$-complete for any $k \geq 3$, and is NP-complete for $k \leq 1$ (the case $k = 2$ being open).

In collaboration with: Geneviève Simonet (LIRMM Algeco team)

Results published DEXA 2011 [24] (extending our work in RFIA 2010 [48], DEXA 2010 [46], AIMSA 2010 [47]).

Let us point out that both theoretical and practical results still hold when the predicates are preordered, which allows to take very light ontologies into account, i.e., where concepts and relations are organized in a specialization preorder.

6.4. Argumentation Systems for Decision Making

Participants: Rallou Thomopoulos, Madalina Croitoru, Jérôme Fortin, Marie-Laure Mugnier.

In collaboration with: Joël Abecassis (IATE/INRA), Jean-Rémi Bourguet (UM3), Patrice Buche (IATE/INRA), Sébastien Destercke (IATE/CIRAD) Nir Oren (Univ. of Aberdeen, Scotland)

Scientific investigations in this axis are guided by applications of our partners in agronomy (IATE laboratory). Substantial part of the work has consisted of analyzing the proposed applications and the techniques they require in order to select appropriate applications with respect to our team project.
Argumentation is a reasoning model based on the construction and the evaluation of arguments. In his seminal paper, Dung has proposed an abstract argumentation framework [56]. In that framework, arguments are assumed to have the same strength. This assumption is unfortunately strong and often unsatisfied. Consequently, several generalizations of the framework have been proposed in the literature. In [49] and [50], we have led a comparative study of these generalizations. It clearly shows under which conditions two proposals are equivalent. We have also integrated those generalizations into a common more expressive framework.

An instantiation of Dung’s abstract framework with the conceptual graph framework has been proposed. This representation uses default conceptual graph rules, an extension of classical conceptual graph rules (equivalent to existential rules, see Axis 1) with Reiter’s defaults [67] allowing for non-monotonic reasoning, that we developed independently of the argumentation framework [42], [43]. In the conceptual graph representation, arguments are represented as nested graphs, attacks between arguments can be computed from the structure of arguments and default rules allow to compute several kinds of extensions (i.e., maximal sets of arguments jointly acceptable according to a given semantics).

This approach has been applied to agrifood chain analysis, which is a highly complex procedure since it relies on numerous criteria of various types: environmental, economical, functional, sanitary, etc. Quality objectives imply different stakeholders, technicians, managers, professional organizations, end-users, public organizations, etc. Since the goals of the implied stakeholders may be divergent, decision-making raises arbitration issues. Arbitration can be done through a compromise—a solution that satisfies, at least partially, all the actors—or favor some of the actors, depending on the decision-maker’s priorities. We have analyzed a case study concerning risks/benefits within the wheat-to-bread chain. It concerns the controversy about the possible change in the ash content of the flour used for commonly used French bread. Several stakeholders of the chain are concerned, in particular the Ministry of Health through its recommendations in a national nutrition and health program, millers, bakers and consumers.

As already pointed out, the proposed approach is novel both for theoretical and application aspects.

▷ Results presented in [30], [28].

Let us mention additional results related to the applications in agronomy on decision making combining machine learning based on decision trees and ontologies [58], [30], as well as results obtained by our collaborators on semi-automatic data extraction from web data (tables), data reliability, and the representation and flexible querying of imprecise data with fuzzy sets [16], [14], [17], [26], [31], [25], [27], [33], [34]. These investigations are complementary to the above mentioned results on argumentation and generally relate to other aspects in the same applicative projects.

6.5. Semantic Data Integration

Participants: Michel Leclère, Michel Chein, Madalina Croitoru, Rallou Thomopoulos, Léa Guizol.

It often happens that different references (i.e. data descriptions), possibly coming from heterogeneous data sources, concern the same real world entity. In such cases, it is necessary: (i) to detect whether different data descriptions really refer to the same real world entity and (ii) to fuse them into a unique representation. Since the seminal paper [66], this issue has been been studied under various names: “record linking”, “entity resolution”, “reference resolution”, ”de-duplication”, “object identification”, “data reconciliation”, etc., mostly in databases (cf. the bibliography by William E. Winckler 1). It has become one of the major challenges in the Web of Data, where the objective is to link data published on the web and to process them as a single distributed database. Most entity resolution methods are based on classification techniques; Fatiha Saïs, Nathalie Pernelle and Marie-Christine Rousset proposed the first logical approach [68]. Many experiments on public data are underway, in France (cf. DataLift2 and ISIDORE3 projects) or internationally (e.g., VIAF project4 led by OCLC5, whose aim is to interconnect authority files coming from 18 national organizations).

2 DataLift, http://datalift.org/
3 ISIDORE, http://www.rechercheisidore.fr/
4 The Virtual International Authority File, http://www.oclc.org/research/activities/viaf/
Two years ago, we began a collaboration with ABES (National Bibliographic Agency for Universities, which takes part in the VIAF project). The aim of this collaboration is to enable the publication of ABES metadata bases on the Web of Data and to provide an identification service dedicated to bibliographic notices. ABES bibliographic bases, and more generally document metadata bases, appear to be a privileged application domain for the representation and reasoning formalisms developed by the team. This work has an interdisciplinary dimension, as it also requires experts in the Library and Information Science domain. We think that a logical approach is able to provide a generic solution for entity resolution in document metadata bases, even though it is generally admitted in Library and Information Science that “there is no single paradigmatic author name disambiguation task—each bibliographic database, each digital library, and each collection of publications, has its own unique set of problems and issues” [69].

6.5.1. SUDOC Metadata Formalization

The first step of collaboration with ABES was to formalize the SUDOC catalogue, which contains all French academic libraries bibliographic notices, into a knowledge base using a suitable knowledge representation and reasoning language. This required to first analyze SUDOC content, as well as document description standards (CRM-CIDOC, FRBR, Dublin Core). We then designed an ontology expressed in the Semantic Web languages RDFS + OWL, compatible with document description standards, as well as translations from any SUDOC set of notices into a set of RDF facts according to this ontology. These translations have been implemented, which allows to export SUDOC bases into Semantic Web formats. Moreover, using the RDFS to CG second translation mentioned above, we are now able to import SUDOC bases into our tools CoGUI + CoGITaNT.

▷ Technical report [40].

6.5.2. Implementation of an Entity Identification Service

In order to perform entity resolution (for entities restricted to "authors" for now), we have defined a set of rules allowing to enrich Sudoc descriptions; then, using enriched descriptions, authors can be classified according to a proximity criterion. A prototype providing this service has been implemented on top of Cogui. Experiments are currently led in the context of the SudocAd project jointly conducted by ABES and GraphIK. SudocAd aims at enriching the author field of a bibliographic record describing a document with links to Sudoc authorities referring to the authors of the target document. A general description of the implemented approach, an analysis of this approach on a representative sample of bibliographic records and first results on 13400 bibliographic records extracted from a corpus independent from Sudoc catalog are presented in the final report of SudocAd.

▷ Link to SudocAd Final Report: http://www.abes.fr/Media/Fichiers/Sudoc-Fichiers/SudocAD_rapportFinal

Finally, we have defined an extension of our own logical framework (existential rules, constraints, homomorphism-based mechanisms) based on Hector J. Levesque and Gerhard Lakemeyer’s Standard Names [62], and the notion of knowledge base faithfulness with respect to the entity resolution problem (intuitively, the fact that the knowledge base is non-ambiguous). This is still ongoing work.

▷ Research Report [38].

6. New Results

6.1. Algorithms and high-performance solvers

6.1.1. Dense linear algebra solvers for multicore processors accelerated with multiple GPUs

In collaboration with the Inria RUNTIME team and the University of Tennessee, we have designed dense linear algebra solvers that can fully exploit a node composed of a multicore processor accelerated with multiple GPUs. This work has been integrated in the latest release of the MAGMA package (http://icl.cs.utk.edu/magma/).

6.1.2. Hybrid direct/iterative solvers based on algebraic domain decomposition techniques

A first release of the MaPHyS package should be made available early in 2012 thanks to the developments conducted in the last year of the ADT. An approximation of the local Schur complement has been studied that is based on approximated inverse technique. This work is a natural extension of part of the PhD research of Mikko Byckling. Furthermore, during his master internship, Stojce Nakov has investigated the design of a Krylov subspace method, namely the conjugate gradient, on a run-time system in order to best exploit the computing capabilities of many-GPU nodes and manycore systems. In the framework of his starting PhD funded by TOTAL, Stojce Nakov will continue his work to design a new implementation of a hybrid linear solver (see Section 3.3) for heterogeneous manycore platforms.

6.1.3. Resilience in numerical simulations

In his master internship work, Mawussi Zounon investigated recovery strategies for core faults in the framework of parallel preconditioned Krylov solvers. The underlying idea is to recover fault entries of the iterate via interpolation from existing values available on neighbor cores. He will continue this work in the framework of his PhD funded by the ANR-RESCUE. Notice that these activities are also part of our contribution to the G8-ECS (Enabling Climate Simulation at extreme scale).

6.1.4. Full geometric multigrid method for 3D Maxwell equations

In the context of a collaboration with the CEA/CESTA center, Mathieu Chanaud continued his PhD work on a tight combination between multigrid methods and direct methods for the efficient solution of challenging 3D irregular finite element problems arising from the discretization of Maxwell equations. A parallel solver dedicated to the ODYSSEE challenge (electromagnetism) of CEA/CESTA has been implemented and integrated. The novel parallel solver was able to solve a 1.3 billion system given a 20 million unknown problem at the coarsest level. The input mesh defines the coarsest level. This mesh is further refined to define the grid hierarchy, where matrix free smoothers are considered to reduce the memory consumption.

6.1.5. Scalable numerical schemes for scientific applications

A work is currently carried on with TOTAL (Rached Abdelkhalek PhD). The extraordinary challenge that the oil and gas industry must face for hydrocarbon exploration requires the development of leading edge technologies to recover an accurate representation of the subsurface. Seismic modeling and Reverse Time Migration (RTM) based on the full wave equation discretization, are tools of major importance since they give an accurate representation of complex wave propagation areas. Unfortunately, they are highly compute intensive. The recent development in GPU technologies with unified architecture and general-purpose languages coupled with the high and rapidly increasing performance throughput of these components made General Purpose Processing on Graphics Processing Units an attractive solution to speed up diverse applications. We have designed a fast parallel simulator that solves the acoustic wave equation on a GPU cluster. Solving the acoustic wave equation in an oil exploration industrial context aims at speeding up seismic modeling and Reverse Time Migration. We consider a finite difference approach on a regular mesh, in both
2D and 3D cases. The acoustic wave equation is solved in a constant density or a variable density domain. All the computations are done in single precision, since double precision is not required in our context. We use nvidia CUDA to take advantage of the GPU computational power. We study different implementations and their impact on the application performance. We obtain a speed up of 16 for Reverse Time Migration and up to 43 for the modeling application over a sequential code running on general purpose CPU. The defense of this thesis is planned early 2012.

For the solution of the elastodynamic equation on meshes with local refinments, we are currently collaborating with Total to design a parallel implementation of a local time refinement technique on top of a discontinuous Galerkin space discretization. This latter technique enables to manage non-conforming meshes suited to deal with multiblock approaches that capture the locally refined regions. this work is developed in the framework of Yohann Dudouit PhD thesis. A software prototype is currently developed to address these simulations.

The calculation of acoustic modes in combustion chambers is a challenging calculation for large 3D geometries. It requires the calculation of a few of the smallest eigenpairs of large unsymmetric matrices in a parallel environment. A new block Arnoldi approach is currently developed to best benefit from the continuation scheme used in this application context. This is part of the PhD research activity of Pablo Salas.

6.2. Efficient algorithmics for code coupling in complex simulations

The performance of the coupled codes depends on how the data are well distributed on the processors. Generally, the data distributions of each code are built independently from each other to obtain the best load-balancing. But once the codes are coupled, the naive use of these decompositions can lead to important imbalance in the coupling area. Therefore, the modeling of the whole coupling is crucial to improve the performance and to ensure a good scalability. The goal is to find the best data distribution for the whole coupled codes and not only for each standalone code. The key idea is to use a graph/hypergraph model that will incorporate information about the coupling itself. Then, we propose new algorithms to perform a coupling-aware partitioning in order to improve the load-balancing of the whole coupled simulation.

Let us consider two coupled codes, modeled by two graphs (or hypergraphs) $A$ and $B$, connected by inter-edges $I(A,B)$ that represents the coupling communications between codes. Formally, the problem consists in partitioning $A$ in $M$ and $B$ in $N$ with accounting for $I(A,B)$. This algorithm should optimize both the edge cut for each graph and the coupling communications while maintaining each graph balance. Our general strategy is divided in three main steps:

1. first, we freely partition $A$ in $M$ to obtain the partition $A/M$;
2. then, we projects this partition to $B$ according to $I(A,B)$, that provides the partition $B/M$;
3. finally, we compute the partition $B/N$ by repartitioning $B$ from $M$ existing parts into $N$.

The final repartitioning step is particularly tiedous, because it must handle a variable number of processes. However, as far as we know, the state-of-the-art graph/hypergraph repartitioning tools are limited to a fixed number of processes (i.e. $M = N$). To overcome this issue, we have proposed a new repartitioning algorithm – assuming the load is constant – based on hypergraph partitioning technics with fixed vertices. Our algorithm uses an optimal communication pattern, that we have proved to minimize the total number of messages between the former and newer parts. Experimental results validate our work comparing it with other approaches [20]. We currently investigate how to extend our algorithm for the dynamic load-balancing of parallel adaptive codes ($A = B$), whose load evolution is variable and difficult to predict. In this case, it would be convenient to dynamically adapt the number of processes used at runtime ($M \neq N$), while minimizing migration cost during the repartitioning step. This work is currently conducted in the framework of Clément Vuchener PhD thesis.

6.3. Distributed Shared Memory approach for the steering of parallel simulations
As a different approach of EPSN, we conceived and developed an in-transit visualization framework for interfacing an arbitrary HPC simulation code with an interactive ParaView session using the HDF5 parallel IO library as the API. The library called H5FDdsm is coupled with a ParaView plugin ICARUS (Initialize Compute Analyze Render Update Steer).

Because our interface is based on files, stored in a distributed shared memory (DSM), we sought during this year different redistribution strategies to optimize the bandwidth and the transfers between the simulation and the ParaView servers hosting the DSM. This work showed real benefits, particularly on one of our Cray XE6 testing machines using a block cyclic redistribution. On these large HPC machines that do not support the dynamic MPI process management set of functions, we improved our connection system so that simulation and post-processing can be coupled within an MPMD job. Taking also advantage of one-sided communication models and of the Cray Gemini interconnect communication performance, our framework has been sensibly improved and should be optimal in the coming months.

The interface has also been enhanced with a steering interface that allows us to control the simulation workflow and send back not only parameters, but also complete meshes in parallel, which can then be read by the simulation using either our steering interface or HDF5 calls. This has been demonstrated with SPH-flow, a CFD code developed by Ecole Centrale de Nantes and HydrOcean, replacing dynamically and in parallel a falling wedge with a deforming sphere.

This work has been realized and is currently carried on at CSCS - Swiss National Supercomputing Centre in the framework of Jérôme Soumagne PhD thesis (under the co-supervision of Mr. John Biddiscombe) and within the NextMuSE European project 7th FWP/ICT-2007.8.0 ([17], [18], [19]).

6.4. Material physics

6.4.1. Hybrid materials

The study of hybrid materials based on a coupling between molecular dynamics (MD) and quantum mechanism (QM) simulation has been conducted in collaboration with IPREM (Pau) within the ANR CIS 2007 NOSSI (ended December 2011). These simulations are complex and costly and may involve several length scales, quantum effects, components of different kinds (mineral-organic, hydro-philic and -phobic parts). Our goal was to compute dynamical properties of hybrid materials like optical spectra. The computation of optical spectra of molecules and solids is the most consuming time in such coupling. This requires new methods designed for predicting excited states and new algorithms for implementing them. Several tracks have been investigated in the project and new results obtained as described below.

Optical spectra.

Some new improvements in our TD-DFT code have been introduced. Our method is based on the LCAO method for densities and excited states that computes electronic excitation spectra. We have worked in two directions:

- As the method introduces a regularization parameter to obtain regularized spectra we have used it to build better algorithms. In particular, we have developed a new hierarchical algorithm that builds a well adapted frequency distribution to better capture the biggest peaks (strongest oscillator strengths) in the spectrum. Moreover, a nonlinear fit method was added and used to compute the transitions and the oscillator strengths of the spectrum.

- In our algorithm, we used a coarse grain paradigm to parallelize the spectrum computation. This approach leads to a memory bottleneck for large systems. In that respect, we have explored a new parallel approach based on a fine grain paradigm (matrix-vector parallelization) to better exploit the manycore architecture of the emerging computers.

Finally, we have improved the packaging of the code to prepare a public release of the code. Our TD-DFT code will be soon available on request.
QM/MM algorithm. For structure studies or dynamical properties, we have coupled QM model based on pseudo-potentials (SIESTA code) with dynamic molecular (DL-POLY code). Therefore we have developed a new algorithm to avoid accounting twice for the forces and the quantum electric field in the molecular model. All algorithms involved in the coupling have been introduced both in SIESTA and in DL-POLY codes. The following new developments needed by the coupling have been introduced in the SIESTA code:

- We have implemented a fast evaluation of the molecular electrostatic field on the quantum grid.
- We have introduced a non periodic Poisson solver based on the parallel linear Hypre solver. This solver allows us to use computation domains as small as possible.
- We have implemented the ElectroStatic Potential (ESP) fit method to obtain more physical point charges than those given by SIESTA with the Mulliken method. These point charges are used by the MM codes to compute electrostatic forces.

Thanks to all our developments introduced in SIESTA a collaboration with the SIESTA research team has started. This enables us to have access to their private svn like repository. Preliminary results on a water dimer and a water box systems show good agreement with other methods developed in SIESTA and DL-POLY teams. All these results were presented in the final international NOSSI workshop in Biarritz on December.

6.4.2. Material failures

We have started in the context of the OPTIDIS ANR to work on dislocation simulations. The main characteristic of these simulations is that they are highly dynamical. This year, we have started the study of the state of the art on this topic in two directions. The first direction concerns the study of the algorithms used in such simulations and how we can efficiently parallelize them on manycore clusters. In the second one for isotropic materials, we are investigating how to adapt our fast multipole method to compute constraints and then forces in this kind of simulations.
6. New Results

6.1. Massive mobile dense wireless networks

Participants: Cédric Adjih, Aline Carneiro Viana, Emmanuel Baccelli, Philippe Jacquet, Pascale Minet, Paul Mühlethaler, Yasser Toor.

6.1.1. Executive summary

Scaling properties of mobile ad hoc network lead to an increase of global capacity when the network density increases or when the packets can be stored for a while in mobile nodes instead of being immediately retransmitted.

Gupta and Kumar have shown in 2000 that the transport capacity per node in a multihop ad hoc network decreases in $1 / \sqrt{N \log N}$, $N$ being the number of nodes in the network. Therefore the global capacity of the network increases in $\sqrt{N} / \sqrt{\log N}$. This is a surprising result since in wired network a collection of nodes connected to a single communication resource has a transport capacity that just remains constant (i.e. the average per node capacity decreases in $1/N$).

Therefore adding space to a multihop wireless network increases the capacity: this is the space capacity paradox.

When nodes randomly move, it turns to be more advantageous to store packets for a while on mobile routers instead of forwarding them immediately like hot potatoes. When the mobile router moves closer to the destination, then it can delivers packets on a much smaller number of hops. Of course the delivery delay is much longer, but the network capacity also increases by slowing non urgent packets. This is the time capacity paradox: by slowing packets, nodes mobility increases network capacity. This was hinted the first time by Grossglauser and Tse in 2002.

The great challenge is to find the good protocol and tunings that allow to adjust the delivery delay from zero to infinity in order to get a continuous increase in capacity. The challenge is two-sided: one has to keep the delivery delay between reasonable bounds and one has to consider realistic mobility models.

Existing protocols for Mobile Ad Hoc Networks (MANET) are highly efficient in routing data between mobile nodes that belong to the same connected component (cf. the protocols which have received the RFC status by the manet group of IETF). What about a disconnected network where source and destination may be located in two different connected components? In this case usual routing protocols drop packet due to host unreachable as no end-to-end route exists at that time.

A simple idea is to allow the router that has no available route to the destination to keep the packet in buffer until the conditions become more appropriate for forwarding. The forwarding conditions will change because of mobility: the router can move closer to the destination so that they belong to the same connected component and the packet can be delivered.

Indeed, the network may be continuously partitionned due to high mobility, and the traditional approach to allow a mobile node to wait for the network to be fully connected (i.e. form a unique component) or to wait to be in range of the destination may lead to unacceptable delays. Furthermore, concrete applications, such as Defence and Disaster-Relief, cannot always rely on such assumptions.

Nevertheless, even if the communicating nodes may never be within the same connected component, it is important to observe that a “communication path” may be available through time using intermediate nodes that are temporarily within reach of each other while moving, hence making such networks viable for critical applications. Depending on the nature of the environment, these networks are now commonly referred as Intermittently Connected MANET and Delay Tolerant Networks.
In between stands the problem of the fully connected network that forms a single connected component, but for which maintaining full knowledge of the topology would simply make the network collapse under its huge control traffic. In fact this is the main problem that wireless network engineering has to face, in most experiments the generation of control traffic is the main source of disruption.

6.1.2. Scientific achievements

6.1.2.1. Scaling and spatial capacity in non uniform wireless networks

We found a more precise instance of Gupta-Kumar result by using a simple but realistic network model based on slotted ALOHA with Poisson traffic. It turns out that when the traffic density increases then the average node neighborhood area shrinks so that the average encircled traffic load remains constant with an analytical expression.

In their original model Gupta and Kumar assume that the traffic density is constant, which is far from realistic. However we have derived similar generalized results when the traffic density is not uniform. In this case, the heavier is the local traffic, the smaller are the local neighborhood and the larger is the number of hops needed to cross the congested region. Therefore the shortest paths (in hop number as computed by OLSR) will have a natural tendency to avoid congested areas. The path tend to follow trajectory that have analogy in non linear optic with variable indices.

6.1.2.2. Time capacity and node mobility

We have defined a protocol that takes advantage of node mobility in a general way. In short the packet stay with its host router as long as the latter does not evade too fast from its next hop (computed via a shortest path protocol such as OLSR). In the way we understand “too fast” stands the tuning parameters we discussed above. There is no need to have node geographical location and to physically measure motion vector, since everything can be done via the analysis of the dynamic of neighborhood intersections. We analytically derived performance evaluation under random walk mobility models. We plan to simulate the protocol in a real mobility scenario. This algorithm has application in Intelligent Transport System.

6.1.2.3. Overhead reduction in large networks

The first limitation of multihop wireless network is the size of the overhead per node that increases linearly with the size of the network. This is a huge improvement compared to classic internet protocols which have quadratic overhead increases. Nevertheless this till limit the network size to some thousands. We have analyzed the performance of OLSR with Fisheye feature that significantly reduce the overhead with respect to distance. In theory the overhead attenuation with distance must be carefully done when the network is mobile, in order to avoid tracking failure. We showed that an overhead reduction within square root of the network size achieve this goal.

An alternative way to overhead reduction is ad hoc hierarchical routing and Distributed Hashing Table. Work has just begun in this area.

6.1.2.4. Coloring in wireless networks

Coloring is used in wireless networks to improve communication efficiency, mainly in terms of bandwidth, energy and possibly end-to-end delays. Nodes access the medium according to their color. It is the responsibility of the coloring algorithm to ensure that interfering nodes do not have the same color. First, we established complexity results about the h-hop coloring problem. Second, we focused on wireless sensor networks with grid topologies. We proposed the Vector-Based Coloring Method, denoted VCM, a new method that is able to provide an optimal periodic coloring for any radio transmission range and for any h-hop coloring. Third, we also designed OSERENA "Optimized SchEduling RoutEr Node Activity", a distributed coloring algorithm optimized for dense wireless networks.

6.1.2.5. Complexity results about the h-hop coloring problem

In the paper we published at the WMNC 2011 conference, we define the h-hop node coloring problem, with h any positive integer, adapted to two types of applications in wireless networks. We specify both general mode for general applications and strategic mode for data gathering applications. We prove that the associated decision problem is NP-complete.
6.1.2.6. Grid coloring and the Vector-Based Coloring Method

In 2011, we also focused on wireless sensor networks with grid topologies. How does a coloring algorithm take advantage of the regularity of grid topology to provide an optimal periodic coloring, that is a coloring with the minimum number of colors? We propose the Vector-Based Coloring Method, denoted VCM, a new method that is able to provide an optimal periodic coloring for any radio transmission range and for any h-hop coloring, $h \geq 1$. This method consists in determining at which grid nodes a color can be reproduced without creating interferences between these nodes while minimizing the number of colors used. We compare the number of colors provided by VCM with the number of colors obtained by a distributed coloring algorithm with line and column priority assignments. We also provide bounds on the number of colors of optimal general colorings of the infinite grid, and show that periodic colorings (and thus VCM) are asymptotically optimal. Finally, we discuss the applicability of this method to a real wireless network.

6.1.2.7. Opportunistic routing

The model of wireless networks based on dynamic graph does not well assess the real processes in a wireless network. In particular the range of transmission can greatly vary between packets, the graph keeping only the average range. Opportunistic routing consists into taking advantage of temporary extension of the transmission range in order to gain several hops.

We have strong established theoretical performance limits in opportunistic routing. The limits are based on realistic interference scenarios in slotted Aloha. We have also investigated the impact of mobility on this theoretical limits.

We have designed an opportunistic routing protocol whose performance are within a small margin of the theoretical limits.

We have also conducted studies to support intelligent and adaptive forwarding, which allows a good trade-off between reliability and resource-efficiency. We then design a new protocol, called GrAnt, a new prediction-based forwarding protocol for complex and dynamic delay tolerant networks (DTNs). The proposed protocol uses the Ant Colony Optimization (ACO) metaheuristic with a greedy transition rule. This allows GrAnt to select the most promising forwarder nodes or allow for the exploitation of previously found good paths. The main motivation for using ACO is to take advantage of its population-based search and the rapid adaptation of its learning framework. Considering data from heuristic functions and pheromone concentration, the GrAnt protocol includes three modules: routing, scheduling, and buffer management.

6.1.2.8. Intermittent and delay tolerant networks

We consider the problem of routing in these networks, with the sole assumption that the speed of the node mobility is less than the speed of transmitting a packet to a neighbour. We compare this problem with sound propagation in liquid. We show that various pattern of mobility and network clustering can be described by a single parameter such as the information speed propagation.

We introduce new algorithms that route a packet toward a remote destination. The different algorithms vary depending on the buffering and the capacity capabilities of the network (i.e. if one or more copies of a packet can be sent and/or be kept). All algorithms are based on link aging rumors across connected components. The packet bounces from connected components to connected components, thanks to node mobility. We establish several analytical properties using an analogy with the sound propagation in liquid where molecules creates temporary connected components where sounds travel very fast.

Previous models assumed that the propagation of information path evolves like in a dynamic Erdos-Renyi graph leading to an epidemic flooding in $O(\log n)$ or $O(1)$, $n$ being the number of nodes in the network. We disprove the Erdos-Renyi model by showing via space-time considerations that the set of information path from a source to a destination is in fact much smaller than the path set in the Erdos-Renyi model. This lead to a much larger minimal delay in square root of $n$ instead of $\log n$. This correspond to a bounded maximal information propagation speed, whose estimate depends on the mobility model and the node density, and is root of multivariate explicit Bessel formulas.
Additionally, we have also considered the problem of data collection in global sensing and intermittently connected systems while avoiding the use of costly infrastructures (e.g., 3G). Motivated by the observation that node encounters are sufficient to build a connected relationship graph, we propose to take advantage of such inherent interactions to transform some mobile devices into delegates. We use then opportunistic delegation as a data traffic offload solution by investigating two main questions: (i) How to gain insights into social mobile networking scenarios?, (ii) How to utilize such insights to design solutions to alleviate overloaded 3G networks?. Our solution leverages usage of mobile applications requiring large data transfers by channeling the traffic to a few, socially important users in the network called VIP delegates. Mobile collectors need then only to meet delegates that, in turn, are responsible for gathering data from a subset of standard producers. We first investigate several delegation strategies based on the relative importance of nodes in their social interactions. Second, by considering a prediction strategy that estimates the likelihood of two nodes meeting each other, we investigate how the delegation strategies perform on predicted traces.

6.1.2.9. Network Coding

We study network coding for multi-hop wireless networks. We focus on the case of broadcasting where one source transmits information to all nodes in the network. Our goal is energy-efficient broadcast, that is, minimizing the total number of transmissions for broadcasting to the entire network. Note that this is a different problem for the classical problem of capacity maximization; and assuming we are far from the network capacity limit, hence in fact, we could assume interference-free transmissions. Our previous results, they had shown that network coding (and a simple coding strategy) was able to reach optimality for asymptotically large and dense networks, with asymptotically 100% of the received transmissions being useful (innovative). We extended the results with the combined use of connected dominating sets and network coding: we were able to quantify (and bound) the benefits of network coding in networks where the area of the network stays fixed, and only the density increases.

We have proved that the performance of wireless random network coding are optimal in the following network model: the Erdos-Renyi random graph model and the unit disk random graph model. In particular we show in the Erdos-Renyi the network coding capacity rate outperform any Connected Dominating Set strategy by a factor of order log n. In the unit disk model we gain is larger than 60%. The result is based on the analysis of the connectivity stretch ratio of the random graphs. The connectivity stretch ratio is the ratio of the smallest degree over the connectivity number, and the connectivity stretch ratio tends to one in the two graph models.

6.1.3. Collaborations

- Professor Bernard Mans, Macquarie University, Sydney, Australia,
- TREC INRIA team,
- Professors Anelise Munaretto and Myriam Regattieri Delgado from Federal Technological University of Parana (UTFPR), Brazil,
- CNRS researcher Marcelo Dias de Amorim, LIP6/UPMC, France,
- Mathias Boc, CEA LIST, France,
- Computer Science Department, Sapienza University of Rome, Italy,
- University of St. Andrews, UK.
- Professor Leila Saidane, ENSI, Tunisia.

6.2. New generation of OLSR, new services and protocols

Participants: Cédric Adjih, Aline Carneiro Viana, Emmanuel Baccelli, Thomas Clausen, Philippe Jacquet, Pascale Minet, Ichrak Amdouni, Ridha Soua, Erwan Livolant, Paul Mühlenthaler, Yasser Toor.

6.2.1. Executive summary

The user of a mobile network very quickly experience problems with quality of service: links fade, connectivity disrupts, delays accumulate.
In a wireless network, the set of neighbors which with one node can communicate depends on transmission range, and numerous factors, and in addition the transmission range is often lower than the interference range (the range within which a node prevents correct transmissions of other nodes). Thus bandwidth reservation, a crucial step of quality of service, is an important and difficult problem.

The services and protocols that need careful adaptation are

- Connectivity continuity
- Bandwidth reservation
- Delay routing
- Connectivity control
- Autoconfiguration
- Security
- Energy efficiency
- Localization

The connectivity continuity is the most important problem. Trivial in the wired world where a link failure is a rare event, it becomes problematic in the mobile world where link failure caused by mobility are frequent and normal. The first experiments of mobile ad hoc networks with regular internet protocols miserably failed simply because either the protocol was to slow to recover link failure, or when tuned appropriately was generating such a huge overhead that the network collapsed under its own weight. A new generation of routing protocols has arised that allow a suitable control of connectivity in mobile networks. Among them the Optimized Link State Routing combines the optimization of overhead for mobile networks and the full internet legacy. It naturally provides path redundancy which accelerate link failure recovery.

The most important lesson that must be retained is that most of these optimization become NP complete, which is a significant complication compared to their counterpart in the classical wired world. The reason for the NP-completeness is two-sided: on one side the co-interferences make impossible an optimization link by link, on the other side, the large dispersion of performance measurement makes simple heuristic ineffective. As an example, routing with respect to shortest delay average does not guarantee smallest probability of high delay.

Since the bandwidth is scarce, any multimedia application such as video streaming is resource demanding. For example a TV broadcast that uses a mesh network will rapidly exhaust the bandwidth if all connections are point to point. In this case multicast protocols that allows to gather all these point to point connections in a single flow is a need.

There are two classes of multicast protocols: the tree based protocols and the network coding protocols. In the first class the protocols take advantage of the relatively small size of the recipient node set. One can show equivalent results of Gupta and Kumar scaling properties but in the multicast plan when the ratio of recipient versus network size is a fundamental parameter. When this ratio tends to one the performance naturally worsen. When the recipient set is the whole network, one can apply the network coding scheme with random packet combination. In network coding the packets are no longer isolated: relay nodes makes linear combination of packets and transmitted mixed packets. In theory the performance of network coding is better than isolated packet multicast. In practice network coding is simpler to operate does not need topology management such as spanning trees or Connected Dominating Set. The reason for this is highly non intuitive, as if packet superposition was acting like state superposition in quantum mechanic, leading to non expected results.

Quality of service has become the central requirement that users expect from a network. High throughput, service continuity are critical issue for multimedia application over the wireless internet where the bandwidth is more scarce than in the wired world. A significant issue in the ad-hoc domain is that of the integrity of the network itself. Routing protocols allow, according to their specifications, any node to participate in the network - the assumption being that all nodes are behaving well and welcome. If that assumption fails - then the network may be subject to malicious nodes, and the integrity of the network fails. An important security service over mobile networks is to ensure that the integrity of the network is preserved even when attacks are launched against the integrity of the network.
6.2.2. Scientific achievements

6.2.2.1. Optimized Link State Routing (OLSR)

The routing protocol OLSR is universally known in the mobile wireless community (more than 475,000 hits on Google). It has numerous implementations and is used in many wireless networks. It is a proactive protocol with full internet legacy which is based on partial topology information exchange, that non the less provide optimal path with additive metrics (such as BGP/OSPF). It is an experimental RFC within IETF and soon will become a full standard under the name OLSRv2.

6.2.2.2. OSPF extension for wireless mesh networking

Long a near-future myth, ad hoc networks are now becoming a reality as a variety of wireless mesh networks are being deployed. Wireless mesh networks are a specific kind of ad hoc network, where terminals are essentially fixed. Even in such cases, which somewhat resembles usual networks, specific routing protocols have nevertheless to be employed, to cope with the characteristics of wireless, multi-hop communications. Such characteristics include scarce bandwidth over inherently unreliable, versatile, semi-broadcast links, and absence of a central authority in general. One of the main difficulties in this context is to cope with contradictory requirements such as, on one hand, dealing with bandwidth scarcity, which typically requires decreasing control traffic, while on the other hand, dealing with unreliable, versatile links which typically requires increasing control traffic. The two prominent routing protocols that have been developed for ad hoc networks and studied over the past decade, are the IETF standards AODV and OLSR. AODV is based on a reactive scheme (i.e. on-demand flooding to discover a path to a new destination), while OLSR is based on a proactive scheme, which is essentially an optimization of link state routing (i.e. pre-provisioning of paths to all possible destinations). OLSR is to date the most deployed such protocol, as it powers numerous wireless mesh community networks that currently flourish in various cities throughout Europe and North America. Based on this experience, the integration of ad hoc networking in the "standard" networking body is going further in several directions. One direction is the IEEE 802.11s standardization effort, which uses AODV and OLSR-derived algorithms to provide wireless mesh routing capabilities below IP. Another direction, spearheaded by the IETF, is the extension of IP routing standards such as OSPF to support ad hoc routing: in this realm we recently spun RFC 5449, as well as a series of academic publications on the subject. The idea behind extending OSPF to support ad hoc networks comes from a simple observation: OSPF is algorithmically quite similar to OLSR, as both are based on a proactive, link state approach. As on the other hand OSPF is a well-understood, widely deployed, industry-standard protocol, employing it to integrate ad hoc networks with existing infrastructure is considered by users as an easy migration path.

6.2.2.3. Multi-metric routing

Quality of service involves finding routes between two nodes in the network that satisfies a number of constraints. These constraints could be the requested bandwidth, the maximum delay, the minimum loss probability, the reliability of links, etc. This problem is NP-Complete because it combines additive metrics in the optimization problem. Hipercom proposed heuristics for finding routes that respect up to four metrics when calculating routes between source and destination. Another QoS issue is the creation of models that estimate the actual value of a metric. For example, computing the available bandwidth or the transfer delay on a link, etc. is very complex in a non-deterministic medium access such as WiFi. To resolve this problem, we developed a model for estimating the available bandwidth in a wireless network. This model is based on considering interfering links in cliques, after which we provide the maximum capacity that could be deployed in a clique. We may still enhance the model by adding a scaling factor to the clique equations in order to become more accurate when compared to real measurements.

In particular we have investigated the metric based on packet delay distribution. Since propagation delays between routers are negligible, most delays occur in queueing and medium access control processing. Contrary to previous common belief there is no need of network synchronization. The objective is to proactively determine the delay in absence of packet data traffic. The estimate of delay distribution is done via analytical method. In order to keep control on quality of service flows we use source routing forwarding options.
6.2.3. Collaborations

- Many contractual collaborations:
  - MoD (QoS, security, interconnection between the OLSR and OSPF routing domains),
  - Hitachi (Vehicular applications, OLSRv2),
- Non contractual:
  - BAE (OLSRv2),
  - Deutsche Telekom Labs/TU-Berlin, Germany,

6.3. Wireless Sensor Networks

Participants: Cédric Adjih, Aline Carneiro Viana, Emmanuel Baccelli, Thomas Clausen, Philippe Jacquet, Pascale Minet, Ichrak Amdouni, Ridha Soua, Erwan Livolant, Paul Mühlthaler, Yasser Toor.

6.3.1. Executive summary

In wireless sensor networks, we focus more particularly on:

- Spatial reuse of the bandwidth,
- Routing according to a cross-layering approach,
- Security,
- Energy efficiency,
- IPv6 support.

6.3.2. Scientific achievements

6.3.2.1. Cryptographic Protocols to Fight Sinkhole Attacks on Tree-based Routing in Wireless Sensor Networks

Wireless Sensor Networks (WSN) are penetrating more and more in our daily life. As a consequence, security has become an important matter for these networks. We introduce two new cryptographic protocols of different complexity and strength in limiting network degradation caused by sinkhole attacks on tree-based routing topologies in Wireless Sensor Networks (WSNs). The main goal of both protocols is to provide continuous operation by improving resilience against, rather than detection of, these attacks. The main benefit of providing resilience is that it allows operating (or graceful degradation) in the presence of attacks. Furthermore, while resilience mechanisms do not dismiss detection mechanisms, detection mechanisms often introduce more complexity and so, more weaknesses to the system, which might not justify their benefits. More specifically our two RESIlient and Simple Topology-based reconfiguration protocols are: RESIST-1 and RESIST-0. RESIST-1 prevents a malicious node from modifying its advertised distance to the sink by more than one hop, while RESIST-0 does not allow such lying at the cost of additional complexity.

6.3.2.2. IPv6 Protocol suite for Sensor Networks

Wireless sensor networking is a key element of the Internet of Things (IoT), a substantial part of the billions of smart objects that are soon to blend into the global IP network, from actuators to home appliances, from smart meters, to smart dust. Sensor nodes are devices used for distributed and automated monitoring of various parameters such as temperature, movement, noise or radioactivity levels etc. Sensors are scattered with minimum planning with respect to their precise physical position (including the central role of the sink, if any), and the set of peers with which a sensor can directly communicate through its wireless interface may change rapidly over time due to asynchronous sleep mode strategies, fluctuations in the radio environment, device failure or mobility. Through its wireless interface, a sensor thus connects to a communication link with undetermined connectivity properties. Sensor networks are a challenge to current IP standards, since on the one hand these protocols were designed to work on wired links and on the other hand these protocols were designed to work on machines that do not have drastic constraints in terms of CPU, power capacities, and memory, as sensor nodes do. In consequence, several key standard protocols (including TCP, UDP, DHCP,
NDP, SLAAC, and OSPF) do not function correctly in this environment. Nevertheless, IPv6-based sensor networking is a viable long term goal because it would enable generic, large scale, seamless integration of millions of sensing devices using heterogeneous radio technologies, at a low cost, and in a future-proof manner. The Internet Engineering Task Force (IETF) is currently engaged into multiple efforts addressing the limitations of existing standards concerning wireless sensor IP networking. Some of the standards under construction aim at fitting IP formats, especially IPv6 formats, to direct wireless communications using low power radio technologies such as IEEE 802.15.4, which require IP format compression. Other standards in development aim at providing multi-hop wireless sensor communication with IPv6, which requires specific routing protocols, efforts in which we actively participate, prompting numerous joint publications with both industrial and academic partners.

6.3.2.3. Coloring in wireless sensor networks

Graph coloring is used in wireless networks to optimize network resources: bandwidth and energy. We focus on grid topologies that constitute regular topologies for large or dense wireless networks. We consider various transmission ranges and identify a color pattern that can be reproduced to color the whole grid with the optimal number of colors. We obtain an optimal periodic coloring of the grid for the considered transmission range. We then evaluate the performance of a 3-hop distributed coloring algorithm, called SERENA. Through simulation results, we highlight the impact of node priority assignment on the number of colors obtained for any network and grids in particular. We then compare these optimal results on grids with those obtained by SERENA and identify directions to improve SERENA.

6.3.2.4. Coloring algorithm optimized for dense wireless networks

In 2011, we also designed OSERENA "Optimized SchEduling RoutEr Node Activity", a distributed coloring algorithm optimized for dense wireless networks. Network density has an extremely reduced impact on the size of the messages exchanged to color the network. Furthermore, the number of colors used to color the network is not impacted by this optimization. We describe the properties of the algorithm and prove its correctness and termination. Simulation results point out the considerable gains in bandwidth.

6.3.2.5. Multichannel access in wireless sensor networks

In 2011 we started a research activity on multichannel access in wireless sensor networks. A state of the art has been published at the IFIP Wireless Days 2011 Conference.

6.3.3. Collaborations

- Many contractual collaborations:
  - Hitachi (Vehicular applications, OLSRv2),
  - OCARI2 project (industrial wireless sensor network, QoS, cross layer, energy efficiency, routing, node activity scheduling),
  - SAHARA project (wireless sensor network embedded in aircrafts),
  - STIC INRIA-Tunisian Universities: the team of Prof. Leila Saidane at ENSI (Performance improvement in a wireless sensor network),

- Non contractual:
  - BAE (OLSRv2),
  - Freie Universitaet (sensor networks, DHT),
  - Deutsche Telekom Labs/TU-Berlin, Germany,
  - University of Athens, Greece.

6.4. Vehicular and mobile applications

Participants: Cédric Adjih, Emmanuel Baccelli, Thomas Clausen, Philippe Jacquet, Pascale Minet, Paul Mühlethaler, Yasser Toor.
6.4.1. Executive summary

We have the following vision: in the future mobile internet and static internet will have their core deeply intricated. This means that mobile ad hoc networks will be attached to the core network, form extension and even be part of it. For example in disaster area, a wireless network could replace the destroyed infrastructure and help to the emergency operations.

With this perspective items such as Autoconfiguration, Security are of crucial importance. However there is a potential conflict between a large population of fixed nodes based on ancient protocol and a smaller but more dynamic population based on new protocols. In the integration both population must cooperate in an hybrid protocol.

The difficulty is to build protocols that are as dynamic and efficient as MANET protocols but can support the legacy of the old and heavy internet protocols. The challenge is nevertheless achievable, because the dynamic part of the network needs less frequent updates from the fixed part of the network. Moreover the natural abundance of resource in the fixed part of the network allows it to support the more frequent updates from the mobile part.

OLSR has been found to be the natural best candidate for this challenge since it gathers dynamic and optimization with internet legacy.

6.4.2. Scientific achievements

6.4.2.1. Military tactical networks

During year 2011, we conducted several expertises about industrial proposals dealing with OLSR use in military tactical networks.

6.4.2.2. Protocols for vehicular networks

We have achieved numerous studies and design of protocols for vehicular networks and more specifically for V2V (Vehicle-to-Vehicle) network.

First we have studied the channel occupancy induced by the OLSR proactive routing protocol used in a linear Vehicular Ad hoc Network (VANET). Unlike previous studies, which usually use simulations to evaluate the overhead, we have proposed a simple analytical model to carry out this evaluation. Moreover, we did not evaluate the total overhead induced by the routing protocol as is usually proposed, but, for a given node, the channel occupation induced by the routing protocol.

We have studied flooding techniques for safety applications in VANETs. The typical scenario is the diffusion of an alert message after a car crash in a platoon of vehicles. The packet is diffused with the pure flooding, the multipoint relay (MPR) diffusion of OLSR and a geographic aware protocol. For OLSR we have introduced a variant (Robust-MPR) to improve the reliability. Different realistic scenarios were considered and various parameters such as vehicle density, and background traffic load were scrutinized. We have shown that the Robust-MPR and the geographic aware protocol satisfy the requirements of the safety applications while using considerably less overhead than pure flooding.

We have shown that the geographic aware protocols can be improved for the diffusion of an alert message by using opportunistic routing. We have designed OB-VAN (Opportunistic Broadcast for VANets ) a new protocol that uses this idea. One of the novelty of this protocol is the use of an active signalling technique in the acknowledgement procedure to select the best relay taking advantage of the reception pattern of each message. We have studied OB-VAN in a linear VANET and have shown that it outperforms the flooding for the delay and the amount of overhead. However the delivery ratio of OB-VAN may be insufficient for safety applications. This remark has led to the design of R-OB-VAN which is a reliable variant of OB-VAN. With extensive simulations, we have shown that R-OB-VAN maintains a high delivery ratio even in the presence of packet loss due to shadowing.
We have studied the performance of the Aloha scheme in linear VANETs. This analysis assumes a SINR (Signal over Interference plus Noise Ratio) based model. In this model, we have derived the probability of a successful transmission between two vehicles at a distance of \( R \) meters. We have also computed the mean throughput according to Shannon’s law. In these two models, we have optimized the two quantities directly linked to the achievable network throughput i.e., the mean packet progress and the density of transport.

Finally, we have studied the utilization of opportunistic routing and shown that this technique is also beneficial for point to point traffic. It decreases the delay and increases the throughput compared with shortest path first routing. Moreover, we have also shown that opportunistic routing for point to point traffic eases considerably the optimization of the MAC scheme e.g. the transmission probability for Aloha and the carrier sense threshold for CSMA.

6.4.3. Collaboration

We received support from MoD for this activity.
6. New Results

6.1. identification of linear systems

6.1.1. Modular identification and damage detection for large structures

Participants: Michael Döhler, Laurent Mevel.

In Operational Modal Analysis (OMA) of large structures it is often needed to process sensor data from multiple non-simultaneously recorded measurement setups, especially in the case of large structures. In this work a new efficient variant of the PreGER algorithm is presented that avoids the numerical explosion of the calculation by using a modular approach, where the data from the measurement setups is processed setup by setup and not at the same time [16].

6.1.2. Fast multi order subspace identification algorithm

Participants: Michael Döhler, Laurent Mevel.

Stochastic subspace identification methods are an efficient tool for system identification of mechanical systems in Operational Modal Analysis (OMA), where modal parameters are estimated from measured vibrational data of a structure. System identification is usually done for many successive model orders, as the true system order is unknown and identification in results at different model orders need to be compared to distinguish true structural modes from spurious modes in so-called stabilization diagrams. An algorithm to estimate the system matrices at multiple model orders has been derived [20].

6.1.3. Evaluation of confidence intervals and computation of sensitivities for subspace methods

Participants: Michael Döhler, Xuan Lam, Laurent Mevel.

In Operational Modal Analysis, the modal parameters (natural frequencies, damping ratios and mode shapes) obtained from Stochastic Subspace Identification (SSI) of a structure, are afflicted with statistical uncertainty. A variant of this approach has been derived for the Eigenvalue-Realization-Algorithm (ERA) [25]. Another version has been proposed for the merging subspace algorithm [17], [17]. This approach has been validated on large scale examples[14].

6.2. damage detection for mechanical structures

6.2.1. Damage detection and localisation

Participants: Michael Döhler, Laurent Mevel.

Statistical methods using output-only data have been shown to offer a robust solution to the damage detection task. These techniques have also been combined with sensitivities extracted from finite element models to offer information on the location of damage accounting for uncertainties in the finite element sensitivities. In some applications, however, the formulation of the finite element model makes implementation impractical and this motivates the search for model-free damage localization alternatives. One option is to use experimentally extracted sensitivities but their computation requires a set of constants (usually absorbed in the normalization of the eigenvectors) that are not available in output only identification. The noted limitation can be circumvented by adding a known perturbation to the mass distribution and repeating the output only identification, a procedure that can be practical in some cases. Linking a null-space based subspace damage index with experimentally extracted sensitivities allows us to infer on the position of damage without formulating a
finite element model and without the need for input measurements. The performance of the algorithm is illustrated on simulated data [19]. Damage detection has also been applied to a large scale example of an European project [23], [15].

6.2.2. Robust subspace damage detection

Participants: Michael Döhler, Laurent Mevel.

Subspace methods enjoy some popularity, especially in mechanical engineering, where large model orders have to be considered. In the context of detecting changes in the structural properties and the modal parameters linked to them, some subspace based fault detection residual has been recently proposed and applied successfully. However, most works assume that the unmeasured ambient excitation level during measurements of the structure in the reference and possibly damaged condition stays constant, which is not possible in any application. This work addresses the problem of robustness of such fault detection methods. A subspace-based fault detection test is derived that is robust to excitation change but also to numerical instabilities that could arise easily in the computations [21].

6.3. Instability monitoring of aeronautical structures

6.3.1. Subspace identification for hinged-blades helicopters

Participants: Ahmed Jhinaoui, Laurent Mevel.

In this work, an extension of the output-only subspace identification, to the class of linear periodically time-varying (LPTV) systems, is proposed. The goal is to identify a useful information about the system’s stability using the Floquet theory which gives a necessary and sufficient condition for stability analysis [24].

6.3.2. Optimal input design for identification and detection

Participants: Alireza Esna Ashari, Laurent Mevel.

Output only techniques rely on the presence on unknown turbulence, which may or may not be enough to excite the system. A new approach for applying artificial input to the system for maximizing detection and identifiability has been developed. This work considers the problem of auxiliary input design for subspace-based fault detection methods. In several real applications, particularly in the damage detection of mechanical structures and vibrating systems, environment noise is the only input to the system. In some applications, white noise produces low quality output data for the subspace-based fault detection method. In those methods, a residual is calculated to detect the fault based on the output information. However, some modes of the system may not influence the outputs and the residual appropriately if the input is not exciting enough for those modes. In this work, rotated inputs method is implemented to excite the system modes. In addition to produce a residual more sensitive to the weak modes, it is possible to detect system order changes due to the fault using the rotated inputs. Simulation results demonstrate the efficiency of injecting these auxiliary inputs to improve the subspace-based fault detection methodology [22]. This work is funded by FP7-NMP Large Scale Integrated Project IRIS.
5. New Results

5.1. Qualitative modeling, simulation, analysis, and verification of gene regulatory networks

GE\textsc{net}i\textsc{c} NET\textsc{work} A\textsc{nu}ly\textsc{zer} (GNA) is a tool for the qualitative modeling and simulation of the dynamics of gene regulatory networks by means of PL models, as described in Section 4.1. GNA has been integrated with the other bioinformatics tools distributed by Genostar (http://www.genostar.com/). Version 8.3 of GNA was released by IBIS and Genostar this year. This version is an update of version 8.0, deposited at the Agence pour la Protection des Programmes (APP). Some bugs have been corrected in the new version and the program has been adapted to the latest versions of Java and the software platform of Genostar. A book chapter describing the current version of GNA has been published in a volume on the modeling of bacterial molecular networks [15]. The chapter is a tutorial illustrating the practical use of recent functionalities of GNA like the network editor and the formal verification module by means of an example network in \textit{E. coli} (see also [14]). A paper on the use of temporal logic and formal verification in the context of GNA appeared in \textit{Theoretical Computer Science} this year [7], in a special issue associated with the conference Computational Methods in System (CMSB), held in Rostock in 2008.

Notwithstanding the above improvements of the software, most of our efforts in the past year have gone into applications in collaboration with users of GNA. For example, Delphine Ropers has worked with several groups at IST Lisbon on the modeling of the FLR1 network in yeast, resulting in a paper in \textit{IET Systems Biology} [8]. The paper reports on the qualitative modelling and simulation of the transcriptional regulatory network controlling the response of the model eukaryote \textit{Saccharomyces cerevisiae} to the agricultural fungicide mancozeb. The model has allowed the analysis of the regulation level and activity of the components of the mancozeb-induced network controlling the transcriptional activation of FLR1. This gene is proposed to confer multidrug resistance to the cell through its putative role as a drug efflux pump. Formal verification analysis of the network allowed us to confront model predictions with experimental data and to assess the model robustness to parameter ordering and gene deletion. This analysis led to a better understanding of the mechanisms regulating the response of FLR1 to mancozeb and confirmed the need for a new transcription factor to account for the full transcriptional activation of the gene \textsc{YAP1}. The result is a model of the response of FLR1 to mancozeb, permitting a quick and cost-effective test of hypotheses prior to experimental validation.

As another example of the use of GNA, Hidde de Jong has contributed to the modeling of the TOL system in \textit{Pseudomonas putida}, carried out at the Spanish National Biotechnology Center (CNB). The gene regulatory network of the TOL plasmid pWW0 of the soil bacterium \textit{Pseudomonas putida} mt-2 for catabolism of m-xylene is an archetypal model for environmental biodegradation of aromatic pollutants. Although nearly every metabolic and transcriptional component of this regulatory system is known in detail, the complexity of its architecture is still perplexing. To gain an insight into the inner layout of this network a PL model of the TOL system was implemented, simulated and experimentally validated by measuring the expression of the genes encoding the regulators XyIR and XyIS when specific portions of the network were activated with selected inducers (m-xylene, o-xylene, 3-methylbenzyalcohol and 3-methylbenzoate). This analysis made sense of the specific regulatory topology on the basis of an unprecedented network motif in the genetic circuit for m-xylene catabolism. The motif appears to ensure a simultaneous expression of the upper and lower segments of the m-xylene catabolic route that would be difficult to bring about with a standard substrate-responsive single promoter. Furthermore, it is plausible that the motif helps to avoid biochemical conflicts between competing plasmid-encoded and chromosomally-encoded pathways in this bacterium. The analysis of the TOL system has been published in \textit{BMC Systems Biology} [11].
5.2. Experimental mapping of gene regulatory networks in bacteria

The use of fluorescent and luminescent reporter genes allows real-time monitoring of gene expression, both at the level of individual cells and cell populations (Section 3.3). In order to fully exploit this technology, we need methods to rapidly construct reporter genes, both on plasmids and on the chromosome, mathematical models to infer biologically relevant quantities from the primary data, and computer tools to achieve this in an efficient and user-friendly manner. For instance, in a typical microplate experiment, 96 cultures are followed in parallel, over several hours, resulting in 10,000-100,000 measurements of absorbance and fluorescence and luminescence intensities. Over the past few years, we put into place an experimental platform and data analysis software, notably the WELLEADER program (Section 4.2), to allow biologists to make the most of the information contained in reporter gene expression data. Several improvements of the platform for measuring gene expression are the subject of ongoing work, including a novel method for efficiently cloning reporter gene constructions on the chromosome of *E. coli*.

These tools are actually used in a series of studies directed at the experimental mapping of gene regulatory networks in *E. coli*. One example, carried out in the framework of the PhD thesis of Guillaume Baptist, is the development of a new screening methodology for identifying all genes that control the expression of a target gene through genetic or metabolic interactions. The screen combines mutant libraries with luciferase reporter constructs. Instead of a static picture of gene expression, this method allows dynamical monitoring in different environmental conditions. Mutants with interesting phenotypes can thus be selected based on multiple criteria, and the expression dynamics of the target gene can be extensively characterized. The method has been applied to the identification of the direct and indirect regulators of the gene *acs* in *Escherichia coli*. We confirmed known genetic regulators of the gene and identified new regulatory influences, many of which involve metabolic intermediates or metabolic sensing. An analysis of mutants involved in glycolysis and glucose transport demonstrates that the classical model of catabolite repression in *E. coli* needs to be amended. A paper describing the above work is currently under revision.

Other examples of on-going work are the analysis of the network involved in motility and sessility and the modulation of the RpoS regulon in *E. coli* by Omaya Dudin and Stephan Lacour, the validation of a model of the network of global regulators of transcription by Sara Berthoumieux and Hidde de Jong, and the analysis of the regulation of cAMP levels in the bacterial cell by Claire Villiers.

5.3. Analysis of metabolic coupling in gene regulatory networks

The regulation of gene expression is tightly interwoven with metabolism and signal transduction. A realistic view of genetic regulatory networks should therefore not only include direct interactions resulting from transcription regulation, but also indirect regulatory interactions mediated by metabolic effectors and signaling molecules. We coined the term metabolic coupling to denote these indirect interactions mediated by metabolism. Ignoring metabolic coupling during the analysis of the network dynamics may lead crucial feedback loops to be missed.

In previous work, published in *PLoS Computational Biology* in 2010, we showed how indirect interactions arising from metabolic coupling can be derived from a model of the underlying biochemical reaction network. We applied this approach to the carbon assimilation network in *Escherichia coli* investigating how the structural properties of the network are modified by the inclusion of metabolic interactions. Our results showed that the derived gene regulatory network is densely connected, contrary to what is usually assumed. Moreover, we found that the signs of the indirect interactions are largely fixed by the direction of metabolic fluxes, independently of specific parameter values and rate laws, and that a change in flux direction may invert the sign of indirect interactions. This leads to a feedback structure that is at the same time robust to changes in the kinetic properties of enzymes and that has the flexibility to accommodate radical changes in the environment.

It remains an open question, however, to which extent the indirect interactions induced by metabolic coupling affect the dynamics of the system. This is a key issue for understanding the relative contributions of the regulation of gene expression and metabolism during the adaptation of the cell to changes in its environment. In collaboration with Valentina Baldazzi, formerly post-doctoral fellow in IBIS and now research scientist
at INRA (Avignon), we have carried out a dynamic analysis by developing a qualitative PL model of the gene regulatory network, including both the direct and indirect interactions. We previously showed, in a paper published in the IEEE/ACM Transactions on Computational Biology and Bioinformatics this year, that PL models provide a good approximation of the direct and indirect interactions occurring in gene regulation [10].

In order to obtain a clearer view of the dynamic role of metabolic coupling in the adaptation of gene expression, we developed several qualitative models corresponding to a network topology including all, some, or none of the indirect interactions. The dynamical properties of the models were analyzed and compared with available experimental data using the computer tool GNA (Section 4.1). In particular, we compared the steady-state concentrations of enzymes and transcription regulators during growth on glucose and acetate, as well as the dynamic response of gene expression to the exhaustion of glucose and the subsequent assimilation of acetate. We find significant differences between the dynamics of the system in the absence and presence of metabolic coupling. This confirms that indirect interactions are essential for correctly reproducing the observed adaptation of gene expression to a change in carbon source. Our work thus underlines the importance of metabolic coupling in gene regulatory networks, and shows that such indirect interactions cannot be neglected when studying the adaptation of an organism to changes in its environment. A short, preliminary paper on this work was presented at an invited session of the 18th IFAC World Congress held in Milano [12] and a long paper has been accepted for publication in the Journal of Theoretical Biology [2].

5.4. Parameter estimation for kinetic models of carbon metabolism in bacteria

Kinetic models capture the dynamics of the large and complex networks of biochemical reactions that endow bacteria with the capacity to adapt their functioning to changes in the environment. In comparison with the qualitative PL models described in Sections 5.1 and 5.3, these more general classes of ODE models are intended to provide a quantitative description of the network dynamics, both on the genetic and metabolic level. New experimental techniques have led to the accumulation of large amounts of data, such as time-course measurements of metabolite, mRNA and protein concentrations and measurements of metabolic fluxes under different growth conditions. However, the estimation of parameter values in the kinetic models from these data remains particularly challenging in biology, mostly because of incomplete knowledge of the molecular mechanisms, noisy, indirect, heterogeneous, and partial observations, and the large size of the systems, with dynamics on different time-scales. We have addressed parameter estimation in the context of the analysis of the interactions between metabolism and gene expression in carbon metabolism in E. coli.

In collaboration with Matteo Brilli and Daniel Kahn (INRA and Université Claude Bernard in Lyon), we have developed an approximate model of central metabolism of E. coli, using so-called linlog functions to approximately describe the rates of the enzymatic reactions. More precisely, linlog models describe metabolic kinetics by means of a linear model of the logarithms of metabolite concentrations. We have used metabolome and transcriptome data sets from the literature to estimate the parameters of the linlog models, a task in principle greatly simplified by the mathematical form of the latter. However, a major problem encountered during parameter estimation was the occurrence of missing data, due to experimental problems or instrument failures. In the framework of her PhD thesis, Sara Berthoumieux has addressed the missing-data problem by developing an iterative parameter estimation approach based on an Expectation-Maximization (EM) procedure. This approach adapted from the statistical literature has the advantage of being well-defined analytically and applicable to other kinds of linear regression problems with missing data. It has been tested on simulations experiments with missing data and performs well compared to basic and advanced regression methods.

On the biological side, we have applied the method to a linlog model of central metabolism in Escherichia coli, consisting of some 23 variables. We estimated the 100 parameters of this model from a high-throughput dataset published in the literature. The data consists of measurements of metabolic fluxes and metabolite and enzyme levels in glucose-limited chemostat under 29 different conditions such as wild-type strain and single-gene mutant strains or different dilution rates. Standard linear regression is difficult to apply in this case due to missing data, which disqualifies for 7 reactions too many datapoints, leaving a dataset of size inferior to the
A second line of work is based on the use of classical kinetic models that are, in comparison with the above-mentioned linlog models, much reduced in scope (the focus is on the metabolic and genetic regulation of the glycolysis pathway) and granularity (individual reactions are lumped together). The models, developed by Delphine Ropers, have been calibrated using experimental data from the experimental part of the IBIS group for the gene expression measurements and the group of Jean-Charles Portais at INSA in Toulouse for the measurements of metabolism. The model with the estimated parameter values is currently being tested and used to understand some key mechanisms in the adaptation of *E. coli* to the exhaustion of glucose. The PhD theses of Stéphane Pinhal and Valentin Zulkower, which started at the end of this year, will further develop these research directions.

5.5. Structural identification of gene regulatory networks

In general, structural identification of genetic regulatory networks involves fitting appropriate network structures and parameters to the data. While modern measurement techniques such as reporter gene systems provide data of ever-increasing quality, the problem remains challenging because exploring all possible network structures in the search of the best fitting model is prohibitive.

In order to address the structural identification problem, Eugenio Cinquemani proposed in collaboration with the Automatic Control Lab at ETH Zürich (Switzerland) and the Computer Engineering & Systems Science Department of the University of Pavia (Italy), an ODE modelling framework which we refer to as models with unate-like structure. In Boolean network modeling, unate functions are argued to capture virtually all observable interactions in gene regulatory networks. In our quantitative framework, unate logics are encoded in the structure of the nonlinear synthesis rates of the network proteins. This framework allows us to integrate *a-priori* information on the most likely network structures, and the models enjoy monotonicity properties that can be exploited to simplify the identification task.

As described in previous work, published in *Bioinformatics* in 2010, the key idea is to divide the identification process into two steps. In the first step, different monotonicity properties of different model structures are exploited to discard those structures whose property is falsified by the observed data points (time-lapse protein concentrations and synthesis rates). In the second step, the parameters of the model structures not discarded in the first step are fitted to the data in the search of the simplest structure explaining the data with sufficient accuracy. The procedure was validated on challenging data from the literature.

On the methodological side, in the context of the same international collaboration, the identification approach has been further developed. For important subclasses of unate models, larger sets of network structures can now be discarded in the hypothesis falsification step, based on additional properties other than monotonicity (namely quasi-convexity). These improvements have been presented at the 18th IFAC World Congress held in Milan, and are reported in a journal paper that has been accepted for publication in the *International Journal of Robust and Nonlinear Control*, in a special issue on system identification for biological systems. In the framework of the PhD thesis of Diana Stefan, in collaboration with Eugenio Cinquemani, Stephan Lacour and Omaya Dudin, the method is now being applied to experimental data produced within IBIS for the study of the gene network regulating motility of *E. coli* bacteria.

Woei-Fuh Wang, who defended her PhD thesis carried out under the supervision of Johannes Geiselmann and Chung-Ming Chen in December 2011, addressed a different problem in the structural identification of gene regulatory networks. The inference of the network topology and regulatory mechanisms is complicated by the fact that we usually do not know all relevant genes that need to be taken into account for explaining the observed expression patterns. The aim of the thesis was to detect the presence of such “missing genes”, as
well as their regulatory roles and expression patterns. Using a well-known class of simplified kinetic models, based on power-law approximations of synthesis rate functions, an inference algorithm was developed. The algorithms are based on factor analysis, a well-developed multivariate statistical analysis approach that is used to investigate unknown, underlying features of a dataset, as well as independent component analysis. The proposed method of inferring the expression profile of a missing gene and connecting it to a known network structure has been applied to artificial networks, as well as a real network studied within IBIS: the acs regulatory network in Escherichia coli.

5.6. Stochastic modeling and identification of gene regulatory networks in bacteria

At the single cell level, the processes that govern gene expression are often better described by stochastic models. Modern techniques for the real-time monitoring of gene expression in single cells enable one to apply stochastic modelling to study the origins and consequences of random noise in response to various environmental stresses, and the emergence of phenotypic variability. The potential impact of single-cell stochastic analysis and modelling is tremendous, ranging from a better comprehension of the biochemical regulatory mechanisms underlying life, to the development of new strategies for the control of bacterial populations and even of single cells, with applications in for example biotechnology and medicine.

In the literature, much effort has been devoted to the analysis of stochastic gene expression models derived from biochemical kinetics and specific knowledge of the systems at hand. Less effort has been dedicated to developing general methods for inferring unknown parameter values of these stochastic models from single-cell experimental data. While some strategies have been proposed in the recent literature, no method of general applicability exists. IBIS recently started a new line of research dedicated to the study of stochastic modelling and identification of gene regulatory networks in single cells. This work, coordinated by Eugenio Cinquemani, focuses on simple network modules in bacterial cells. Our reference system is the regulation of the inset of arabinose uptake in E. coli upon depletion of glucose.

In the past year we developed a working method for the estimation of unknown network parameters of a simple stochastic model of the arabinose uptake process. The method was tested on simulated data and applied with success to time-lapse fluorescence microscopy data acquired by Guillaume Baptist. This application involved the development by Michel Page of a microscopy data processing program based on a customization of the freely accessible Matlab tool CellTracer. Preliminary results were presented in the poster session of the Conference on Stochastic Systems Biology held in Monte Verità (Switzerland). The work is currently being extended in preparation for a journal publication. A generalization of the method and the investigation of alternative stochastic modelling and identification methodologies are being pursued in parallel. Other ongoing work concerns the study of noise propagation in gene regulatory networks in collaboration with Irina Mihalcescu (Université Joseph Fourier).

5.7. Control of regulatory networks in bacteria

While systems biology is primarily concerned with natural systems shaped by evolution, synthetic biology opens up a new generation of fundamental research by trying to redesign natural systems or create novel systems from scratch. Mathematical modeling and analysis are essential components of synthetic biology, as they help understanding the consequences of (changes in) the network of interactions on the dynamical behavior of the system. More specifically, a model can be a powerful tool for the control and regulation of the system towards a desired goal.

Within the projects ColAge and GeMCo (Section 5.1), we attempt to control one of the fundamental physiological properties of bacterial cells, their growth rate. In particular, in order to control the growth rate, we propose to focus on the gene expression machinery of E. coli, whose activity is controlled by a complex regulatory network with many components and intertwined feedback loops. Delphine Ropers is developing models of the gene expression machinery and Jérome Izard, in the context of his PhD thesis, is rewiring part of the network to enable control of the network dynamics. The results on these projects are currently being prepared for publication.
6. New Results

6.1. High speed autonomous driving on roads

Participants: Fawzi Nashashibi, Laurent Bouraoui, Paulo Lopes Resende.

In this exceptional year, IMARA-INRIA had a very busy agenda with several scheduled demonstrations in the frameworks of several European projects, especially HAVEit, CityMobil and CityNetMobil.

The HAVEit project final event took place at Boras (Sweden) in June. IMARA was tightly involved in the development of the Joint Demonstrator called FASCar-II. In this demonstrator, IMARA was responsible for the development of the Co-Pilot system. This is the main decisional system that handles the manoeuvres to be executed taking into account the multisensor data fusion sub-system, the driver monitoring system and the infrastructure (data provided by the infrastructure-to-vehicle telecommunications). The system also generates the trajectories to be executed as well the control-command laws to be send to the actuators [40] and provides passive or active assistance to the driver according to the active automation level.

In parallel, IMARA has also developed the “Wireless Infrastructure to Vehicle communication system”. Here, a specific hardware and software systems have been developed to allow V2I and V2V applications integrated on the Joint System demonstrator. This architecture – called the 4GCube – is based on the wireless communications devices and standards (802.11 a/b/g); they are IPv6 / CALM compliant architectures that have been tested with 2.4 GHz and 5 GHz bands, allowing multiple services handling.

The integration and the validation of the Co-pilot system as well as the communication device were done during the Final Event of HAVEit with a tremendous success and with high professional standards. The FASCar was able to demonstrate high driving autonomous skills at high speeds (up to 120 km/h) and was able to demonstrate new advanced features like overtaking mobile and static obstacles.

6.2. New urban transportation platforms: INRIA’s Cybus

Participants: Laurent Bouraoui, François Charlot, Carlos Holguin, Fawzi Nashashibi, Tony Noël, Michel Parent, Paulo Lopes Resende, Jianping Xie, Armand Yvet.
In order to achieve autonomous driving, autonomous systems (robots, intelligent vehicles, UAV’s, UGV’s,...) must have a decisional system that integrates an advanced perception system that performs sensors data fusion and environment modeling. From perception to control, task planning and path planning algorithms have to plan safe and optimized itineraries while processing sensory data. Motion control is the last link of the processing chain where itineraries and dynamic trajectories are executed by the low level control system. IMARA works on each of the topics mentioned above.

With the European projects CityMobil and CityNet Mobil, IMARA had the opportunity to validate the autonomous driving architecture developed through the projects showcases held in European cities. In 2011, several cities hosted IMARA team in charge of demonstrating autonomous driving and autonomous sensor-based navigation using sensory data (laser scanners) and GNSS (GPS). These events were a total success and were the opportunity to deploy and test the large-scale SLAMMOT system used for environment mapping, vehicle localization and mobile obstacles detection but also the new VMS (Vehicle Management System) developed in order to coordinate the mobility and navigation of several Cybercars (INRIA’s Cybus platforms).

For this purpose, the perception sub-system was based on the generic SLAM-based system that was already presented in detail last year [43]. The proposed localization architecture has been implemented in two different vehicle platforms. AGV is a fully autonomous vehicle equipped with two IBEO Alasca-XT laser scanners (left and right front corner). Cycab is a prototype of smart car mounted with a single IBEO-ML laser scanner in front.

This year, because of delivery problems related to an industrial partner, IMARA had to design and develop its own cybercars. Thus the Cybus are the newest prototyping and demonstration platforms designed at INRIA. Apart from the chassis and engines, the whole hardware and software systems were developed thanks to IMARA’s researchers and engineers talents. These electric vehicles are based on a Yamaha chassis but the embedded intelligence is the result of this year’s IMARA developments. Much of the perception and control software is now registered.

The system developed can be seen as an experimental platform for a new public mobility transportation system operating in mixed environments. This electric vehicle is a “clean” transportation mean that is capable to achieve the well known last-mile itinerary in urban areas where classical transportation means are inefficient or simply non profitable. In order to demonstrate the feasibility of the system, a 3-months service has been programmed in the City of La Rochelle. The Mayor of the City authorized the Cybus to operate during 3-months providing free transport service to the inhabitants of the city. For that purpose, a 2 kilometers route has been defined on which 5 calling stations where installed. The users were able to call the Cybus from any station to reach any other station. The evaluation of the system has shown an acceptability of more than 95% among population; very low failures or technical leakages were reported. Following this successful operation,
the European Commission asked INRIA to extend this operation as well as its technical capabilities in order to achieve a simultaneous multiple Cybus navigation. This was achieved last December and was a real success.

Figure 3. The Cybus hardware architecture

Figure 4. The Cybus operated at La Rochelle City during 3 months as a free transport service.

The platforms developed here (Cybus) were exploited and demonstrated in the context of the EU-CityNetMobil project. The cities of Antibes (France) and Reggio di Calabria (Italy) hosted the team for 2 weeks respectively in order to experiment this new mobility and transportation mean in the heart of their cities.

Following this success, a new proposal of CityMobil-2 project is under submission with the objective this time to extend real operational mobility services to 6-12 months in selected European cities!

6.3. Communications Management in Cooperative Intelligent Transportation Systems

Participants: Thierry Ernst, Manabu Tsukada.

Cooperative Intelligent Transportation Systems (Cooperative ITS) are systems where the vehicles, the roadside infrastructure, central control centers and other entities exchange information in order to achieve better road safety, traffic efficiency and comfort of the road users. This exchange of information must rely on a common communication architecture. The ITS Station reference architecture has thus been specified in ISO and ETSI. It allows vehicles and roadside ITS stations to organize themselves into Vehicular Ad-hoc Network (VANET), presumably though IPv6 GeoNetworking using IEEE802.11p and to connect seamlessly to the
Internet though any available access technology. Several paths may thus be available at a given vehicle ITS station to communicate with other ITS stations. Paths are of three types: direct path, optimize path and anchor path. The objective of the study is to optimize the communication between ITS Stations by selecting the best available communication path. This requires first to gather information available locally at the ITS station (position, speed, application requirements, media characteristics, capabilities, path status, ... ) and collected from neighbors ITS stations (position, speed, services, ... ) and then to process this information through a decision-making algorithm. First, we define a network module allowing the combination of IPv6 together with GeoNetworking. Second, we propose a cross-layer path selection management module. Our contributions are mapped to the ITS station reference architecture by defining the relation between the ITS station network and transport layer (which hosts our IPv6 GeoNetworking contribution) and the vertical ITS station cross-layer entity (which hosts the path decision-making algorithm). We specify the functions allowing the exchange of parameters through the Service Access Point (SAP) between the network layer and the management entity (MN-SAP). The parameters used at the cross layer ITS station management entity are abstracted in a way so that they are agnostic to the protocols used at the ITS station network and transport layer, therefrom allowing easy replacement of protocol elements (e.g. replacing NEMO by other mobility support protocol) or permutation of the network stack (IPv6 or GeoNetworking, a combination of both or other network stack).

6.4. Managing the system (via probabilistic modeling)

6.4.1. Belief propagation inference for traffic prediction

Participants: Cyril Furtlehner, Jean-Marc Lasgouttes, Arnaud Lewden, Victorin Martin.

This work [41] deals with real-time prediction of traffic conditions in a setting where the only available information is floating car data (FCD) sent by probe vehicles. The main focus is on finding a good way to encode some coarse information (typically whether traffic on a segment is fluid or congested), and to decode it in the form of real-time traffic reconstruction and prediction. Our approach relies in particular on the belief propagation algorithm.

These studies are done in particular in the framework of the projects TRAVESTI and Pumas.

This year’s highlights are

- A particular effort has been done this year in studying the theoretical aspects of the ways to encode real valued variable into an binary Ising model. A publication on the subject is in preparation.
- A review of our work on road traffic inference using methods from statistical physics has been published [21].
- The investigation of the effect of various types of normalization in the belief propagation algorithm has lead to a technical report [38].
- Arnaud Lewden has specified and implemented the new software BPlstruction, which is our contribution to the Pumas project. Besides implementing traffic reconstruction from FCD, it is intended as a testbench for our research on inference using Belief Propagation.
- Victorin Martin has given a talk at the “Séminaire de Modélisation des Réseaux de Transport” at IFSTTAR. He presented there our method for real-time traffic reconstruction and prediction.
- Jean-Marc Lasgouttes also presented this work at the Xerox Research Centre Europe seminar.

6.4.2. Evaluation of dual mode transport system by event-driven simulation

Participants: Arnaud de La Fortelle, Sami Mahari.

The European project CATS — City Alternative Transport System — is developing and evaluating a new vehicle system using a single type of vehicle for two different usages: individual use or collective transport. Real experiments will necessarily take place with a limited number of vehicles and stations. Hence there is a need for evaluation using simulations. We have been developing a discrete events simulator for that purpose, based on a previous work done for collective taxis [42].
Our model relies on an adapted events/decision graph that extends previous graphs. The new feature of this model is the way we deal with two modes that can be extended to many other modes. This work therefore shows on a concrete example a method to efficiently merge multiple modes into one model.

- This year has seen the design and first implementation of the simulator.
- The results have been presented at a conference [29].

### 6.4.3. Multi-speed exclusion processes

**Participants:** Cyril Furtlehner, Jean-Marc Lasgouttes, Maxim Samsonov.

The slow-to-start mechanism is known to play an important role in the particular shape of the Fundamental diagram of traffic and to be associated to hysteresis effects of traffic flow. We study this question in the context of stochastic processes, namely exclusion and queueing processes, by including explicitly an asymmetry between deceleration and acceleration in their formulation. Spatial condensation phenomena and metastability are observed, depending on the level of the aforementioned asymmetry. The relationship between these 2 families of models is analyzed on the ring geometry, to yield a large deviation formulation of the fundamental diagram (FD).

This work has been presented at the TGF’11 conference [22], and a more extensive article is in preparation for a journal.

### 6.4.4. Dynamics of points of interest in a social game

**Participants:** Guy Fayolle, Jean-Marc Lasgouttes.

*Ma Micro Planète* is a geolocalized video game which entices players to use sustainable means of transport. At the heart of the game are community-driven points of interest (POI’s), or sites, which have a score that depends on the players activity. The aim of this work is to understand the dynamics of the underlying stochastic process.

We examine the system in the thermodynamic limit, as the number of players tends to infinity, the existence of which is proved under general conditions, where the probability of increasing the score of a visited POI is a function of the state of the system. Concerning the existence of a stationary regime, some complete answers are given for particular values of the parameters, and the existence of possible phase transition phenomena is enlightened.

A publication on the subject is in preparation.

### 6.4.5. Random walks in the quarter plane

**Participant:** Guy Fayolle.

In collaboration with K. Raschel (CNRS, Université F. Rabelais à Tours), we pursued the works initiated in 2010 in two main directions.

#### 6.4.5.1. The zero drift case

In several recent studies on random walks with small jumps in the quarter plane, it has been noticed that the so-called group of the walk governs the behavior of a number of quantities, in particular through its order.

In the article [11], when the drift of the random walk is equal to 0, we provide an effective criterion giving the order of this group. More generally, we also show that in all cases where the genus of the algebraic curve defined by the kernel is 0, the group is infinite, except precisely for the zero drift case, where finiteness is quite possible.

#### 6.4.5.2. Counting and asymptotics

The enumeration of planar lattice walks, is a classical topic in combinatorics. For a given set $S$ of allowed unit jumps (or steps), it is a matter of counting the number of paths starting from some point and ending at some arbitrary point in a given time, and possibly restricted to some regions of the plane.

Like in the probabilistic context, a common way of attacking these problems relies on the following analytic approach. Let $f(i, j, k)$ denote the number of paths in $\mathbb{Z}_+^2$ starting from $(0, 0)$ and ending at $(i, j)$ at time $k$. Then the corresponding CGF
Robotics - New Results - Project-Team IMARA

\[ F(x, y, z) = \sum_{i,j,k \geq 0} f(i, j, k)x^i y^j z^k \]

satisfies the functional equation

\[ K(x, y)F(x, y, z) = c(x)F(x, 0, z) + \tilde{c}(y)F(0, y, z) + c_0(x, y), \]

where \( x, y, z \) are complex variables, although the time variable \( z \) plays somehow the role of a parameter. The question of the type of the associated counting generating functions, that is rational, algebraic, holonomic (solution of a linear differential equation with polynomial coefficients), was solved whenever the group is finite (see RA 2010). When the group is infinite, the problem is still largely.

It turns out that the nature of singularities play a deep important role in this classification. Making use of the general and powerful approach proposed in the book [3], a paper entitled *Some exact asymptotics in the counting of walks in the quarter-plane* has been submitted to AofA (International Conference on Analysis of Algorithms, Montreal, June 2012), in which a new approach is proposed to obtain some exact asymptotics for walks confined to the quarter plane.

### 6.4.6. Statistical physics and hydrodynamic limits

**Participants:** Guy Fayolle, Cyril Furtlehner.

Having in mind a global project concerning the analysis of complex systems, we first focus on the interplay between discrete and continuous description: in some cases, this recurrent question can be addressed quite rigorously via probabilistic methods.

To attack this class of problems, in touch with many applications domains (e.g. biology, telecommunications, transportation systems), we started from paradigmatic elements, namely the discrete curves subjected to stochastic deformations, as those mentioned for instance in [39]. After convenient mappings, it appears that most models can be set in terms of interacting exclusion processes, the ultimate goal being to derive hydrodynamic limits for these systems after proper scalings. We extend the key ideas of [39], where the basic ASEP system on the torus was the toy model. The usual sequence of empirical measures, converges in probability to a deterministic measure, which is the unique weak solution of a Cauchy problem.

The Gordian knot is the analysis of a family of specific partial differential operators in infinite dimension. Indeed, the values of functions at given points play here the role of usual variables, their number becoming infinite. The method presents some new theoretical features, involving promeasures (as introduced by Bourbaki), variational calculus, functional integration, and the construction of generalized measures. In [20], we present a detailed analysis of the ASEP system on the torus \( \mathbb{Z}/N\mathbb{Z} \). Then we claim that most of the arguments a priori work in higher dimensions (ABC, multi-type exclusion processes, etc), leading to systems of coupled partial differential equations of Burgers’ type. In the course of the study, several fascinating multi-scale problems emerge quite naturally, bringing to light some connections with the so-called renormalization in theoretical physics.
6. New Results

6.1. Feature space modelling

6.1.1. A novel shape boundary based description for leaf identification

Participants: Itheri Yahiaoui, Olfa Mzoughi, Nozha Boujemaa.

The problem of automatic leaf identification is particularly difficult for two main reasons: (i) the first is the enormous number of leaf species and (ii) the second, which is relevant for some special species but more complex, is the high inter-species and the low intra-species similarity.

Our research has focused on analysing leaf morphology in order to determine a numeric key description for leaf species robust to all the above mentioned constraints. The approach that we propose is a shape boundary description that combines two complementary information: (i) the first one outlines local variations of the leaf margin. This is performed using the Directional Fragment Histogram (DFH), introduced in [25], which encodes the relative frequency distribution of groups of contour points with uniform orientation, (ii) the second property emphasizes the spatial distribution of contour points (in terms of distances). This is done by comparing the shape to standard geometric ones (such as circle, rectangle, ellipse, convex hull, etc.).

This descriptor was evaluated within the framework of ImageCLEF 2011 plant task where a crowd-sourced database, called Pl@ntLeaves [13], was used and a high number of image retrieval techniques was tested (a total of 8 groups from all around the world that have submitted 20 runs [19]). Our descriptor brought the best rate for scan-like pictures and was close to the best rate for scan pictures. Besides to the accuracy, this descriptor requires very low computational time, which accomplishes a basic condition for real world application.

6.1.2. Visual-based plant species identification from crowdsourced data

Inspired by citizen sciences, the main goal of this work is to speed up the collection and integration of raw botanical observation data, while providing to potential users an easy and efficient access to this botanical knowledge. We therefore designed and developed an original crowdsourcing web application dedicated to the access of botanical knowledge through automated identification of plant species by visual content.

Technically, the first side of the application deals with content-based identification of plant leaves. Whereas state-of-the-art methods addressing this objective are mostly based on leaf segmentation and boundary shape features, we developed a new approach based on local features and large-scale matching. This approach obtained the best results within one sub-task of ImageCLEF 2011 plant identification benchmark [19]. The second side of the application deals with interactive tagging and allow any user to validate or correct the automatic determinations returned by the system.

Overall, this collaborative system allows to enrich automatically and continuously the visual botanical knowledge and therefore to increase progressively the accuracy of the automated identification. A demo of the developed application was presented at ACM Multimedia conference [13]. This work was done in collaboration with INRIA team ZENITH and with the botanists of the AMAP UMR team (CIRAD). It is also closely related to a citizen science project around plant’s identification that we developed with the support of the TelaBotanica social network inside the Pl@ntNet project.

6.1.3. Spatial relations between salient points on a leaf

Participants: Sofiène Mouine, Itheri Yahiaoui, Anne Verroust-Blondet.
Figure 1. Normalized classification scores for scan images (up) and scan-like images (down). Our approach bin is in red, other ImageCLEF methods in blue.
In the scope of the Pl@ntNet project, our recent work has consisted in finding spatial relationships between salient points on a leaf. As a first step, classic detectors were used to find significant points in the leaf area and then the Shape context descriptor, originally applied on contour points, was introduced to measure a spatial relation between interest points. We have tested different configurations by varying the set of voting points. First results confirm that including spatial relations enriches the local description of each point. We are currently improving a veins and landmark extraction approach [12] in order to include also veins points in the voting set.

6.1.4. 3D mesh segmentation by example

Participants: Esma Elghoul, Anne Verroust-Blondet.

In recent years, there has been an increasing interest for automatic 3D segmentation. Indeed, segmentation of 3D objects is an important step in many applications such as part indexing of 3D objects, pattern recognition, compression, morphing, texture mapping and simplification. It refers to the process of partitioning 3D shapes into multiple parts, based on semantic criteria and/or geometric criteria.

Our work consists in introducing an approach to segment a 3D object class referring to a given segmented object from this class (we called it segmentation by example). The considered segmentation method is not automatic: we want to use interactive tools that proved advantageous to segment a 3D shape into relevant parts.

As a first task, we reviewed the state of the art in 3D segmentation techniques recently proposed in the literature. The different techniques were evaluated and classified for the purpose of choosing the more appropriate one for our work. We opted for extending the technique of random walks [24] to build an interactive tool of 3D segmentation.

For the second task, we had to solve a basic problem: that of similarly direct objects belonging to the same class. Indeed, each 3D model is provided in a random orientation in the space. In order to align objects of a same class, we used the alignment approach developed in [22] which computes 3 alignment axes. To properly orient our objects between them, we had to develop an additional process to the last one. It combines a 2D ICP and a 3D ICP approaches to give the best orientation among 48 possibilities and pair each two objects meshes.

So having a user-supplied already segmented model (model (1)) and a second model (model (2)) belonging to the same class (not segmented but similarly oriented), we developed a method to put into correspondence segmented parts of model (1) with faces of model (2). Then we computed a segmentation of model (2) using a derivative approach of the random walks. We applied this technique as well to segment all the objects that belong to the class of model (1). Our approach provides good results for manufactured object classes such as chairs and tables.

6.2. Feature space structuring

6.2.1. Random Maximum Margin Hashing

Participant: Alexis Joly.

Following the success of hashing methods for multidimensional indexing, more and more works are interested in embedding visual feature space in compact hash codes. Such approaches are not an alternative to using index structures but a complementary way to reduce both the memory usage and the distance computation cost. Several data dependent hash functions have notably been proposed to closely fit data distribution and provide better selectivity than usual random projections such as LSH. However, improvements occur only for relatively small hash code sizes up to 64 or 128 bits due to the lack of independence between the produced hash functions. In this work, we introduced a new hash function family that attempts to solve this issue in any kernel space. Rather than boosting the collision probability of close points, this method focus on data scattering. By training purely random splits of the data, regardless the closeness of the training samples, it is indeed possible to generate consistently more independent hash functions. On the other side, the use of large margin classifiers allows to maintain good generalization performances. Experiments did show that our
new Random Maximum Margin Hashing scheme (RMMH) outperforms four state-of-the-art hashing methods, notably in kernel spaces. Overall, this new concept of randomly trained classifiers opens the door to many other problems including large-scale learning, visual vocabulary construction or distributed content-based retrieval methods. A paper describing RMMH was published in the proceedings of CVPR 2011 [14].

6.2.2. Scalable information retrieval in distributed architectures

**Participants:** Mohamed Riadh Trad, Alexis Joly, Nozha Boujemaa.

Organizing media according to the occurrence of real-life events is attracting increasing interest in the multimedia community. However, whereas text based methods are now mature enough to deal with huge datasets, there are still some challenging issues managing multimedia contents. This becomes even more challenging in the context of User Generated Contents. Low-level visual metadata are indeed not simple textual or scalar values, their management requires efficient similarity search in high dimensional spaces.

Similarity search in high dimensional spaces has been the focus of many works in the database community in the recent years. State-of-the-art methods focus mainly on space partitioning techniques and more recently on hash-based probabilistic algorithms.

Although, hash-based approaches proved to be scalable, the computational cost is still too high for some real world applications and K-Nearest Neighbours Graph constructed can be more desirable than the costly online K-NN search. In fact, the basic LSH algorithm partitions the space uniformly and thus it does not exploit the clustering property of the data, which may result in slow query response and wasted space with additional hash tables. These limitations were pointed out with our scalable prototype for large scale event matching [18].

Scaling up LSH-based techniques and applications is then closely related to buckets occupations and objects distribution within the index structure. Recent works achieve better data distribution over the buckets with guarantees on occupation. As one result, we easily bound the similarity join size and evaluate bound algorithms complexity.

Based on these works, we designed and implemented a scalable prototype for distributed similarity search and K-NN graph construction. We have made several experiments querying real world large datasets. The prototype proved to be efficient for both search and K-NN graph construction.

Ongoing experiments process a 1.2 million images dataset. Results will be submitted for publication.

6.2.3. Visual similarity sensitive hashing methods for semantic image search in very large collections of images

**Participants:** Saloua Ouertani-Litayem, Alexis Joly, Nozha Boujemaa.

With the rapid development of information acquisition technology, we have witnessed an explosive growth in the scale of shared data collections. Then, it is now possible to tackle fundamental problems with very large datasets’ context. Especially those addressing challenging tasks in machine learning for developing large scale approaches for multimedia retrieval and mining. Computer Vision is experiencing this paradigm shift, with large annotated image and video datasets becoming available. Indeed, various benchmark datasets for image classification have been released such as image-net and LabelMe. Therefore, a key challenge is taken up through out the Phd aiming to build efficient methods for training and matching efficiently very large collections of images.

We proposed several SVM-based strategies to build new supervised hash function families from large annotated collections of features. We indeed investigated with an approach consisting in benefitting from different embedding approaches in order to build compact codes indexed with efficient similarity search structures. Therefore, we have extended a kernelized hashing method [14] with multi-class SVM to solve a K-class classification problem by choosing the maximum applied to the outputs of K SVMs. We indeed proposed hashing methods based on the multi-class SVM classification strategies: One vs One (OVO) And One vs All (OVA). An important task during this process was to experimentally evaluate the quality lost induced by such representations with respect to the efficiency gains. We then compared multi-class SVM strategies with different underlying kernels.
Inspired by state of the art hashing in kernel space methods we investigated an approach consisting of benefiting from both semantic hashing like techniques and kernel embedding approach in order to build compact category aware codes indexed with efficient similarity. Experiments, are performed on image-net ILSVRC 2010 dataset [23]. Results will be submitted for publication.

6.3. Pattern recognition and statistical learning

6.3.1. Machine identification of biological shapes

Participants: Asma Rejeb Sfar, Donald Geman, Nozha Boujemaa.

Stored images of biological objects are accumulating at a staggering rate due to new sensor technologies, expanding use in medical diagnostics, web-based search engines and growing demands for web-based services in traditional sciences such as botany. These developments have been accompanied by an increasing demand for the automated analysis of these data, such as counting cell types, detecting lesions and other abnormalities in medical images, and identifying botanical shapes.

All these tasks have one feature in common: massive diversity among the shapes. Indeed, such shapes display enormous within-class variation and are generally highly deformable. Also, they often exhibit a hierarchical organization resulting from evolutionary processes.

There is currently no existing methodology in image analysis and computer vision which can be applied to a multi-class shape recognition problem of this complexity. Consequently, there is a need for a new, generic methodology for categorizing hierarchically-structured families of deformable shapes, particularly when both the number of categories and the within-category variation are very large.

We proposed a coarse-to-fine (CTF) approach in both shape representation and image parsing. The representation is hierarchical in both class and pose.

We focused on botanical shapes, specifically categorizing simple leaves according to species. So, we determined a suitable representation for the pose of a simple leaf and designed and tested a two-stage pose detector. Then, we constructed classifiers based on the plant taxonomy.

Results will be submitted for publication.

6.4. Interactive search and personalisation

6.4.1. Database denoising and multi visual queries

Participant: Sébastien Poullot.

One of IMEDIA’s task inside the SCARFACE project is to introduce and develop a character retrieval system. For this purpose, we take as entries the tracking of the persons in video sequences computed by Thalès and construct a database of the profiles. A profile is a 3D frame, a bounding box that changes along the time line. Two original works have been proposed for searching in the profile database. The first one consists in analysing features of each profile with respect to all the profiles in order to extract relevant features from it, and construct more representative databases. The second one is to be able to search inside the database with a set of queries (pictures of the same person). An a priori work can be done on this set of queries in order to extract the relevant features (and remove the irrelevant ones). On the other side an a posteriori work can be done on late merging depending on the specificities of each sub query.

TRECVID Instance Search 2011

Before starting the developments for SCARFACE, we tested various algorithms in TRECVID 2011 INS (instance search) task. This task is close to the SCARFACE one: from a set of captures of one object, one should find its occurrences in a set of video sequences. This work has been done during the stay of Sébastien Poullot at NII (the Japan National Institute of Informatics) in July and August 2011.
The differences with SCARFACE are:

- a high diversity in the type of the objects (people but also, places, vehicle, animals, etc),
- the location of the object in the database is not given.

Our approach obtains good results (above the median scores of all teams) and works in a very short time (and without indexing system for speeding up the process) [15]. The choice for SCARFACE’s method partially depends on these results. We still continue on the INS task in order to achieve better scores (various descriptors and various post and late fusion between sub queries).

Query generative models

Moreover, in order to enhance visual query results, we want to create some visual query generative models. It is directly linked to SCARFACE (a priori processes) and TRECVID works: given a set of images (considered as queries), we extract what gather them and what separate them in order to construct artificial relevant queries. For now we essentially work on some logo databases.

6.4.2. Object-based Visual Query Suggestion

After our work on the shared neighbours clustering methods in multi-sources case published in [10], we are interested now to the case of a bipartite graph that we apply to object-based visual query suggestion using the visual words mining technique [16]. In fact, state-of-the-art visual search systems allow to retrieve efficiently small rigid objects in very large datasets. They are usually based on the query-by-window paradigm: a user selects any image region containing an object of interest and the system returns a ranked list of images that are likely to contain other instances of the query object. User’s perception of these tools is however affected by the fact that many submitted queries actually return nothing or only junk results (complex non-rigid objects, higher-level visual concepts, etc.). We address the problem of suggesting only the object’s queries that actually contain relevant matches in the dataset. This requires to first discover accurate object’s clusters in the dataset (as an off-line process); and then to select the most relevant objects according to user’s intent (as an online process). We therefore introduce a new object’s instances clustering framework based on two main contributions: efficient object’s seeds discovery with adaptive weighted sampling and bipartite shared-neighbours clustering. Experiments show that this new method outperforms state-of-the-art object mining and retrieval results on OxfordBuilding dataset. We finally describe two object-based visual query suggestion scenarios using the proposed framework and show examples of suggested object queries.

6.4.3. Interpretable Visual Models for Human Perception-based Object Retrieval

Understanding the results returned by automatic visual concept detectors is often a tricky task making users uncomfortable with these technologies. In this work we attempt to build humanly interpretable visual models, allowing the user to visually understand the underlying semantic. We therefore proposed a supervised multiple instance learning algorithm that selects as few as possible discriminant local features for a given object category. The method finds its roots in the lasso theory where a L1-regularization term is introduced in order to constraint the loss function, and subsequently produce sparser solutions. Efficient resolution of the lasso path is achieved through a boosting-like procedure inspired by BLasso algorithm. Quantitatively, the method achieved similar performance as current state-of-the-art, and qualitatively, it allows users to construct their own model from the original set of patches learned, thus allowing for more compound semantic queries. This work is part of the PhD of Ahmed Rebai [8] and it was published in ICMR 2011 proceedings [17]. This work was then extended to using geometrically checked feature sets rather than using single local features to describe the content of visual patches. We did show that this allows drastically reducing the number of the selected visual words while improving their interpretability. A publication was submitted to pattern recognition journal [11].
6.4.4. Relevance feedback on local features: Application to plants annotations and identification

Participants: Wajih Ouertani, Michel Crucianu, Nozha Boujemaa.

As biological image databases are increasing rapidly, automated species identification based on digital data is of great interest for accelerating biodiversity assessment, researches and monitoring. In this context, our work falls within an investigation of computer vision techniques or more precisely: object recognition and content based image retrieval techniques to help botanist identifying and organizing his digital images’ collections. Under believe that perception, recognition and decision are parts of human skills, this work focus on an interactive mechanism which tries to extract useful information from the user and gives him help to deal with large data amount. We adopted an explicit relevance feedback (RF) schema and we worked on extending it to deal with local intention through local features (LF) description. This mechanism helps discovering and dynamically defining new concept and interesting plant parts and feed identification ways interactively. Moreover since it relies to the content rather than labels one direct application is to fill the initially sparse annotation space with right annotations and in a reasonable time and with the introduce of one or many expertises. We recently explored and tested images local features matching involving high order features and non-rigid adaptation tentative to structure database with a patterns’ discovery stage. Using those type of methods we expect to introduce a high level appearance information that tends to go beyond classical bag of features and histogram based distances at least from semantic gap and interpretation point of view. We argue our exploration way with the fact that initial search space can be exceedingly rich. By pre-structuring it we can hope to obtain a smaller search space together with more reliable inference. Also learning parts interactively with localized local features may require a lot of interaction since it requires a considerable number of examples. We experienced the design of combined machine learning and prior mining of matches which we are actually improving.

6.5. Software

6.5.1. IKONA/MAESTRO software

This year, IKONA has been extended in the context of Pl@ntNet, Glocal, I-SEARCH and R2I projects. For the Pl@ntNet project, along the continuing improvements in the MAESTRO software, a number of new features were added. Namely the support for the automatic image segmentation and subsequent use of segmented regions; descriptors with the various shape’s geometric parameters; use of multiple orientations for Harris points; run-time additions to the external database and immediate availability of the new images for the search; descriptors to facilitate external data usage; colour SIFT and Affine Covariance descriptors; integration of the thesis work of Ahmed Rebai for objects retrieval; and tools for statistical tests.

In addition, a number of new web services were developed and deployed: the dynamic indexation system of the on-line pad (“carnet-en-ligne” of Tela Botanica)images; the search with multiple views; the update of Pl@ntNet internal demonstration allowing to present features such as visual similarity search, textual search, filtering (pre- and post-filtering), and different methods of research; the implementation of the organ prediction web service and other web services of botanical information statistics; the administration of the indexation system and the experimentation of new research methods (GPS spatial and temporal search).

For the Glocal project, an interface was developed for the demonstrations of a search engine in large scale events database (the queries are event images and the result is a list of the closest events in terms of time alignment and image content), and new web services were developed and updated according to the data exchange format and the middle-ware of the project - among others: fraud detection, import media from the web, associate media with existing event in the repository, and event matching web services. The queries are composed of either a medium link (an external image) or an event link (set of external images).
For the I-SEARCH project, an integration was performed to provide global and local 2D image low level descriptors. For videos, an automated extraction of visual words tool was integrated to show to users image patches which are the most meaningful.

For the R2I project, a detailed technical documentation of the procedure of maestro’s installation, web services and tomcat server were provided to Exalead partner.
6. New Results

6.1. Interaction Techniques

Participants: Caroline Appert, Michel Beaudouin-Lafon [correspondant], David Bonnet, Anastasia Bezerianos, Olivier Chapuis, Guillaume Faure, Emilien Ghomi, Stéphane Huot, Mathieu Nancel, Wendy Mackay, Cyprien Pindat, Emmanuel Pietriga, Theophanis Tsandilas, Julie Wagner.

Acquiring a target, such as pointing to an icon, a button or a landmark on a digital map, is the most common action in today’s graphical user interfaces. We have continued our work to better understand this seemingly simple action and make it faster and more reliable. This year we have conducted theoretical work on small target [12] and more practical work with TorusDesktop [4].

Targets of only a few pixels are notoriously difficult to acquire. Despite many attempts at facilitating pointing, the reasons for this difficulty are poorly understood. We confirm a strong departure from Fitts’ Law for small target acquisition using a mouse and investigate three potential sources of problems: motor accuracy, legibility, and quantization. We find that quantization is not a problem, but both motor and visual sizes are limiting factors. This suggests that small targets should be magnified in both motor and visual space to facilitate pointing. Since performance degrades exponentially as targets get very small, we further advocate the exploration of uniform, target-agnostic magnification strategies. We also confirm Welford’s 1969 proposal that motor inaccuracy can be modeled by subtracting a “tremor constant” from target size. We argue for the adoption of this model, rather than Fitts’ law, when reflecting on small target acquisition.

With TorusDesktop [4], we revisited a pointing technique that allows to wrap the mouse cursor around screen edges in conventional desktop environments. Allowing the cursor to jump from one edge of the screen to the opposite one (i.e., turning the desktop into a torus) was already explored, but never studied empirically nor designed for everyday desktop usage. We have introduced a dead zone and an off-screen cursor feedback that ease the use of this technique. We also conducted three controlled experiments to refine the design and evaluate its performance. Our results suggest clear benefits in several conditions, but also some potential limitations due to users’ over-estimation of cursor wrapping advantages. An implementation of TorusDesktop for the Mac OS X desktop can be downloaded for free at http://insitu.lri.fr/TorusDesktop.

We continued our work on wall-sized displays, focusing on the study of high-level tasks such as pan-zoom navigation (Figure 10), that have received little attention. Indeed, while pointing on this type of display has been studied extensively, it remains unclear which techniques are best suited to perform multiscale navigation in these environments. Building upon empirical data gathered from studies of pan-and-zoom on desktop computers and studies of remote pointing, we identified three key factors for the design of mid-air pan-and-zoom techniques: uni- vs. bimanual interaction, linear vs. circular movements, and level of guidance to accomplish the gestures in mid-air. After an extensive phase of iterative design and pilot testing, we ran a controlled experiment aimed at better understanding the influence of these factors on task performance. This work received a best paper award at CHI 2011 [6].

On the opposite side, we have studied small displays such as the ones smartphones are equipped with. One major challenge with this type of device is to make the user able to interact in parallel with both the device and other artefacts in his environment (e.g., giving a phone call while holding a paper document). The Swiss Army Menu (SAM) [27] is a radial menu that enables a very large number of functions accessible via small thumb movements. The design of SAM relies on four different kinds of items, support for navigating in hierarchies of items and a control that requires only the thumb of the hand that holds the device. SAM can offer a set of functions so large that it would typically have required a number of widgets that could not have been displayed in a single viewport at the same time.

Interaction and Visualization - New Results - Project-Team IN-SITU

Figure 10. Panning and zooming in Spitzer’s 396,032 x 12,000 = 4.7 billion pixels images of the inner part of our galaxy.

The different interaction techniques presented above are aimed at improving the control within a given representation. As a complement, we have also worked on improving the user’s experience by providing him with two (or more) representations of the data he is interacting with and ways to transition between these representations.

Gliimpse [17] is a quick preview technique that smoothly transitions between document markup code (HTML, wiki markup or LaTeX) and its visual rendering (see Figure 11). It allows users to regularly check the code they are editing in-place, without leaving the text editor. Gliimpse can complement classical preview windows by offering rapid overviews of code-to-document mappings and leaving more screen real-estate. As the technique smoothly show the links between the code and the rendered result, it can also help to learn how complex markup code will result in the final document (e.g., HTML tables or LaTeX formulae).

Figure 11. Gliimpse smoothly transitions between document markup code and its visual rendering.

In collaboration with University of Toronto and OCAD University, we designed a novel visualization technique called ChronoLenses [14], aimed at supporting users in time-series visual exploration tasks. ChronoLenses perform on-the-fly transformation of the data points in their focus area, tightly integrating visual analysis with user actions, and enabling the progressive construction of advanced visual analysis pipelines, supporting tasks that require visualizing derived values, identifying correlations, or discovering anomalies beyond obvious outliers.

We further explored user understanding of data presented in Dual-Scale data charts, charts that incorporate two different data resolutions into one chart in order to emphasize data in regions of interest (focus) or to enable the comparison of data from distant regions (context) [13]. In collaboration with researchers from inria AVIZ, we presented a unified description of different Dual-Scale data charts, and we compared them in terms of user understanding using elementary graphical perception tasks, such as comparing lengths and distances. Our study suggests that cut-out charts which include collocated full context and focus are the best alternative, and that superimposed charts in which focus and context overlap on top of each other should be avoided.

6.2. Research Methods
Participants: Caroline Appert, Michel Beaudouin-Lafon, Anastasia Bezerianos, Olivier Chapuis, Jérémie Garcia, Stéphane Huot, Ilaria Liccardi, Wendy Mackay [correspondant], Emmanuel Pietriga.

InkSplore [19]. We conducted three studies with contemporary music composers at IRCAM. We found that even highly computer-literate composers use an iterative process that begins with expressing musical ideas on paper, followed by active parallel exploration on paper and in software, prior to final execution of their ideas as an original score. We conducted a participatory design study that focused on the creative exploration phase, to design tools that help composers better integrate their paper-based and electronic activities. We then developed InkSploerer as a technology probe that connects users? hand-written gestures on paper to Max/MSP and OpenMusic. Composers appropriated InkSploerer according to their preferred composition styles, emphasizing its ability to help them quickly explore musical ideas on paper as they interact with the computer. We conclude with recommendations for designing interactive paper tools that support the creative process, letting users explore musical ideas both on paper and electronically.

Wikibook: [22]. With the Wikibook project [22] we investigate how Wikibooks authors collaborate to create high-quality books. We combined Information Retrieval and statistical techniques to examine the complete multi-year lifecycle of over 50 high-quality Wikibooks. We found that: 1. The presence of redundant material is negatively correlated with collaboration mechanisms; 2. For most books, over 50% of the content is written by a small core of authors; and 3. Use of collaborative tools (predicted pages and talk pages) is significantly correlated with patterns of redundancy. Non-redundant books are well-planned from the beginning and require fewer talk pages to reach high-quality status. Initially redundant books begin with high redundancy, which drops as soon as authors use coordination tools to restructure the content. Suddenly redundant books display sudden bursts of redundancy that must be resolved, requiring significantly more discussion to reach high-quality status. These findings suggest that providing core authors with effective tools for visualizing and removing redundant material may increase writing speed and improve the book’s ultimate quality.

6.3. Engineering of interactive systems

Participants: Caroline Appert, Michel Beaudouin-Lafon, Olivier Chapuis, James Eagan, Tony Gjerlufsen, Stéphane Huot, Wendy Mackay, Clemens Nylandsted Klokmose, Emmanuel Pietriga [correspondant], Clément Pillias, Romain Primet.

We started working on jBricks [24], a Java toolkit enabling the exploratory prototyping of interaction techniques and rapid development of post-WIMP applications running on cluster-driven interactive visualization platforms such as the WILD wall display (Section 7.1). Research on cluster-driven wall displays has mostly focused on techniques for parallel rendering of complex 3D models. There has been comparatively little research effort dedicated to other types of graphics and to the software engineering issues that arise when prototyping novel interaction techniques or developing full-featured applications for such displays. To fill this gap, jBricks integrates a high-quality 2D graphics rendering engine and a versatile input configuration module into a coherent framework, hiding low-level details from the developer. The goal of this framework is to ease the development, testing and debugging of interactive visualization applications for wall-sized displays. It also offers an environment for the rapid prototyping of novel interaction techniques and their evaluation through controlled experiments, such as the one we recently conducted about mid-air pan-and-zoom techniques for wall-sized displays (see Section 6.1).

We developed the Shared Substance framework for multisurface interaction [20]. It is based on Substance, which implements a novel programming model called data orientation that separates functionality from data. Shared Substance extends Substance to distributed environments. It makes distribution explicit so that the programmer can dynamically add, reconfigure and remove components at runtime. An application built with Shared Substance is a collection of processes called environments that run on different machines. Environments are discovered dynamically and can appear and disappear at any time. Each environment contains a hierarchical data structure that can be shared, in whole or in part, with other environments. Sharing can be done through replication or mounting, which entail different performance trade-offs. Shared Substance also includes the Instrumental Interaction Kit (IIK) to facilitate the development of instruments in a multisurface environment [34], [42]. We have used Shared Substance to develop several applications...
for our WILD multisurface environment: Substance Canvas manages a virtual canvas that can span multiple interactive surfaces managed by different computers, such as the tiled display, interactive table and users’ laptops of the WILD room; Content can be added to the canvas from various an extensible set of sources, including live applications using Scotty (see below). Substance Grise wraps an existing application for displaying 3D brain scans into a Shared Substance environment; This allows us to run 64 copies of the application, each showing a different brain scan, and synchronize the 3D orientation of the scans using a brain prop that the user turns in his hand.

We explored the notion of user interface programming at run-time to create more malleable software [18]. Rather than creating a new user interface toolkit or supporting the customization of an interactive application from outside, we explored how well-defined hooks and a few high-level constructs could allow a programmer to modify an application “from inside”, i.e. using code that is dynamically loaded by the application at runtime. Compared with existing approaches, this supports deep customization that involve the behavior of the application, not just the surface of its user interface. The Scotty prototype implements run-time interface programming in the Mac OS X environment for any application written with the native Cocoa framework. We have used Scotty to distribute the user interface of an application over multiple devices, e.g. to move the Print button of an application onto an iPhone so the user can safely print while physically close to the printer; to replace a tool palette in an application with a toolglass; to check for the presence of attachments in an email application before sending an email; to add subtitles to a video viewer that does not have this functionality. We have also used Scotty in connection with the work on Shared Substance (see above) to teleport a live vector-based representation of a running applications to the WILD wall display. The advantage of this approach over, e.g., VNC, is that the content is properly scaled, taking advantage of the full resolution of the wall.
6. New Results

6.1. Security

Participants: Ilaria Castellani, Zhengqin Luo, Tamara Rezk [correspondent], José Santos, Manuel Serrano.

6.1.1. Secure session calculi

We have pursued our work on controlling information flow in session calculi, started in previous years in collaboration with colleagues from the university of Torino. We also started investigating a notion of (objective) reputation for principals participating in sessions. The reputation of a principal is based on her previous behaviour as a user of a service. A principal’s reputation can be checked both by the service itself, before admitting again the principal as a user, or by other principals to evaluate the reputation of the current users before they join a service (we consider multi-user services). We plan to apply this idea to refine our previous work on information flow control in multiparty sessions, by considering reputations built on the “security behaviour” of principals.

In the work “Information flow safety in multiparty sessions” [11], we consider a calculus for multiparty sessions enriched with security levels for messages. We propose a monitored semantics for this calculus, which blocks the execution of processes as soon as they attempt to leak information. We illustrate the use of our monitored semantics with various examples, and show that the induced safety property implies the security property studied previously for the same calculus. This work was presented at the 18th International Workshop on Expressiveness in Concurrency (EXPRESS’11).

In the work “A Reputation System for Multirole Sessions” [10], we extend role-based multiparty sessions with reputations and policies associated with principals. The reputation associated with a principal in a service is built by collecting her relevant behaviour as a participant in sessions of the service. The service checks the reputation of principals before allowing them to take part in a session, and decides whether to accept them or not depending on their reputation and on the role they want to play. Furthermore, principals can declare policies that must be fulfilled by the other participants of the same service. These policies are used by principals to check the reputation of the current participants and to decide accordingly whether or not to join the service. Our approach is illustrated by an example describing a real-world protocol. This work was presented at the 6th International Symposium on Trustworthy Global Computing (TGC’11).

Both [11] and [10] were partially funded by the ANR-08-EMER-010 grant PARTOUT.

6.1.2. Automatic Code Injection Prevention for Web Applications

We propose a new technique based on multitier compilation for preventing code injection in web applications. It consists in adding an extra stage to the client code generator which compares the dynamically generated code with the specification obtained from the syntax of the source program. No intervention from the programmer is needed. No plugin or modification of the web browser is required. The soundness and validity of the approach are proved formally by showing that the client compiler can be fully abstract. The practical interest of the approach is proved by showing the actual implementation in the Hop environment.

This work was presented in TOSCA’11 and appeared in the LNCS series [13]. See also software section.

6.1.3. A Certified Lightweight Non-Interference Java Bytecode Verifier

We propose a type system to verify the non-interference property in the Java Virtual Machine. We verify the system in the Coq theorem prover.

This work will appear in the journal of Mathematical Structures in Computer Science [8].
6.1.4. Information-flow types for homomorphic encryptions

We develop a flexible information-flow type system for a range of encryption primitives, precisely reflecting their diverse functional and security features. Our rules enable encryption, blinding, homomorphic computation, and decryption, with selective key re-use for different types of payloads. We show that, under standard cryptographic assumptions, any well-typed probabilistic program using encryptions is secure (that is, computationally non-interferent) against active adversaries, both for confidentiality and integrity. We illustrate our approach using ElGamal and Paillier encryption.

We present two applications of cryptographic verification by typing: (1) private search on data streams; and (2) the bootstrapping part of Gentry’s fully homomorphic encryption.

We provide a prototype typechecker for our system.

This work appeared in CCS’11 [12]. See also software section.

6.1.5. The Mashic compiler

Mashups are a prevailing kind of web applications integrating external gadget APIs often written in the Javascript programming language. Writing secure mashups is a challenging task due to the heterogeneity of existing gadget APIs, the privileges granted to gadgets during mashup executions, and Javascript’s highly dynamic environment.

We propose a new compiler, called Mashic, for the automatic generation of secure Javascript-based mashups from existing mashup code. The Mashic compiler can effortlessly be applied to existing mashups based on a wide-range of gadget APIs. It offers security and correctness guarantees. Security is achieved by using the Same Origin Policy. Correctness is ensured in the presence of benign gadgets, that satisfy confidentiality and integrity constrains with regard to the integrator code. The compiler has been successfully applied to real world mashups based on Google maps, Bing maps, YouTube, and Zwibbler APIs.

See also software section.

6.1.6. Secure Information Flow by Self-Composition

Information flow policies are confidentiality policies that control information leakage through program execution. A common means to enforce secure information flow is through information flow type systems. Although type systems are compositional and usually enjoy decidable type checking or inference, their extensibility is very poor: type systems need to be redefined and proven sound for each new single variation of security policy and programming language for which secure information flow verification is desired. In contrast, program logics offer a general mechanism to enforce a variety of safety policies, and for this reason are favored in Proof Carrying Code, a promising security architecture for mobile code. However, the encoding of information flow policies in program logics is not straightforward, because they refer to a relation between two program executions. The purpose of this work is to investigate logical formulations of secure information flow based on the idea of self-composition, that reduces the problem of secure information flow of a program P to a safety property for program P composed with itself.

This work appeared in the special issue of MSCS of PLID [7].

6.1.7. Secure Information flow enforcement techniques for dynamic security policies

We performed a comprehensive investigation of alternative static mechanisms to enforce information flow policies considering a setting in which programs run under an authority that is only known at runtime and that yields a relaxation of the base security policy. The devised method aims at eliminating the need to reanalyse a program each time its authority changes. The soundness of the proposed approach was established for a concurrent higher-order imperative lambda calculus with reference creation. This work resulted in the report “Typing Illegal Information Flows as Program Effects” available at http://www-sop.inria.fr/members/Jose.Santos/reportInfFlow.pdf.
6.2. Models, semantics, and languages

Participants: Pejman Attar, Gérard Berry [correspondant], Gérard Boudol, Frédéric Boussinot, Johan Grande, Cyprien Nicolas, Manuel Serrano.

6.2.1. HipHop

HipHop is a new Domain Specific Language for Hop dedicated to request and event orchestration. HipHop follows the synchronous reactive model of the Esterel and ReactiveC languages, originally developed for embedded systems programming. It is based on synchronous concurrency and preemption primitives, which are known to be key components for the modular design of complex temporal behaviors. Although the language is concurrent, the generated code is purely sequential and thread-free. HipHop is translated to Hop code to be interpreted by the Hop runtime, either on server or client sides. HipHop has been described in a paper [9] accepted at the new International Workshop on Programming Language And Systems Technologies for Internet Clients (Plastic 2011).

6.2.2. Tesard

Tesard is a programming language of the Caml family, designed to offer simple constructs for shared memory concurrency and a deadlock-free semantics.

It features in particular the 2 following constructs:

- \texttt{thread e} which launches a thread that will execute expression \texttt{e}, and returns immediately;
- \texttt{lock x in e} which takes a lock on mutable value \texttt{x} (possibly waiting to be able to do so), executes expression \texttt{e}, releases the lock on \texttt{x} and returns the result of the execution of \texttt{e}.

A type and effect system is used at compile-time to:

- associate a mutex with every mutable value
- make the \texttt{lock \ldots in\ldots} construct implement deadlock avoidance.

The language is implemented as an interpreter and a bytecode compiler. It is a fork of Llama Light, which is itself derived from Caml. Llama Light is functionnaly roughly equivalent to Caml Light, but a large part of its code comes from OCaml, along with the threads library and runtime that we ported ourselves.

Several key parts of the language have been implemented: the runtime and most of the type and effect system, including inference of the creation of mutexes \texttt{(let region r in \ldots)} but not region polymorphism yet. The project is not in a usable state (no release has been made yet). Development versions are publicly available via GitHub at https://github.com/nahoj/llama.

6.2.3. Synchronous orchestration and beyond

We studied DSL, an orchestration language based on the synchronous/reactive model. In DSL, systems are composed of several sites executed asynchronously. Within each site, scripts are run in a synchronous parallel way. Scripts may call functions that are treated in an abstract way: their effect on the memory is not considered, but only their “orchestration”, \textit{i.e.}, the organisation of their calls in time and in place (the site where they are called). The mapping of sites onto cores allows one to benefit from multicore architectures. Two properties are required by DSL: reactivity of sites and absence of interferences between scripts run by distinct sites. We also introduced DSLM, which adds a memory level to DSL and a way to automatically adapt the execution to get a maximal use of the available cores. This work, presented respectively in [18] and [15], was funded by the ANR-08-EMER-010 grant PARTOUT.

6.3. Web programming

Participants: Zhengqin Luo, Cyprien Nicolas, Tamara Rezk, Bernard Serpette, Manuel Serrano [correspondant].
6.3.1. A new evaluator for Hop

At the time where Hop programs were basic scripts, the performance of the server-side interpreter was not a concern. An inefficient interpreter was acceptable. As Hop expanded, Hop programs got larger and more complex. A more efficient interpreter was necessary. Therefore, this year we have design and implemented a new interpreter for Hop. It is compact, its whole implementation counting no more than 2.5 KLOC. It is more than twice faster than the old interpreter and consumes less than a third of its memory. The architecture and the performance of the new interpreter are described in [14].

6.3.2. Abstraction of Hop with a bicolored lambda-calculus

We have studied an extension of the $\lambda$-calculus where each expression has a color. These colors designate the sites where expressions are evaluated, i.e., in the server or in the client. Colors are similar to the $\$\$ and $\sim$ annotations of Hop. With this, we have defined a transformation, using $\beta$-expansion, which groups together expressions with the same color. Correction, confluence and termination of the transformation was verified using the Coq system and its description was described in paper to appear in 2012 [16]. Following Hop’s syntax, $\$\$ mentions that the followed expression is evaluated on the server while the $\sim$ character introduce client code. Inside the client code it is allowed to reintroduce some server expressions by reusing a $\$\$. We can imagine, for example, that the action associated to a client’s button is dependent on some server’s data (order number, proxies, data bases, ...). This kind of example is depicted with the abstract syntax tree in the upper left part of figure 1.

![Figure 1. Example of Hop colored tree](image)

From the server’s point of view, the client’s code following a $\sim$ is ignored, but the environment in which this client code is activated must be preserved for all $\$\$ inside this code. Therefore, there exists a relation between a node $\sim$ and its including $\$\$. These relations are depicted by the dashed arrows in the upper right tree of Figure 1. The proposed transformation highlights this relation and is shown in the bottom of the figure where it can be observed that the transformation groups together expressions of the same color.

6.3.3. HopTeX, an Hop application for authoring documents

HopTeX is a Hop application for authoring HTML and LaTeX documents. The content of the document is either expressed in HTML or in a blending of HTML and a dedicated wiki syntax, for the sake of conciseness and readability. The rendering of the document is expressed by a set of CSS rules. The main originality of HopTeX is to consider LaTeX as a new media type for HTML and to express the compilation from HTML to LaTeX by the means of dedicated style sheet rules. HopTeX can then be used to generate high quality documents for both paper printed version and electronic version.
HOPTEX is implemented in HOP, a multi-tier programming language for the Web 2.0. This implementation extensively relies on two facilities generally only available on the client-side that HOP also supports on the server-side of the application: DOM manipulations and CSS server-side resolutions.

The online version of the paper describing HOPTEX [17] is available at the HOPTEX web page (http://hop.inria.fr/hop/weblets/homepage?weblet=hoptex). Contrary to the PDF version published in the proceeding of the workshop, the online version is convenient for both desktop computers and Smartphones.
6. New Results

6.1. Modeling

6.1.1. Reassembly

Participants: Nicolas Mellado, Patrick Reuter, Gaël Guennebaud, Pascal Barla, Christophe Schlick.

In the context of cultural heritage, 3D laser scanning and photogrammetric 3D acquisition of broken content is becoming increasingly popular, resulting in large collections of detailed fractured archaeological 3D objects that have to be reassembled virtually. We recently investigated a semi-automatic reassembly approach for pairwise matching of digital fragments, that makes it possible to take into account both the archeologist’s expertise, as well as the power of automatic geometry-driven matching algorithms. In order to increase matching efficiency and robustness, we currently focus on shape analysis with higher level representation to guide ICP-like algorithms.

6.2. 3D Data Rendering and Visualization

6.2.1. Soft shadows

Participant: Gaël Guennebaud.

Shadows are a fundamental visual effect which both increase the level of realism of a 3D scene, and help to identify spatial relationships between objects. This latter observation makes them particularly important in the context of interactive 3D applications. Generating high quality soft shadows in real-time is still an open challenge. In the continuity of our previous collaboration with the State Key Lab of CAD&CG of Zhejiang University (China) [39], we developed a perceptually based metric dedicated to the prediction of ideal shadow map resolutions [16]. This metric allows us to adaptively generate shadow map tiles. As a result, we managed to render wide and complex exterior scenes with high quality while maintaining high performance (see figure 2).

Figure 2. Our soft shadow rendering system generates adaptive shadow map tiles and can therefore render softer shadows (right @ 25 fps) faster than their hard shadow counter part (left @ 15 fps).

6.2.2. Synthesis and control of breaking waves

Participants: Nicolas Maréchal, Pascal Barla, Gaël Guennebaud, Patrick Reuter.
Modeling complex breaking waves over arbitrary bathymetry is a tedious problem. Currently, most of the existing methods are based on physical simulations by solving the Navier-Stokes equation. Controlling the shape of breaking waves is almost impossible with such approaches, and the simulation does not run in real-time. In order to overcome these limitations, we propose a phenomenological approach based on a real-time simulation using Airy's wave theory. Our system handles phenomena such as shoaling, refraction and grouping (see figure 3), and the rendering style can be adapted by the user.

Figure 3. Breaking waves generated using our system over an arbitrary bathymetry. 2D wave shape profiles are shown for better legibility.

6.2.3. Analysis and visualization of surface relief

Participants: Lucas Ammann, Pascal Barla, Gaël Guennebaud, Xavier Granier, Patrick Reuter.

Given a base surface with relief, we developed an analysis technique that leverages the complexity found in detailed 3D models for illustrative shading purposes. The key originality of our approach is to extract the relief features such as concavities, convexities and inflections at multiple scales and directions using local cubic-polynomial fitting. We use this information to guide a variety of shading techniques. Our approach is parametrization-free and meshless, allowing for a wide variety of applications ranging from scientific visualization to special effects for the movie industry.

6.3. Expressive Rendering

Figure 4. Conveying visual information through expressive rendering
6.3.1. Line-based Rendering

Participants: Pascal Barla, Jiazhou Chen, Xavier Granier, Christophe Schlick.

We have introduced [18] a new technique called Implicit Brushes to render animated 3D scenes with stylized lines in real-time with temporal coherence. An Implicit Brush is defined at a given pixel by the convolution of a brush footprint along a feature skeleton; the skeleton itself is obtained by locating surface features in the pixel neighborhood. Features are identified via image-space fitting techniques that not only extract their location, but also their profile, which permits to distinguish between sharp and smooth features. Profile parameters are then mapped to stylistic parameters such as brush orientation, size or opacity to give rise to a wide range of line-based styles. This work has won the 3rd best paper award at Eurographics annual conference.

6.3.2. Shape Depiction through Shading

Participants: Pascal Barla, Xavier Granier, Christophe Schlick.

Recently, a number of techniques have been proposed to exaggerate the depiction of shape through the shading of 3D objects. However, existing methods are limited to a single type of material, simple light sources, and they give a fake percept where 3D shape seems to be flattened or embossed, or produce temporal artifacts. We have recently shown that adjusting lighting amplitude for each direction (Radiance Scaling [38], selected as a best paper at I3D 2010 and extended as a TVCG journal paper [17]) may enhance the shape depiction. The technique has been ported to Meshlab (http://meshlab.sourceforge.net/).

6.3.3. Dynamic Expressive Shading Primitives

Participant: Pascal Barla.

Shading appearance in illustrations, comics and graphic novels is designed to convey illumination, material and surface shape characteristics at once. Moreover, shading may vary depending on different configurations of surface distance, lighting, character expressions, timing of the action, to articulate storytelling or draw attention to a part of an object. We have developed [31] a method that imitates such expressive stylized shading techniques in dynamic 3D scenes, and which offers a simple and flexible means for artists to design and tweak the shading appearance and its dynamic behavior. The key contribution of our approach is to seamlessly vary appearance by using a combination of shading primitives that take into account lighting direction, material characteristics and surface features.

6.3.4. Non-Uniform Compositing of Styles

Participants: Jiazhou Chen, Xavier Granier.

In order to investigate how the composition of different styles may help in directing user attention, we have developed [22] a non-uniform composition that integrates multiple rendering styles in a picture driven by an importance map. This map, either issued from salience estimation or designed by a user, is introduced both in the creation of the multiple styles and in the final composition. Our approach accommodates a variety of stylization techniques, such as color desaturation, line drawing, blurring, edge-preserving smoothing and enhancement.

6.4. Interaction

6.4.1. Toucheo: Multitouch + Stereo

Participants: Martin Hachet, Benoit Bossavit, Aurélie Cohé.
We propose a new system that efficiently combines direct multitouch interaction and 3D stereoscopic visualization (see Figure 5). In our approach, the users interact by means of simple 2D gestures on a monoscopic touchscreen, while visualizing occlusion-free 3D stereoscopic objects floating above the surface at an optically correct distance. By coinciding the 3D virtual space with the physical space, we produce a rich seamless workspace where both the advantages of direct and indirect interaction are jointly exploited. In addition to standard multitouch gestures and controls (e.g. pan, zoom, and standard 2D widgets) from which we take advantage, we have designed a dedicated multitouch 3D transformation widget. This widget allows the near-direct control of rotations, scaling, and translations of the manipulated objects. To illustrate the power of our setup, we have designed a demo scenario where participants reassemble 3D virtual fragments. This scenario, as many others, takes benefit of our proposal, where the strength of both multitouch interaction and stereoscopic visualization are unified in an innovative and relevant workspace [19] [25]. See highlights.

6.4.2. Touch-based interaction

Participants: Jérémy Laviole, Aurélie Cohé, Martin Hachet.

We have continued exploring 3D User Interfaces for [multi-]touch screens. In particular, in [26], we conducted a user study to better understand the impact of directness on user performance for a RST docking task, for both 2D and 3D visualization conditions. We have also designed a new 3D transformation widget, called tBox, that can be operated easily and efficiently from simple gestures on touch-screens. In our approach, users apply rotations by means of physically plausible gestures, and we have extended successful 2D tactile principles to the context of 3D interaction [23].

6.4.3. Immersive environments

Participant: Martin Hachet.

We have continued working on immersive environments. In particular, with the "Digital Sound" group of LaBRI, we have studied how sound processes should be visualized in immersive setups [13]. Another collaboration is with the REVES Inria project-team, where we have explored how to design 3D pieces of architecture in a CAVE [21].

6.4.4. Brain-Computer Interaction

Participant: Fabien Lotte.

With Fabien Lotte joining the IPARLA team as a research scientist in January 2011, a new research topic related to interaction is being explored: Brain-Computer Interfaces (BCI). BCI are communication systems that enable its users to send commands to the computer by means of brain activity only, this activity being generally measured using ElectroEncephaloGraphy (EEG). This is therefore a new way to interact with computers and interactive 3D applications. In this area, we have explored new techniques to analyze and process EEG signals in order to identify the mental state of the user [14] [20]. This has led to improved robustness and mental state recognition performances. Another challenge in BCI is that it requires the collection of several examples...
of EEG signals from the user in order to calibrate the system. This makes the calibration step long and inconvenient. In order to alleviate this problem, we have proposed to generate artificial EEG signals from a few EEG signals already available. Our evaluations have shown that it can indeed significantly reduce the calibration time [28]. Together with the Inria VR4I-team, we have also explored the use of a new mental state to drive a BCI: attention and relaxation states. We have shown that it is indeed possible to identify relaxation and concentration in EEG signals, and that it can be used to drive a BCI [24]. Finally, we have critically analyzed the usefulness and potential of BCI for 3D video games [27].

6.4.5. Tangible user interfaces

**Participant:** Patrick Reuter.

Tangible user interfaces have proven to be useful for the manipulation of 3D objects, such as for selection and navigation tasks, and even for deformation tasks. Deforming 3D models realistically is a crucial task when it comes to study the physical behavior of 3D objects, for example in engineering, in sculpting applications, and in other domains. With recent progress in physical deformation models and the increasing computing power, physically-realistic deformation simulations can now be driven at interactive rates. Consequently, there is an increasing demand for efficient and user-friendly user interfaces for physically-realistic deformation in real-time. We designed a general concept for designing physically-realistic deformations of 3D models with a tangible user interface, and instantiated our concept with a concrete prototype using a passive tangible user interface that incarnates the 3D model and that runs in real-time [32].
5. New Results

5.1. Asymptotic preserving schemes

Participant: Nicolas Crouseilles.

In [18], we extend the micro-macro decomposition based numerical schemes developed previously to the collisional Vlasov-Poisson model in the diffusion and high-field asymptotics. In doing so, we first write the Vlasov-Poisson model as a system that couples the macroscopic (equilibrium) part with the remainder part. A suitable discretization of this micro-macro model enables to derive an asymptotic preserving scheme in the diffusion and high-field asymptotics. In addition, two main improvements are presented: On the one hand a self-consistent electric field is introduced, which induces a specific discretization in the velocity direction, and represents a wide range of applications in plasma physics. On the other hand, as suggested in a previous reference, we introduce a suitable reformulation of the micro-macro scheme which leads to an asymptotic preserving property with the following property: It degenerates into an implicit scheme for the diffusion limit model when $\varepsilon \rightarrow 0$, which makes it free from the usual diffusion constraint $\Delta t = O(\Delta x^2)$ in all regimes. Numerical examples are used to demonstrate the efficiency and the applicability of the schemes for both regimes.

In [45], a Two-Scale Macro-Micro decomposition of the Vlasov equation with a strong magnetic field is derived. This consists in writing the solution of this equation as a sum of two oscillating functions with circumscribed oscillations. The first of these functions has a shape which is close to the shape of the Two-Scale limit of the solution and the second one is a correction built to offset this imposed shape.

5.2. Resolution of the quasi-neutrality equation

Participant: Nicolas Crouseilles.

In reference [39], different parallel algorithms are proposed for the numerical resolution of the quasi-neutrality equation in the GYSELA code. A set of benchmarks on a parallel machine has permitted to evaluate the performance of the different versions of the quasi-neutrality solver. In particular, in [40], these improvements are combined with memory optimization which enable a scalability of the GYSELA code up to 64k cores.

In [20], a new discretization scheme of the gyrokinetic quasi-neutrality equation is proposed. It is based on Isogeometric Analysis; the IGA which relies on NURBS functions, seems to accommodate arbitrary coordinates and the use of complicated computation domains. Moreover, arbitrary high order degree of basis functions can be used. Here, this approach is successfully tested on elliptic problems like the quasi-neutrality equation.

5.3. High order schemes for Vlasov-Poisson system

Participant: Nicolas Crouseilles.

In [44], we derive the order conditions for fourth order time splitting schemes in the case of the 1D Vlasov-Poisson system. Computations to obtain such conditions are motivated by the specific Poisson structure of the Vlasov-Poisson system: this structure is similar to Runge-Kutta-Nyström systems. The obtained conditions are proved to be the same as RKN conditions derived for ODE up to the fourth order. Numerical results are performed and show the benefit of using high order splitting schemes in that context.
In [19], we present a discontinuous Galerkin scheme for the numerical approximation of the one-dimensional periodic Vlasov-Poisson equation. The scheme is based on a Galerkin-characteristics method in which the distribution function is projected onto a space of discontinuous functions. We present comparisons with a semi-Lagrangian method to emphasize the good behavior of this scheme when applied to Vlasov-Poisson test cases.

The CEMRACS is an annual summer research session promoted by the SMAI. The 15th edition of 2010 has been organized by N. Crouseilles, H. Guillard, B. Nkonga and E. Sonnendrücker around "Numerical modeling of fusion plasmas". The volume [38] gathers artless resulting from research projects initiated during the CEMRACS 2010.

### 5.4. Second order averaging for the nonlinear Schrödinger equation with strong anisotropic potential

**Participants:** Florian Méhats, François Castella.

In [10], we consider the three dimensional Gross-Pitaevskii equation (GPE) describing a Bose-Einstein Condensate (BEC) which is highly confined in vertical $z$ direction. The confining potential induces high oscillations in time. If the confinement in the $z$ direction is a harmonic trap -- an approximation which is widely used in physical experiments -- the very special structure of the spectrum of the confinement operator implies that the oscillations are periodic in time. Based on this observation, it can be proved that the GPE can be averaged out with an error of order of $\epsilon$, which is the typical period of the oscillations. In this article, we construct a more accurate averaged model, which approximates the GPE up to errors of order $O(\epsilon^2)$. Then, expansions of this model over the eigenfunctions (modes) of the confining operator $H_z$ in the $z$-direction are given in view of numerical applications. Efficient numerical methods are constructed to solve the GPE with cylindrical symmetry in 3D and the approximation model with radial symmetry in 2D, and numerical results are presented for various kinds of initial data.

### 5.5. A problem of moment realizability in quantum statistical physics

**Participant:** Florian Méhats.

This work [34] is a generalization of the results previously obtained by F. Méhats and O. Pinaud, in J. Stat. Phys. (2010), in a one-dimensional setting: we revisit the problem of the minimization of the quantum free energy (entropy + energy) under local constraints (moments) and prove the existence of minimizers in various configurations. While the above quoted article addressed the 1D case on bounded domains, we treat in the present paper the multi-dimensional case as well as unbounded domains and non-linear interactions as Hartree/Hartree-Fock. Moreover, whereas this article dealt with the first moment only, namely the charge density, we extend the results to the second moment, the current density.

### 5.6. Orbital stability of spherical galactic models

**Participant:** Florian Méhats.

In [33] we consider the three dimensional gravitational Vlasov Poisson system which is a canonical model in astrophysics to describe the dynamics of galactic clusters. A well known conjecture is the stability of spherical models which are nonincreasing radially symmetric steady states solutions. This conjecture was proved at the linear level by several authors in the continuation of the breakthrough work by Antonov in 1961. In a previous work, we derived the stability of anisotropic models under spherically symmetric perturbations using fundamental monotonicity properties of the Hamiltonian under suitable generalized symmetric rearrangements first observed in the physics literature. In this work, we show how this approach combined with a new generalized Antonov type coercivity property implies the orbital stability of spherical models under general perturbations.
5.7. The Schrödinger Poisson system on the sphere  
**Participant:** Florian Méhats.

In [31] we study the Schrödinger-Poisson system on the unit sphere $S^2$ of $\mathbb{R}^3$, modeling the quantum transport of charged particles confined on a sphere by an external potential. Our first results concern the Cauchy problem for this system. We prove that this problem is regularly well-posed on every $H^s(S^2)$ with $s > 0$, and not uniformly well-posed on $L^2(S^2)$. The proof of well-posedness relies on multilinear Strichartz estimates, the proof of ill-posedness relies on the construction of a counterexample which concentrates exponentially on a closed geodesic. In a second part of the paper, we prove that this model can be obtained as the limit of the three dimensional Schrödinger-Poisson system, singularly perturbed by an external potential that confines the particles in the vicinity of the sphere.

5.8. A boundary matching micro-macro decomposition for kinetic equations  
**Participant:** Florian Méhats.

In [32], we introduce a new micro-macro decomposition of collisional kinetic equations which naturally incorporates the exact space boundary conditions. The idea is to write the distribution function $f$ in all its domain as the sum of a Maxwellian adapted to the boundary (which is not the usual Maxwellian associated with $f$) and a reminder kinetic part. This Maxwellian is defined such that its ‘incoming’ velocity moments coincide with the ‘incoming’ velocity moments of the distribution function. Important consequences of this strategy are the following. i) No artificial boundary condition is needed in the micro/macro models and the exact boundary condition on $f$ is naturally transposed to the macro part of the model. ii) It provides a new class of the so-called ‘Asymptotic preserving’ (AP) numerical schemes: such schemes are consistent with the original kinetic equation for all fixed positive value of the Knudsen number $\epsilon$, and if $\epsilon \to 0$ with fixed numerical parameters then these schemes degenerate into consistent numerical schemes for the various corresponding asymptotic fluid or diffusive models. Here, the strategy provides AP schemes not only inside the physical domain but also in the space boundary layers. We provide a numerical test in the case of a diffusion limit of the one-group transport equation, and show that our AP scheme recovers the boundary layer and a good approximation of the theoretical boundary value, which is usually computed from the so-called Chandrasekhar function.

5.9. 1D quintic nonlinear equation with white noise dispersion  
**Participant:** Arnaud Debussche.

Under certain scaling the nonlinear Schrödinger equation with random dispersion converges to the nonlinear Schrödinger equation with white noise dispersion. The aim of these works is to prove that this latter equation is globally well posed in $L^2$ or $H^1$. In [28], we improve the Strichartz estimates obtained previously for the Schrödinger equation with white noise dispersion in one dimension. This allows us to prove global well posedness when a quintic critical nonlinearity is added to the equation. We finally show that the white noise dispersion is the limit of smooth random dispersion.

5.10. Weak approximation of stochastic partial differential equations: the nonlinear case  
**Participant:** Arnaud Debussche.

In [22] we study the error of the Euler scheme applied to a stochastic partial differential equation. We prove that as it is often the case, the weak order of convergence is twice the strong order. A key ingredient in our proof is Malliavin calculus which enables us to get rid of the irregular terms of the error. We apply our method to the case a semilinear stochastic heat equation driven by a space-time white noise.

5.11. Ergodic BSDEs under weak dissipative assumptions  
**Participant:** Arnaud Debussche.
In [27] we study ergodic backward stochastic differential equations (EBSDEs) dropping the strong dissipativity assumption needed previously. In other words we do not need to require the uniform exponential decay of the difference of two solutions of the underlying forward equation, which, on the contrary, is assumed to be non degenerate. We show existence of solutions by use of coupling estimates for a non-degenerate forward stochastic differential equations with bounded measurable non-linearity. Moreover we prove uniqueness of “Markovian” solutions exploiting the recurrence of the same class of forward equations. Applications are then given to the optimal ergodic control of stochastic partial differential equations and to the associated ergodic Hamilton-Jacobi-Bellman equations.

5.12. Asymptotic first exit times of the Chafee-Infante equation with small heavy tailed noise

Participant: Arnaud Debussche.

Motivated by paleoclimatological issues, we determine in [26] asymptotic first exit times for the Chafee-Infante equation forced by heavy-tailed Levy diffusions from reduced domains of attraction in the limit of small intensity. We show that in contrast to the case of Gaussian diffusion the expected first exit times are polynomial in terms of the intensity.

5.13. Stochastic Cahn-Hilliard equation with double singular nonlinearities and two reflections

Participant: Arnaud Debussche.

In [25] we consider a stochastic partial differential equation with two logarithmic nonlinearities, two reflections at 1 and -1, and a constraint of conservation of the space average. The equation, driven by the derivative in space of a space-time white noise, contains a bi-Laplacian in the drift. The lack of a maximum principle for the bi-Laplacian generates difficulties for the classical penalization method, which uses a crucial monotonicity property. Being inspired by the works of Debussche, Goudenège, and Zambotti, we obtain existence and uniqueness of a solution for initial conditions in the interval $(-1, 1)$. Finally, we prove that the unique invariant measure is ergodic, and we give a result of exponential mixing.

5.14. Diffusion limit for a stochastic kinetic problem

Participants: Arnaud Debussche, Erwan Faou.

In [29] we consider numerical approximations of stochastic differential equations by the Euler method. In the case where the SDE is elliptic or hypo-elliptic, we show a weak backward error analysis result in the sense that the generator associated with the numerical solution coincides with the solution of a modified Kolmogorov equation up to high order terms with respect to the stepsize. This implies that every invariant measure of the numerical scheme is close to a modified invariant measure obtained by asymptotic expansion. Moreover, we prove that, up to negligible terms, the dynamic associated with the Euler scheme is exponentially mixing.

5.15. Convergence of stochastic gene networks to hybrid piecewise deterministic processes

Participant: Arnaud Debussche.

In [47] we consider numerical approximations of stochastic differential equations by the Euler method. In the case where the SDE is elliptic or hypo-elliptic, we show a weak backward error analysis result in the sense that the generator associated with the numerical solution coincides with the solution of a modified Kolmogorov equation up to high order terms with respect to the step-size. This implies that every invariant measure of the numerical scheme is close to a modified invariant measure obtained by asymptotic expansion. Moreover, we prove that, up to negligible terms, the dynamic associated with the Euler scheme is exponentially mixing.
5.16. Exponential mixing of the 3D stochastic Navier-Stokes equations driven by mildly degenerate noise

Participant: Arnaud Debussche.

In [11] we prove the strong Feller property and exponential mixing for 3D stochastic Navier-Stokes equation driven by mildly degenerate noises (i.e. all but finitely many Fourier modes are forced) via Kolmogorov equation approach.

5.17. Ergodicity results for the stochastic Navier-Stokes equations: an introduction

Participant: Arnaud Debussche.

In this survey article [46], we review recent progresses in the study of ergodicity for the stochastic Navier-Stokes equations. The first part introduces general concept, the second deals with the 2D case and the 3D case is treated in the third part.

5.18. Local Martingale and Pathwise Solutions for an Abstract Fluids Model

Participant: Arnaud Debussche.

In the first article [23], we establish the existence and uniqueness of both local martingale and local pathwise solutions of an abstract nonlinear stochastic evolution system. The primary application of this abstract framework is to infer the local existence of strong, pathwise solutions to the 3D primitive equations of the oceans and atmosphere forced by a nonlinear multiplicative white noise. In the second article [24] global existence is obtained.

5.19. Geometric numerical integration and Schrödinger equations

Participant: Erwan Faou.

The goal of geometric numerical integration is the simulation of evolution equations by preserving their geometric properties over long times. This question is of particular importance in the case of Hamiltonian partial differential equations typically arising in many application fields such as quantum mechanics or wave propagations phenomena. This implies many important dynamical features such as energy preservation and conservation of adiabatic invariants over long times. In this setting, a natural question is to know how and to which extent the reproduction of such long time qualitative behavior is ensured by numerical schemes.

Starting from numerical examples, these notes [37] try to provide a detailed analysis in the case of the Schrödinger equation in a simple setting (periodic boundary conditions, polynomial nonlinearities) approximated by symplectic splitting methods. This text analyzes the possible stability and instability phenomena induced by space and time discretization, and provides rigorous mathematical explanations for them.

5.20. On the influence of the geometry on skin effect in electromagnetism

Participant: Erwan Faou.

In [14], we consider the equations of electromagnetism set on a domain made of a dielectric and a conductor subdomain in a regime where the conductivity is large. Assuming smoothness for the dielectric-conductor interface, relying on recent works we prove that the solution of the Maxwell equations admits a multiscale asymptotic expansion with profile terms rapidly decaying inside the conductor. This skin effect is measured by introducing a skin depth function that turns out to depend on the mean curvature of the boundary of the conductor. We then confirm these asymptotic results by numerical experiments in various axisymmetric configurations. We also investigate numerically the case of a nonsmooth interface, namely a cylindrical conductor.
5.21. Reconciling alternate methods for the determination of charge distributions: A probabilistic approach to high-dimensional least-squares approximations

Participant: Erwan Faou.

In [17], we propose extensions and improvements of the statistical analysis of distributed multipoles (SADM) algorithm put forth by CHIPOT in 1998 for the derivation of distributed atomic multipoles from the quantum-mechanical electrostatic potential. The method is mathematically extended to general least-squares problems and provides an alternative approximation method in cases where the original least-squares problem is computationally not tractable, either because of its ill-posedness or its high-dimensionality. The solution is approximated employing a Monte Carlo method that takes the average of a random variable defined as the solutions of random small least-squares problems drawn as subsystems of the original problem. The conditions that ensure convergence and consistency of the method are discussed, along with an analysis of the computational cost in specific instances.

5.22. Hamiltonian interpolation of splitting approximations for nonlinear PDEs

Participant: Erwan Faou.

In [30], we consider a wide class of semi linear Hamiltonian partial differential equations and their approximation by time splitting methods. We assume that the nonlinearity is polynomial, and that the numerical trajectory remains at least uniformly integrable with respect to an eigenbasis of the linear operator (typically the Fourier basis). We show the existence of a modified interpolated Hamiltonian equation whose exact solution coincides with the discrete flow at each time step over a long time. While for standard splitting or implicit-explicit schemes, this long time depends on a cut-off condition in the high frequencies (CFL condition), we show that it can be made exponentially large with respect to the step size for a class of modified splitting schemes.

5.23. Energy cascades for NLS on the torus

Participant: Erwan Faou.

In the work [16], we consider the nonlinear Schrödinger equation with cubic (focusing or defocusing) nonlinearity on the multidimensional torus. For special small initial data containing only five modes, we exhibit a countable set of time layers in which arbitrarily large modes are created. The proof relies on a reduction to multiphase weakly nonlinear geometric optics, and on the study of a particular two-dimensional discrete dynamical system.

5.24. A Nekhoroshev type theorem for the nonlinear Schrödinger equation on the d-dimensional torus

Participant: Erwan Faou.

In [49] we prove a Nekhoroshev type theorem for the nonlinear Schrödinger equation

\[ iu_t = -\Delta u + V \hat{u} + \partial_{\hat{u}} g(u, \hat{u}), \quad x \in \mathbb{T}^d, \]

where \( V \) is a typical smooth Fourier multiplier and \( g \) is analytic in both variables. More precisely we prove that if the initial datum is analytic in a strip of width \( \rho > 0 \) whose norm on this strip is equal to \( \epsilon \) then, if \( \epsilon \) is small enough, the solution of the nonlinear Schrödinger equation above remains analytic in a strip of width \( \rho/2 \), with norm bounded on this strip by \( C\epsilon \) over a very long time interval of order \( \epsilon^{-\alpha \ln \epsilon} \beta \), where \( 0 < \beta < 1 \) is arbitrary and \( C > 0 \) and \( \alpha > 0 \) are positive constants depending on \( \beta \) and \( \rho \).
5.25. Sobolev stability of plane wave solutions to the cubic nonlinear Schrödinger equation on a torus

**Participant:** Erwan Faou.

In [48], it is shown that plane wave solutions to the cubic nonlinear Schrödinger equation on a torus behave orbitally stable under generic perturbations of the initial data that are small in a high-order Sobolev norm, over long times that extend to arbitrary negative powers of the smallness parameter. The perturbation stays small in the same Sobolev norm over such long times. The proof uses a Hamiltonian reduction and transformation and, alternatively, Birkhoff normal forms or modulated Fourier expansions in time.

5.26. Approximate travelling wave solutions to the 2D Euler equation on the torus

**Participants:** Erwan Faou, Nicolas Crouseilles.

In [43], we consider the two-dimensional Euler equation with periodic boundary conditions. We construct approximate solutions of this equation made of localized travelling profiles with compact support propagating over a stationary state depending on only one variable. The direction or propagation is orthogonal to this variable, and the support is concentrated around flat points of the stationary state. Under regularity assumptions, we prove that the approximation error can be made exponentially small with respect to the width of the support of the travelling wave. We illustrate this result by numerical simulations.

5.27. Markov chains competing for transitions: applications to large-scale distributed systems

**Participant:** François Castella.

We consider in [12] the behavior of a stochastic system composed of several identically distributed, but non-independent, discrete-time absorbing Markov chains competing at each instant for a transition. The competition consists in determining at each instant, using a given probability distribution, the only Markov chain allowed to make a transition. We analyze the first time at which one of the Markov chains reaches its absorbing state. We obtain its distribution and its expectation and we propose an algorithm to compute these quantities. We also exhibit the asymptotic behavior of the system when the number of Markov chains goes to infinity. Actually, this problem comes from the analysis of large-scale distributed systems and we show how our results apply to this domain.

5.28. Analysis of a large number of Markov chains competing for transitions

**Participant:** François Castella.

This text [41] generalizes the previous one [12] in the following sense. In the situation on the previous article, we analyze the first time at which one of the Markov chains reaches its absorbing state. When the number of Markov chains goes to infinity, we analyze the asymptotic behavior of the system for an arbitrary probability mass function governing the competition. We give conditions for the existence of the asymptotic distribution and we show how these results apply to cluster-based distributed storage when the competition is handled using a geometric distribution.

5.29. Splitting methods with complex coefficients for some classes of evolution equations

**Participant:** Philippe Chartier.
We are concerned in [13] with the numerical solution obtained by splitting methods of certain parabolic partial differential equations. Splitting schemes of order higher than two with real coefficients necessarily involve negative coefficients. In a previous paper, Castella et al. demonstrated the possibility to overcome this second-order barrier by considering splitting methods with complex-valued coefficients and built up methods of orders 3 to 14. In this paper, we reconsider the technique employed therein and show that it is inherently bound to order 14 and largely sub-optimal with respect to error constants. As an alternative, we solve directly the algebraic equations arising from the order conditions and construct several methods of orders 4, 6, 8 and 16 that are the most accurate ones available at present time.

5.3.0. Higher-order averaging, formal series and numerical integration

**Participant:** Philippe Chartier.

The paper [42] considers non-autonomous oscillatory systems of ordinary differential equations with \( d = 1 \) non-resonant constant frequencies. Formal series like those used nowadays to analyze the properties of numerical integrators are employed to construct higher-order averaged systems and the required changes of variables. With the new approach, the averaged system and the change of variables consist of vector-valued functions that may be written down immediately and scalar coefficients that are universal in the sense that they do not depend on the specific system being averaged and may therefore be computed once and for all. The new method may be applied to obtain a variety of averaged systems. In particular we study the quasi-stroboscopic averaged system characterized by the property that the true oscillatory solution and the averaged solution coincide at the initial time. We show that quasi-stroboscopic averaging is a geometric procedure because it is independent of the particular choice of co-ordinates used to write the given system. As a consequence, quasi-stroboscopic averaging of a canonical Hamiltonian (resp. of a divergence-free) system results in a canonical (resp. in a divergence-free) averaged system. We also study the averaging of a family of near-integrable systems where our approach may be used to construct explicitly \( d \) formal first integrals for both the given system and its quasi-stroboscopic averaged version. As an application we construct three first integrals of a system that arises as a nonlinear perturbation of coupled harmonic oscillators with one slow frequency and four resonant fast frequencies.

The stroboscopic averaging method (SAM) is a technique for the integration of highly oscillatory differential systems \( \dot{y} = f(y, t) \) with a single high frequency. The method may be seen as a purely numerical way of implementing the analytical technique of stroboscopic averaging which constructs an averaged differential system \( \dot{Y} = F(Y) \) whose solutions \( Y \) interpolate the sought highly oscillatory solutions \( y \). SAM integrates numerically the averaged system without using the analytic expression of \( F \); all information on \( F \) required by the algorithm is gathered on the fly by numerically integrating the originally given system in small time windows. SAM may be easily implemented in combination with standard software and may be applied with variable step sizes. Furthermore it may also be used successfully to integrate oscillatory DAEs. The paper [15] provides an analytic and experimental study of SAM and two related techniques: the LISP algorithms of Kirchgraber and multirevolution methods.
6. New Results

6.1. BlobSeer and Map-Reduce programming

6.1.1. BlobSeer-based cloud storage

Participants: Alexandra Carpen-Amarie, Alexandru Costan, Gabriel Antoniu, Luc Bougé.

As data volumes generated and processed by such applications increase, a key requirement that directly impacts the adoption rate of the Cloud paradigm is efficient and reliable data management. In this context, we investigate the requirements of Cloud data services in terms of data-transfer performance and access patterns and we explore the ways to leverage and adapt existing data-management solutions for Cloud workloads. We aim at building a Cloud data service both compatible with state-of-the-art Cloud interfaces and able to deliver high-throughput data storage.

To achieve this goal, we developed a file system layer on top of BlobSeer, which exposes a hierarchical file namespace enhanced with the concurrency-optimized BlobSeer primitives. Furthermore, we integrated the BlobSeer file system as a backend for Cumulus, an efficient open-source Cloud storage service. We validated our approach through extensive evaluations performed on Grid’5000. We devised a set of synthetic benchmarks to measure the performance and scalability of the Cumulus system backed by BlobSeer, showing it can sustain high-throughput data transfers for up to 200 concurrent clients.

Next, we explored the advantages and drawbacks of employing Cloud storage services for distributed applications that manage massive amounts of data. We investigated two types of applications. We relied on an atmospheric phenomena modeling application to conduct a set of evaluations in a Nimbus Cloud environment. This application is representative for a large class of simulators that compute the evolution in time set of parameters corresponding to specific points in a spatial domain. As a consequence, such applications generate important amounts of output data. We evaluated an S3-compliant Cloud storage service as a storage solution for the generated data. To this end, we employed distributed Cumulus services backed by various storage systems. The reason for targeting this approach is that storing output data directly into the Cloud as the application progresses can benefit higher-level applications that further process such simulation data. As an example, visualization tools need to have real-time access to output data for analysis and filtering purposes.

We built an interfacing module to enable the application to run unmodified in a Cloud environment and to send output data to an S3-based Cloud service. Our experiments show that distributed Cumulus backends, such as BlobSeer or PVFS, sustain a constant throughput even when the number of application processes that concurrently generate data becomes 3 times higher than the number of storage nodes.

6.1.2. Optimizing Intermediate Data Management in MapReduce Computations

Participants: Diana Moise, Gabriel Antoniu, Luc Bougé.

MapReduce applications, as well as other cloud data flows, consist of multiple stages of computations that process the input data and output the result. At each stage, the computation produces intermediate data that is to be processed by the next computing stage. We studied the characteristics of intermediate data in general, and we focused on the way it is handled in MapReduce frameworks. Our work addressed intermediate data at two levels: inside the same MapReduce job, and during the execution of pipeline applications.
We focused first on efficiently managing intermediate data generated between the “map” and “reduce” phases of MapReduce computations. In this context, we proposed to store the intermediate data in the distributed file system used as underlying backend. In this direction, we investigated the features of intermediate data in MapReduce computations and we proposed a new approach consisting in storing this kind of data in a DFS. The major benefit of this approach is better illustrated when considering failures. Existing MapReduce frameworks store intermediate data on nodes local disk. In case of failures, intermediate data produced by mappers can no longer be retrieved and processed further by reducers. The solution of most frameworks is to reschedule the failed tasks and to re-generate all the intermediate data that was lost because of failures. This solution is costly in terms of additional execution time. With our approach of storing intermediate data in a DFS, we avoid the re-execution of tasks in case of failures that lead to data loss. As storage for intermediate data, we considered BSFS as being a suitable candidate for providing for the requirements of intermediate data: availability and high I/O access. The tests we performed in this context, measured the impact of using a DFS as storage for intermediate data instead of the local-disk approach. We then assessed the performance of BSFS and HDFS when serving as storage for intermediate data produced by several MapReduce applications.

We then considered another type of intermediate data that appears in the context of pipeline MapReduce applications. In order to speed-up the execution of pipeline MapReduce applications (applications that consist of multiple jobs executed in a pipeline) and also, to improve cluster utilization, we proposed an optimized Hadoop MapReduce framework, in which the scheduling is done in a dynamic manner. We introduced several optimizations in the Hadoop MapReduce framework in order to improve its performance when executing pipelines. Our proposal consisted mainly in a new mechanism for creating tasks along the pipeline, as soon as the tasks’ input data becomes available. As our evaluation showed, this dynamic task scheduling leads to an improved performance of the framework, in terms of job completion time. In addition, our approach ensures a more efficient cluster utilization, with respect to the amount of resources that are involved in the computation.

We evaluated both approaches for intermediate data through a set of experiments on the Grid’5000 [56] testbed. Preliminary results [17] show the scalability and efficiency of our proposals, as well as additional benefits brought forward by our approach.

6.1.3. A-Brain: Perform genetic and neuroimaging data analysis in Azure clouds

Participants: Radu Tudoran, Alexandru Costan, Gabriel Antoniu, Louis-Claude Canon.

Joint genetic and neuroimaging data analysis on large cohorts of subjects is a new approach used to assess and understand the variability that exists between individuals. This approach has remained poorly understood so far and brings forward very significant challenges, as progress in this field can open pioneering directions in biology and medicine. As both neuroimaging- and genetic-domain observations represent a huge amount of variables (of the order of $10^6$), performing statistically rigorous analyses on such amounts of data represents a computational challenge that cannot be addressed with conventional computational techniques.

In order to perform an accurate analysis we need to provide a programming platform and a high throughput storage. The target infrastructure is the Azure clouds. Hence we have adapted the BlobSeer storage approach for Azure, thus providing a new way to store data in clouds, that federates the local storage space from computational nodes into a uniform shared storage, called TomusBlobs. Using this storage system as a storage backend, we have built a MapReduce prototype for Azure clouds. This MapReduce system, called TomusMapReduce -TMR, is used to perform the simulation of the joint genetic and neuroimaging application. For validating the framework, a toy application that simulate the data access and computation patterns of the real application, was used. The next step, after the evaluation of the framework, that has just began, consists in replacing the toy application with the real one and the scaling of the framework in the limit allowed by the cloud provider. In addition a demo for this project is in progress, that will consists in providing a visualization tool for the framework. This will be used to intuitively represent the results for the simulation of the scientific application, this being useful both for better presenting the project to interested parties and for the researchers from bioinformatics.

6.2. Efficient VM management in clouds

Participants: Alexandru Costan, Alexandra Carpen-Amarie, Gabriel Antoniu.
Infrastructure as a Service (IaaS) cloud computing allows users to lease computational resources from the cloud provider’s datacenter for a short time by deploying virtual machines (VMs) on these resources. This model raises new challenges in the design and development of IaaS middleware. One of those challenges is the need to deploy a large number (hundreds or even thousands) of VM instances simultaneously. Once the VM instances are deployed, another challenge is to simultaneously take a snapshot of many images and transfer them to persistent storage to support fault tolerance and management tasks, such as suspend-resume and migration. With datacenters growing rapidly and configurations becoming heterogeneous, it is important to enable efficient concurrent deployment and snapshotting that are at the same time hypervisor independent and ensure a maximum compatibility with different configurations.

We addressed these challenges by proposing a virtual file system specifically optimized for virtual machine image storage [19]. It is based on a lazy transfer scheme coupled with object versioning that handles snapshotting transparently in a hypervisor-independent fashion, ensuring high portability for different configurations. Large-scale experiments on hundreds of nodes demonstrate excellent performance results: speedup for concurrent VM deployments ranges from a factor of 2 up to 25, with a reduction in bandwidth utilization of as much as 90% [18]. We implemented this deployment scheme in the Nimbus cloud and presented a demo illustrating it at the Grid’5000 School [26].

Given the dynamic nature of IaaS clouds and the long runtime and resource utilization of scientific applications, an interesting use-case for the multi-snapshotting techniques is for efficient checkpoint-restart. We introduced an approach that leverages VM disk-image multi-snapshotting and multi-deployment inside checkpoint-restart protocols running at guest level in order to efficiently capture and potentially roll back the complete state of the application, including file system modifications. This framework is specifically optimized for tightly-coupled scientific applications that were written using a message passing system (in particular MPI) and need to be ported to IaaS clouds. Our solution introduces a dedicated checkpoint repository that is able to efficiently take incremental snapshots of the whole disk attached to the virtual machine instances, thus offering support to use any checkpointing protocol that can save the state of processes into files, including application level mechanisms, where the process state is managed by the application itself, and process-level mechanisms, where the process state is managed transparently at the level of the message passing library. Experiments on the G5K testbed show substantial improvement for MPI applications over existing approaches, both for the case when customized checkpointing is available at application level and the case when it needs to be handled at process level.

We integrated this checkpointing scheme inside the Nimbus cloud with some promising preliminary results. We plan to complement the existing solution with live incremental snapshotting using asynchronous background transfers for high checkpointing efficiency and with adaptive prefetching to achieve high restart efficiency.

### 6.3. Cloud data storage management

#### 6.3.1. Autonomic storage for cloud services

**Participants:** Alexandru Costan, Alexandra Carpen-Amarie, Gabriel Antoniu, Florin Pop, Ciprian Dobre, Elena Apostol.

A means to achieve performance improvement and resource-usage optimization in cloud storage systems consists in enabling an autonomic behavior based on introspection. Self-adaptation incurs a high degree of complexity in the configuration and tuning of the system, with possible repercussions on its availability and reliability. To address these challenges we introduced in BlobSeer in [11] a three-layered architecture designed to identify and generate relevant information related to the state and the behavior of the system, based on the MonALISA monitoring framework. Such information is then expected to serve as an input to a higher-level self adaptation engine. These data are yielded by an (1) introspection layer, which processes the raw data collected by a (2) monitoring layer. The lowest layer is represented by the (3) instrumentation code that enables BlobSeer to send monitoring data to the upper layers.
A first approach to leverage the introspection framework aims at enhancing BlobSeer with \textit{self-configuration} capabilities, as a means to support storage elasticity through dynamic deployment of data providers. This solution enables the data providers to scale up and down depending on the detected system’s needs. The component we designed adapts the storage system to the environment by contracting and expanding the pool of storage providers based on the system’s load. The key idea of this component is the automatic decision that has to be made on how many resources the system needs to operate normally while keeping the resources utilization down to a minimum. This problem is addressed by using a test-decided heuristic based on the monitoring data. The introspective architecture has been evaluated on the Grid’5000 testbed, with experiments that prove the feasibility of generating relevant information related to the state and the behavior of the system.

We plan to use the introspective BlobSeer to develop a distributed data aggregation service. Its primary goal will be to serve as a repository backend for complex analysis and automatic mining of scientific data. Another direction that will be explored is to use the introspective BlobSeer as a cloud-based storage layer for sensitive context data, collected from a vast amount of sources: from smartphones to sensors located in the environment.

Clouds are perfect candidates to handle the storage and aggregation of such data for even larger context-aware applications. Such solutions rely on more relaxed storage capabilities than traditional relational databases (eventual consistency suffices for example). This, combined with the high concurrency support and the flexible storage schema make BlobSeer a suitable candidate for the storage layer. We plan to develop a new layer on top of BlobSeer targeting context aware applications. At the logical level, this layer will provide transparency, mobility, real-time guarantees and access based on meta-information. At the physical layer, the most important capability will rely on BlobSeer’s elasticity to scale up and down according to real-time usage, in order to reduce the costs within the Cloud.

\subsection{Managing data access on Clouds through security policies}

\textbf{Participants:} Alexandru Costan, Alexandra Carpen-Amarie, Gabriel Antoniu.

With the emergence of Cloud computing, there has been a great need to provide an adequate security level in such environments, as they are vulnerable to various attacks. Malicious behaviors such as Denial of Service attacks, especially when targeting large-scale data management systems, cannot be detected by typical authentication mechanisms and are responsible for drastically degrading the overall performance of such systems.

In \cite{14} we proposed a generic security management framework allowing providers of Cloud data management systems to define and enforce complex security policies. The generality of this approach comes from the flexibility both in terms of supporting custom security scenarios and interfacing with different Cloud storage systems. This security framework is designed to detect and stop a large array of attacks defined through an expressive policy description language and to be easily interfaced with various data management systems. We introduced a modular architecture consisting of three components. The \textit{Policy Management} module represents the core of the framework, where security policies definition and enforcement takes place. This module is completely independent of the Cloud system, as its input only consists in user activity events monitored from the system. The \textit{User Activity History} module is a container for monitoring information describing users’ actions. It collects data by employing monitoring mechanisms specific to each storage system and makes them available for the Policy Management module. The \textit{Trust Management} module incorporates data about the state of the Cloud system and provides a trust value for each user based on his past actions. The trust value identifies a user as a fair or a malicious one. Furthermore, the trust values enable the system to take custom actions for each detected policy violation, by taking into account the history of each user.

As a case study, we applied the proposed framework to BlobSeer. We defined a specific policy to detect DoS attacks in BlobSeer and we evaluated the performance of our framework through large scale experiments on the Grid’5000 testbed. The results show that the Policy Management module meets the requirements of a data storage system in a large-scale deployment: it was able to deal with a large number of simultaneous attacks and to restore and preserve the performance of the target system.

As a next step we will focus on more in-depth experiments involving the detection of various types of attacks in the same time. Moreover, we will investigate the limitations of our Security Management framework, with
respect to the accuracy of the detection in the case of more complex policies, as well as the probability and the impact of obtaining false positive or false negative results. Another research direction is to further develop the Trust Management component of the security management framework and study the impact it has on the Policy Enforcement decisions for complex scenarios.

6.4. Storage architecture and adaptive consistency for clouds

Participants: Houssem-Eddine Chihoub, Gabriel Antoniu.

As more and more applications are becoming data-intensive, the design of a scalable storage architecture providing a huge file sharing and fine grain access with high throughput under heavy concurrency is a timely and relevant challenge.

In [24], we introduce a storage architecture for Cloud computing. This architecture proposes efficient and scalable storage support for both VM images and application data. Our architecture relies on BlobSeer [12], a data sharing platform optimized for concurrent accesses, as a basic storage backend enhanced in term of quality of service and efficiency by GloBeM tool [61] that rely on behavior modeling and monitoring to avoid bad case scenarios. The architecture uses this approach to have a better and efficient storage VM images, that allow a faster image deployment and efficient versioning and snapshotting. Furthermore, the architecture provides a platform to store, manage, and share cloud application data allowing several key features to clouds such as storage elasticity.

The main aim is to provide high availability and good scalable performance at low cost. This is justified by the growing need of data-intensive applications for managing huge sets of data replicated over several data centers. In order to provide good performance and high availability, data replication is mandatory. But this generates the issue of replicas consistency as shown by the CAP theorem [52]. To achieve the aforementioned goals, relaxing consistency rules is unavoidable. On the other hand, opting for weaker consistency, all the time, can be too costly.

In current work we leverage the trade-off between consistency and availability and performance. We are investigating an approach that changes the consistency level at runtime considering system and application needs. In order to choose the most suitable consistency level, our approach monitor the storage system and collect useful information, such as network load and applications access patterns, that enable the system to estimate the amount of expected stale reads.

6.5. Modelling cloud storage performance

Participants: Daniel Higuero, Louis-Claude Canon, Alexandru Costan, Gabriel Antoniu.

The objective of this research direction is to provide comprehensive performance models for storage systems. Their role is to capture how the system components interact for different usage patterns (number of reads or writes). The objective is to determine the incurred costs in terms of storage space and efficiency for a given workload.

One application of this model consists in dynamically adjusting the parameters of the storage system as required in an autonomic approach. For this purpose, it is necessary to identify the characteristics of the storage system for meeting a given level of requirements. Progress has been made on this part during the 3-month visit of Daniel Higuero (University Carlos III, Madrid). A preliminary performance model currently predicts the available bandwidth when multiple concurrent transfers occur. This model serves as a basis for a dimensioning strategy that is formulated through a linear program.

This approach has further been complemented with an offline analysis of several traces of the BlobSeer storage system when it is used as a backend for MapReduce applications. Mining this information in an automated fashion allowed to detect the different trade-offs that influence a BlobSeer deployment: time required to execute the application vs. number of machines used by the storage system, communication costs vs. space usage. The final goal is to tune BlobSeer for specific applications. The proposed strategy is currently being evaluated.
Future directions are directed towards refining the proposed model. Several parameters significantly impact the performance of storage systems such as the redundancy mechanism, the data placement strategy or disk-related effects. As a first step, experiments for assessing the quality of finer models will be designed. Ultimately, we aim to capture the I/O variability of storage systems, in particular in the context of the cloud.

This work will enable new collaborations. It is planned to work on the models mentioned above with the Mescal INRIA team in the context of a collaboration between the MapReduce ANR project and the Songs ANR project. Moreover, in the framework of the MapReduce project, we expect to work on a performance model for designing decision algorithms that are required by the component-based MapReduce framework that is developed in the GRAAL/Avalon INRIA team. Finally, the GRAAL/AVALON team works on scheduling algorithms that could beneficially profit from a storage performance model.

6.6. Scalable I/O and visualization for post-petascale HPC simulations

Participants: Matthieu Dorier, Gabriel Antoniu.

In the context of the Joint INRIA/UIUC Laboratory for Petascale computing (JLCP), we are addressing the new challenges related to I/O, data analysis and visualization for extreme-scale simulations. As HPC resources approaching millions of cores become a reality, a growing challenge in maintaining high performance is the presence of high variability in the effective throughput of codes performing I/O operations. Since I/O is mainly performed for the purpose of subsequent data analysis and visualization, another way to limit the impact of I/O performance on scientific discovery consists in enabling in-situ visualization. This brings again new challenges such as how to efficiently couple large-scale simulations with visualization software.

We started the development of Damaris, a middleware targeting multicore SMP nodes to efficiently address the problems mentioned above. Damaris has been evaluated with the CM1 atmospheric simulation [43], one of the targeted application for the BlueWaters project. To show the capability of our approach to efficiently hide I/O jitter and related costs, experiments have been carried on the French Grid’5000, on a Power5 cluster at NCSA and on the Kraken Cray XT5 supercomputer (currently 11th in the Top500) with up to 9K cores. By gathering data into large files while avoiding synchronization between processes, our solution brings several benefits:

1. it increases the sustained write throughput of the simulation by a factor of almost 15;
2. it provides almost 70% overall application speedup on 9,000 cores;
3. it fully hides I/O-related costs;
4. it enables a 600% compression ratio without any additional overhead, leading to a major reduction of storage requirements.

A poster [16] presenting some of these results has been accepted at ICS’11 and awarded the second price at the ACM Student Research Competition. All these results are presented in a research report [25] pending for publication.

Current work addresses the efficient coupling of large-scale simulations and visualization tools through Damaris. We have been able to get access to the Jaguar supercomputer hosted at ORNL and we are planning very-large scale experiments on up to 100,000 cores to show the benefits of our Damaris approach.

6.7. Scalable array-oriented active storage

Participants: Viet-Trung Tran, Gabriel Antoniu, Luc Bougé.
The recent explosion in data sizes manipulated by distributed scientific applications has prompted the need to develop specialized storage systems capable of dealing with specific access patterns in a scalable fashion. In this context, a large class of applications focuses on parallel array processing: small parts of huge multi-dimensional arrays are concurrently accessed by a large number of clients, both for reading and writing. However, many established storage solutions such as parallel file systems and database management systems expose data access models (e.g., file systems, structured databases) that are too general and do not exactly match the nature requirements of the application. This forces the application developer to either adapt to the exposed data access model or to use an intermediate layer that performs a translation. In either case, the mismatch leads to suboptimal data management: the one-storage-solution-fits-all-needs has reached its limits.

Thus, there is an increasing need to specialize the I/O stack to match the requirements of the application. The objective of this research is to design Pyramid: an array-oriented active storage system optimizing for applications that represent and manipulate data as huge multi-dimensional arrays. However, a specialized storage system that deals with such an access pattern faces several challenges at the level of data/metadata management, we carefully design the system with the following principles: (1) we introduce a dedicated array-oriented data access model that offers support for active storage and versioning; (2) we enrich striping techniques specifically optimized for multi-dimensional arrays with a distributed metadata management scheme that avoids potential I/O bottlenecks observed with centralized approaches.

We evaluated Pyramid through a set of experiments on the Grid’5000 testbed that aims to evaluate both the performance and the scalability of our approach under concurrent accesses. Preliminary evaluation in our recent papers shows promising results: our prototype demonstrates good performance and scalability under concurrency, both for read and write workloads.
6. New Results

6.1. Visual tracking

6.1.1. 3D model-based tracking

Participants: Antoine Petit, Eric Marchand.

Our 3D model-based tracking algorithm [3] was used in various contexts. First, it has been studied and tested on a mock-up of a telecommunication satellite using a 6-DOF robotic arm, with satisfactory results in terms of accuracy of the pose estimation and computational costs [41], [42]. A potential application would be the final phase of space rendezvous mission using visual navigation. Then, it has been considered for designing a visual servoing scheme able to control the walking of a humanoid robot [29].

6.1.2. Omnidirectional stereovision

Participants: Guillaume Caron, El Mustapha Mouaddib, Eric Marchand.

Omnidirectional cameras allow direct tracking and motion estimation of planar regions in images during a long period of time. However, using only one sensor leads to plane and trajectory reconstruction up to a scale factor. We proposed to develop dense plane tracking based on omnidirectional stereovision to answer this issue. The method estimates simultaneously the parameters of several 3D planes along with the camera motion using a spherical projection model formulation [20].

6.1.3. Motion estimation using mutual information

Participant: Eric Marchand.

Our work with Amaury Dame related to template tracking using mutual information as registration criterion has been extended to motion estimation applications. It has been applied to mosaicing from an image sequence [28]. The main advantage is that this approach is robust to noise, lighting variations and does not require a statistically robust estimation process.

6.1.4. Augmented reality

Participants: Pierre Martin, Hideaki Uchiyama, Eric Marchand.

We developed an approach for detecting and tracking various types of planar objects with geometrical features[45]. We combine traditional keypoint detectors with Locally Likely Arrangement Hashing (LLAH) for keypoint matching. In order to produce robustness to scale changes, we build a non-uniform image pyramid according to keypoint distribution at each scale. It demonstrates that it is possible to detect and track different types of textures including colorful pictures, binary fiducial markers and handwritings. This approach was extended to consider non-rigidly deformable markers [46].

6.2. Visual servoing

6.2.1. Micro-manipulation

Participant: Eric Marchand.

We developed an accurate nanopositioning system based on direct visual servoing [43],[17]. This technique relies only on the pure image signal to design the control law, by using the pixel intensity of each pixel as visual features. The proposed approach has been tested in terms of accuracy and robustness in several experimental conditions. The obtained results have demonstrated a good behavior of the control law and very good positioning accuracy: 89 nm, 14 nm, and 0.001 degrees in the \(x, y\) and \(\theta_z\) axes of a positioning platform, respectively.
6.2.2. Multi sensor-based control  
Participants: Olivier Kermorgant, François Chaumette.

We have designed a generic sensor-based control approach to automatically tune the weights related to the features involved as inputs of a control scheme, allowing to take constraints into account. This scheme has been applied to several configurations, such as fusing the data provided by an eye-in-hand camera and an eye-to-hand camera, ensuring the visibility constraint, and avoiding the robot joint limits [30], [31], [32], [11].

6.2.3. Visual navigation of mobile robots  
Participants: Eric Marchand, Andrea Cherubini, Fabien Spindler, François Chaumette.

We have developed a visual servoing scheme based on the mutual information between the images acquired by an onboard camera and a visual memory to control the orientation of a vehicle during its navigation [27]. We have also fused the data provided by a pan-tilt camera and a laser range sensor for the autonomous navigation of a mobile vehicle while avoiding obstacles [23], [22]. Real experiments with our Cycab (see Section 5.4) have been conducted on Place de Jaude in Clermont-Ferrand in the scope of the ANR Tosa CityVIP project (See Section 8.2.1).

6.2.4. Visual servoing for aircrafts  
Participants: Céline Teulière, Eric Marchand, Laurent Coutard, François Chaumette.

A dynamic controller has been designed for the homing of a quadri-rotor aerial vehicle [39]. A color-based tracking algorithm has also been designed and combined with an image-based visual servoing for chasing a moving target from a a flying UAV [44]. Finally, a method has been developed to detect and localize an aircraft carrier in an image sequence, from which visual servoing control laws have been designed for the automatic landing [25], [26].

6.3. Medical robotics

6.3.1. Visual servoing based on ultrasound images  
Participants: Caroline Nadeau, Alexandre Krupa.

We developed a new approach of ultrasound image based visual servoing that directly uses the intensities of the ultrasound image pixels as visual features. This method that spares any segmentation or image processing time consuming step was initially proposed to control the 6 DOF of a conventional 2D probe for positioning and tracking tasks [38], [48]. To increase the tracking performance we also adapted this method by considering a predictive control law based on the periodicity of physiological motions [36]. Rigid motion compensation experiments were conducted in the context of the ANR USComp project (See Section 8.2.3). The method was also improved by estimating on-line the image 3D gradient required for the positioning task and extended for the use of a bi-plane ultrasound probe [37]. Finally, the use of a 3D motorized probe was also considered to compute directly the image 3D gradient and a comparison of the results obtained with the different probes (2D, bi-plan, 3D) was performed [12].

6.3.2. Autonomous control modes for ultrasound probe guidance  
Participants: Tao Li, Alexandre Krupa.
In the context of the ANR Prosit (See Section 8.2.2), we developed several autonomous control modes in order to assist a doctor during a robotized and teleoperated ultrasound examination (tele-echography). The robotic tasks we proposed concern: an automatic scanning of the patient by a 2D probe, a shared control mode that maintains the visibility of an anatomic element of interest while the doctor teleoperates the slave robot holding the 2D probe, an automatic positioning task that allows the doctor to retrieve a desired anatomic section that was previously captured by the doctor. The two latter modes are based on visual servoing schemes that use as input image moments extracted from the observed 2D ultrasound image. This extraction is performed thanks to an active contour (snake) based on Fourier descriptors that we developed and implemented on GPU in order to provide real-time performance [34], [47]. The proposed autonomous control modes were experimentally validated on the Lagadic medical robotics platform (see Section 5.3) and are now in the process of being integrated on the Prosit robot platform.

6.3.3. Real-time 3D ultrasound image reconstruction and 3D deformation tracking

Participants: Deukhee Lee, Alexandre Krupa.

We developed and implemented on GPU an algorithm that reconstructs in real-time a sequence of dense ultrasound volumes from a set of pre-scan 2D ultrasound images provided online by a motorized ultrasound probe [33]. Then we proposed a dense ultrasound tracking algorithm that estimates in real time both rigid and non-rigid motions of a region of interest observed in the sequence of reconstructed ultrasound volumes [33]. The algorithm consists in estimating in real-time, from intensity-value changes between successive 3D ultrasound images, motions of a set of 3D control points that describe the evolution of 3D Thin-Plate Splines (TPS) modeling the deformation. The estimated rigid motion was then used in a pose-based control scheme to automatically displace the probe held by a robot for soft tissue motion compensation. These works were conducted in the context of the ANR USComp project (See Section 8.2.3).
6. New Results

6.1. Large-scale image search

6.1.1. Aggregating local image descriptors into compact codes

**Participants:** Matthijs Douze, Hervé Jégou [INRIA Rennes], Patrick Pérez [Technicolor], Florent Perronnin [Xerox RCE], Jorge Sánchez [Xerox RCE], Cordelia Schmid.

In [5] we consolidate and extend earlier results for large-scale image search. Different ways of aggregating local image descriptors into a vector are compared. The Fisher vector, see Figure 1, is shown to achieve better performance than the reference bag-of-visual words approach for any given vector dimension. Furthermore, we jointly optimize dimensionality reduction and indexing in order to obtain a precise vector comparison as well as a compact representation. The evaluation shows that the image representation can be reduced to a few dozen bytes with good search accuracy. Given such small codes, searching a 100 million image dataset takes about 250 ms on one processor core.

![Figure 1. Illustration of the similarity of the Fisher vectors of local image regions despite viewpoint changes.](image)

6.1.2. Searching in one billion vectors: re-rank with source coding

**Participants:** Laurent Amsaleg [CNRS, IRISA], Matthijs Douze, Hervé Jégou [INRIA Rennes], Romain Tavenard [University Rennes I].

In this work [13] we extend our earlier work [4]. An additional level of processing is added to the product quantizer to refine the estimated distances. It consists in quantizing the difference vector between a point and the corresponding centroid. When combined with an inverted file, this gives three levels of quantization. Experiments performed on SIFT and GIST image descriptors show excellent search accuracy outperforming three state-of-the-art approaches.

6.1.3. Combining attributes and Fisher vectors for efficient image retrieval

**Participants:** Matthijs Douze, Arnau Ramisa, Cordelia Schmid.

Attributes were recently shown to give excellent results for category recognition. In [9] we demonstrate their performance in the context of image retrieval. We show that combining attributes with Fisher vectors improves performance for retrieval of particular objects as well as categories. Furthermore, we implement an efficient coding technique for compressing the combined descriptor to very small codes. Experimental results show that our approach significantly outperforms the state of the art, even for a very compact representation of 16 bytes per image. We show that attribute features combined with Fisher vectors improve the retrieval of image categories and that those features can supplement text features.

6.1.4. Bag-of-colors for improved image search

**Participants:** Matthijs Douze, Hervé Jégou [INRIA Rennes], Christian Wengert [Kooaba].
In [19] we investigate the use of color information when used within a state-of-the-art large scale image search system. We introduce a simple color signature generation procedure, used either to produce global or local descriptors. As a global descriptor, it outperforms several state-of-the-art color description methods, in particular the bag-of-words method based on color SIFT. As a local descriptor, our signature is used jointly with SIFT descriptors (no color) to provide complementary information.

6.2. Learning and structuring of visual models

6.2.1. Learning to rank and quadratic assignment

Participants: Thomas Mensink, Jakob Verbeek, Tiberio Caetano [NICTA Canberra].

In [16] we show that the optimization of several ranking-based performance measures, such as precision-at-k and average-precision, is intimately related to the solution of quadratic assignment problems, especially when the score function allows for pairwise label dependencies. Both the task of test-time prediction of the best ranking and the task of constraint generation in estimators based on structured support vector machines can all be seen as special cases of quadratic assignment problems. Although such problems are in general NP-hard, we identify a polynomially-solvable subclass (for both inference and learning) that still enables the modeling of a substantial number of pairwise rank interactions. We show preliminary results on a public benchmark image annotation data set, which indicates that this model can deliver higher performance over ranking models without pairwise rank dependencies. This work was performed during a visit to NICTA Canberra by T. Mensink (March – June, ’11) and J. Verbeek (May ’11).

![Figure 2. An automatically obtained dependency tree over 96 labels, that contains 3 labels per node.](image)

6.2.2. Learning structured prediction models for interactive image labeling

Participants: Thomas Mensink, Jakob Verbeek, Gabriela Csurka [Xerox RCE].

In [25] we propose structured models for image labeling that take into account the dependencies among the image labels explicitly. These models are more expressive than independent label predictors, and lead to more accurate predictions. While the improvement is modest for fully-automatic image labeling, the gain is significant in an interactive scenario where a user provides the value of some of the image labels. Such an interactive scenario offers an interesting trade-off between accuracy and manual labeling effort. The structured models are used to decide which labels should be set by the user, and transfer the user input to more accurate
predictions on other image labels. Experimental results on three publicly available benchmark data sets show that in all scenarios our structured models lead to more accurate predictions, and leverage user input much more effectively than state-of-the-art independent models. See Figure 2.

6.2.3. Modeling spatial layout with Fisher vectors for image categorization

Participants: Frédéric Jurie [University of Caen], Josip Krapac, Jakob Verbeek.

In [15] we introduce an extension of bag-of-words image representations to encode spatial layout. Using the Fisher kernel framework we derive a representation that encodes the spatial mean and the variance of image regions associated with visual words. We extend this representation by using a Gaussian mixture model to encode spatial layout, and show that this model is related to a soft-assign version of the spatial pyramid representation. We also combine our representation of spatial layout with the use of Fisher kernels to encode the appearance of local features. Through an extensive experimental evaluation, we show that our representation yields state-of-the-art image categorization results, while being more compact than spatial pyramid representations. In particular, using Fisher kernels to encode both appearance and spatial layout results in an image representation that is computationally efficient, compact, and yields excellent performance while using linear classifiers.

6.2.4. Unsupervised metric learning for face identification in TV video

Participants: Ramazan Cinbis, Jakob Verbeek, Cordelia Schmid.

The goal of face identification is to decide whether two faces depict the same person or not. In [8] we address the identification problem for face-tracks that are automatically collected from uncontrolled TV video data. Face-track identification is an important component in systems that automatically label characters in TV series or movies based on subtitles and/or scripts: it enables effective transfer of the sparse text-based supervision to other faces. We show that, without manually labeling any examples, metric learning can be effectively used to address this problem. This is possible by using pairs of faces within a track as positive examples, while negative training examples can be generated from pairs of face tracks of different people that appear together in a video frame. In this manner we can learn a cast-specific metric, adapted to the people appearing in a particular video, without using any supervision. Identification performance can be further improved using semi-supervised learning where we also include labels for some of the face tracks. We show that our cast-specific metrics not only improve identification, but also recognition and clustering. See Figure 3.

Figure 3. Projections of face signatures projected to two dimensions, using (a) a metric trained on faces detected in still images, (b) using hand labeled faces detected in videos, (c) a metric trained from face tracking results (no manual labeling). Face signatures of different people are color coded. A good face metric can be learned directly from face tracking results, without using any hand labeled examples.
6.2.5. Large-scale image classification

Participants: Miro Dudik [Yahoo! Research], Zaid Harchaoui, Jerome Malick [INRIA Grenoble, BIPOP Team].

We introduced in [10] a new scalable learning algorithm for large-scale multi-class image classification, based on the multinomial logistic loss and the trace-norm regularization penalty. Reframing the challenging non-smooth optimization problem into a surrogate infinite-dimensional optimization problem with regular $\ell_1$-regularization penalty, we propose a simple and provably efficient coordinate descent algorithm. Furthermore, we showed how to perform efficient matrix computations in the compressed domain for quantized dense visual features, scaling up to 100,000s examples, 1,000s-dimensional features, and 100s of categories. Promising experimental results on the “Fungus”, “Ungulate”, and “Vehicles” subsets of ImageNet were obtained, where our approach performed significantly better than state-of-the-art approaches for Fisher vectors with 16 Gaussians.

6.3. Human action recognition

6.3.1. Action recognition by dense trajectories

Feature trajectories have shown to be efficient for representing videos. Typically, they are extracted using the KLT tracker or matching SIFT descriptors between frames. However, the quality as well as quantity of these trajectories is often not sufficient. Inspired by the recent success of dense sampling in image classification, in [18] we propose an approach to describe videos by dense trajectories. An overview of our framework is shown in Figure 4. We sample dense points from each frame and track them based on dense optical flow. Our trajectories are robust to fast irregular motions as well as shot boundaries. Additionally, dense trajectories cover the motion information in videos well. We also investigate how to design descriptors to encode the trajectory information. We introduce a novel descriptor based on motion boundary histograms, which is robust to camera motion. This descriptor consistently outperforms other state-of-the-art descriptors, in particular in uncontrolled realistic videos. We evaluate our video description in the context of action classification with a bag-of-features approach. Experimental results show a significant improvement over the state of the art on four datasets of varying difficulty, e.g., KTH, YouTube, Hollywood2 and UCF sports.

![Figure 4. Illustration of dense trajectories extraction and description. Left: dense sampling of feature points at multiple scales; middle: tracking feature points with a dense optical flow field; right: descriptors are computed along the trajectory.](image-url)
6.3.2. Weakly supervised learning of interactions between humans and objects

**Participants:** Vittorio Ferrari [ETH Zürich], Alessandro Prest, Cordelia Schmid.

In [7] we introduced a weakly supervised approach for learning human actions modeled as interactions between humans and objects. Our approach is human-centric: we first localize a human in the image and then determine the object relevant for the action and its spatial relation with the human. The model is learned automatically from a set of still images annotated only with the action label. Our approach relies on a human detector to initialize the model learning. For robustness to various degrees of visibility, we build a detector that learns to combine a set of existing part detectors. Starting from humans detected in a set of images depicting the action, our approach determines the action object and its spatial relation to the human. Its final output is a probabilistic model of the human-object interaction, i.e. the spatial relation between the human and the object. We present an extensive experimental evaluation on the sports action dataset from Gupta et al., the PASCAL 2010 action dataset, and a new human-object interaction dataset. In the PASCAL visual object classes challenge 2011 our approach achieved best results on three out of ten action classes and the best result on average over all classes.

6.3.3. Explicit modeling of human-object interactions in realistic videos

**Participants:** Vittorio Ferrari [ETH Zürich], Alessandro Prest, Cordelia Schmid.

In [26] we introduced an approach for learning human actions as interactions between persons and objects in realistic videos. Previous work typically represents actions with low-level features such as image gradients or optical flow. In contrast, we explicitly localize in space and track over time both the object and the person, and represent an action as the trajectory of the object wrt to the person position. Our approach relies on state-of-the-art approaches for human and object detection as well as tracking. We show that this results in human and object tracks of sufficient quality to model and localize human-object interactions in realistic videos. Our human-object interaction features capture relative trajectory of the object wrt the human. Experimental results on the Coffee & Cigarettes dataset show that (i) our explicit human-object model is an informative cue for action recognition; (ii) it is complementary to traditional low-level descriptors such as 3D-HOG extracted over human tracks. When combining our human-object interaction features with 3D-HOG features, we show to improve over their separate performance as well as over the state of the art. See Figure 5.

6.3.4. Actom sequence models for efficient action detection

**Participants:** Adrien Gaidon, Zaid Harchaoui, Cordelia Schmid.

In [12] we address the problem of detecting actions, such as drinking or opening a door, in hours of challenging video data. We propose a model based on a sequence of atomic action units, termed "actoms", that are characteristic for the action. Our model represents the temporal structure of actions as a sequence of histograms of actom-anchored visual features. Our representation, which can be seen as a temporally structured extension of the bag-of-features, is flexible, sparse and discriminative. We refer to our model as Actom Sequence Model (ASM). Training requires the annotation of actoms for action clips. At test time, actoms are detected automatically, based on a non-parametric model of the distribution of actoms, which also acts as a prior on an action’s temporal structure. We present experimental results on two recent benchmarks for temporal action detection. We show that our ASM method outperforms the current state of the art in temporal action detection.

6.3.5. A time series kernel for action recognition

**Participants:** Adrien Gaidon, Zaid Harchaoui, Cordelia Schmid.

In [11] we address the problem of action recognition by describing actions as time series of frames and introduce a new kernel to compare their dynamic aspects. Action recognition in realistic videos has been successfully addressed using kernel methods like SVMs. Most existing approaches average local features over video volumes and compare the resulting vectors using kernels on bags of features. In contrast, we model actions as time series of per-frame representations and propose a kernel specifically tailored for the purpose of action recognition. Our main contributions are the following: (i) we provide a new principled way to compare
the dynamics and temporal structure of actions by computing the distance between their auto-correlations, (ii) we derive a practical formulation to compute this distance in any feature space deriving from a base kernel between frames, and (iii) we report experimental results on recent action recognition datasets showing that it provides useful complementary information to the average distribution of frames, as used in state-of-the-art models based on bag-of-features.
LEO Team

6. New Results

6.1. Efficient XML and RDF data management

Participants: Mohamed Amine Baazizi, Nicole Bidoit, Dario Colazzo, François Goasdoué, Konstantinos Karanasos, Asterios Katsifodimos, Julien Leblay, Noor Mallia, Ioana Manolescu, Alexandra Roatis, Marina Sahakyan, Federico Ulliana.

6.1.1. Materialized views for XML

We have continued our work on optimizing XML queries through materialized view-based rewriting, implemented within the ViP2P system. We published in IEEE ICDE 2011 an algorithm for rewriting XQuery queries using materialized XQuery view, which improves the state of the art in terms of expressive power of the supported XQuery subset, in collaboration with V. Vassalos (AUEB, Greece) [41]. Two follow-up works concern: efficient algebraic algorithms for incrementally maintaining the materialized views when the underlying documents change, in collaboration with A. Bonifati (CNR, Italy) [35], and algorithms for automatically recommending views to materialize for a given XML query workload, with V. Vassalos.

6.1.2. Type-based Update Optimization for XML

XML projection is a well-known optimization technique for reducing memory consumption for XQuery in-memory engines in order to overcome the main-memory limitations of these systems (Galax, Saxon, QizX, and eXist). One of our main research line focuses on a schema-based projection technique for for update optimization. The update language considered is XQuery Update Facility (XUF). The main idea behind this technique is: given a query q over an XML document t, instead of evaluating q over t, the query q is evaluated on a smaller document t' obtained from t by pruning out, at loading time, parts of t that are irrelevant for q. The queried document t', a projection of the original one, is often much smaller than t due to selectivity of queries.

The scenario and type-based projection proposed for XML queries, cannot be applied directly for updates. We have proposed a new scenario which is composed of four steps:

1. from the update U and the DTD D, a type projector P is inferred;
2. the document t, valid wrt D, is projected following P in a streaming manner, at loading time;
3. U is evaluated over the projection P(t) and produces a partial result U(P(t));
4. the initial document t is merged with U(P(t)), in a streaming manner, at writing (serializing) time in order to produce the final result U(t).

The scenario has been first studied and implemented for a kind of type projector which is a good compromise between simplicity and effectiveness, and corresponding results have been published in [31]. Subsequently, we have improved this technique by designing: (i) a new kind of type projector that minimizes the amount of data kept in the projection, and (ii) a new merge algorithm using the improved type projector. This analysis is complicated by the strong interconnection between the two tasks: while minimizing the projection we need to ensure a fast and correct merge process [17].

These results have also been presented in [34], providing an overview on the use of types and constraints from relational to XML data, and in the tutorial [63] focusing on schema-based techniques for safe and efficient XML processing.
6.1.3. XML query-update independence

A query and an update are independent when the query result is not affected by update execution, on any possible input database. Detecting query-update independence is of crucial importance in many contexts: view maintenance, concurrency, access control policies etc. Benefits are amplified when query-update independence can be checked statically. We propose a novel schema-based approach for detecting XML query-update independence. Differently from traditional schema-based analysis for XQuery, our system infers sequence of labels, called chains, that are vertically navigated in each schema instance by query and update paths. More precisely, for each node that can be selected by a query/update path in a schema instance, the system infers a chain recording: a) all labels that are encountered from the root to the selected node, and b) the order in which these labels are traversed. The contextual and ordering information provided these chains is at the basis of and extremely precise static independence analysis. We have devised a quite precise chain-inference system, and devised techniques for efficient implementation of the chain-based independence analysis. Results and experiments concerning this line of research have been recently submitted to an international conference.

6.1.4. Precision and complexity of XQuery type inference

A key feature of XQuery is its type system. Any language expression is statically typed and its type is used during program type-checking. In XQuery, types of input data and functions are defined in terms of regular expression types, but it is quite easy to write queries that generate non-regular languages. As a consequence, any type system for XQuery has to rely on a type inference process that approximates the (possibly non-regular) output type of a query with a regular type. This approximation process, while mandatory and unavoidable, may significantly decrease the precision of the inferred types. In [37] we study and compare in terms of precision and computational complexity two main existing XQuery type systems.

6.1.5. Managing temporal XML documents

The management of temporal data is a crucial issue in many database applications. We are currently investigating efficient storage and update methods for temporal XML documents, with a focus on compactness of the representation. One of the method developed relies on the type based optimization method developed for updates [31]. First results about this line of research are included in recent publications [29], [30]. Next research activities focus on the design of expressive temporal query and update languages, and on the use of techniques proposed in [29] for query and update optimization.

6.1.6. Materialized view selection for RDF

Syntactically, RDF, the data format of the Semantic Web, resembles relational data. However, RDF query processing is significantly complicated by the irregular nature of RDF data and by its simplistic data model, which leads to syntactically complex queries (involving many joins over the whole triple data set). When a query workload is known, the performance of the workload can be significantly improved by materializing access support data structures such as materialized views. Our efficient algorithms for selecting a set of views to materialize in order to speed up the processing of a set of RDF queries are described in a recent publication [21]. The prototype implementing them has been demonstrated at [53].

6.1.7. Hybrid models for XML and RDF

We have obtained interesting results in the area of jointly managing XML and RDF data. A first direction of work in this area was to support annotated documents, that is, XML documents where individual nodes or fragments could be annotated with RDF triples. This model allows to capture, for instance, blog comments, user ratings on social sites etc. We have proposed a general model based on W3C standards for modeling such data [39].

6.1.8. RDF query answering

The current trend for efficiently querying RDF datasets consists of delegating query evaluation to a scalable RDBMS. However, RDF query answering requires in addition to handle – outside the RDBMS – the RDF semantics. We have introduced the database (DB) fragment of RDF, encompassing the popular Description
Logic (DL) one with essential RDF features like modeling incomplete information, for which we have devised novel saturation- and reformulation-based techniques for answering the Basic Graph Pattern (BGP) queries of SPARQL. This extends the state of the art on pushing RDF query processing within RDBMSs.

6.2. Models for Web data management

Participants: Serge Abiteboul, Emilien Antoine, Meghyn Bienvenu, Alban Galland.

A book on Web Data Management and Distribution [54] was published this year.

6.2.1. A rule-based language for Web data management

We recently proposed [26] a Datalog-style rule-based language (called Webdamlog) for web data management. A novel feature of our language is delegation, that is, the possibility of installing a rule at another peer. In its simplest form, delegation is essentially a remote materialized view. In its general form, it allows peers to exchange rules, i.e., knowledge beyond simple facts, and thereby provides the means for a peer to delegate work to other peers.

A key contribution of our work is a study of the impact on expressiveness of delegations and explicit timestamps. We showed that both strictly augment the power of the language. In order to validate the semantics of our model, we demonstrated that under certain natural conditions, our semantics converges to the same semantics as the centralized system with the same rules.

6.2.2. Web information management with access control

We investigated the problem of sharing private information on the Web, where the information is hosted on different machines that may use different access control and distribution schemes. Based upon our work on Webdamlog, we introduced a distributed knowledge-base model, termed WebdamExchange, that comprises logical statements for specifying data, access control, distribution and knowledge about other peers. In a demo at ICDE [28], we showed how the model can be used in a social-network context to help users keep control on their data on the web. In particular, we demonstrated how users within very different schemes of data distribution (centralized, DHT, unstructured P2P, etc.) can still transparently collaborate while keeping a good control over their own data.

6.3. Ontology-based data and document Management

Participants: Meghyn Bienvenu, François Goasdoué, Yassine Mrabet, Nathalie Pernelle, Gianluca Quercini, Chantal Reynaud, Brigitte Safar, Fabian Suchanek.

6.3.1. Semantic Annotation

We have started a work on semantic annotation of public administration data in the setting of the project DataBridges, an ICT Labs activity. We considered public data represented in tables. The tables that we studied were tables created and published by INSEE. They are spreadsheets filled with statistics about geographic locations and are usually composed of multiple columns, of which one, that we term the subject column, contains a list of textual references to geographic entities, or toponyms, while the others contain numeric attributes. We proposed an approach and an algorithm that assigns a type, or header to the subject column of an INSEE table and identifies the geographic entities referred to by the toponyms in the column [64]. An external resource, DBpedia, is used to help to disambiguate the entities mentioned in the tables and a domain ontology ensures that the types are relative to the geographic domain. This work is continued in the setting of a post-doctoral work granted by the ANR project DataBridges. The aim of the project being to enrich a data warehouse, a first work is to automatically build an initial RDF data warehouse from data collected from the web.

6.3.2. Adaptive Ontologies for Information Retrieval

We published the approach supported by the TARGET framework for Web Information Retrieval in the International Journal of Web Portals (IJWP) [22]. This approach was the core of the PhD of Cédric Pruski defended in April 2009.
6.3.3. **Querying ontology-based annotations**

We have pursued our work on integrating knowledge bases and semantic annotations made on more or less structured tagged documents. We have defined an approach where RDF named graphs are used to distinguish uncertain semantic annotations from rdf triples that are provided by the populated ontology. A user domain query is then reformulated to obtain answers that are ranked according to their provenance (knowledge bases or annotations) [61].

6.3.4. **Watermarking for ontologies**

Ontologies are usually available under some type of license. The large ontologies of the Semantic Web, e.g., are commonly licensed under a Creative Commons License or a GNU license. These licenses require giving credit to the authors of the ontology if the ontology is ever used somewhere else. However, it can be hard to prove whether an ontology is used somewhere else, because ontologies contain world knowledge. If someone “steals” an ontology and uses it somewhere else, he can always claim that he collected the data by himself from real-world sources. To tackle this problem, we have studied approaches that watermark an ontology [43]. If a watermarked ontology is used somewhere else, the mark proves that the ontology has been stolen. Existing approaches have mainly modified the facts in the ontology to create a mark. This, however, compromises the precision of the ontology. Therefore, we have developed an approach that does not modify, but remove certain facts. Thereby, the precision of the ontology is not affected. We show that only a handful of facts have to be removed from an ontology to protect it against theft.

6.3.5. **Consistent query answering in DL-Lite**

An important problem which arises in ontology-based data access is how to handle inconsistencies. In the database community, the related problem of querying databases which violate integrity constraints has been extensively studied under the name of consistent query answering. The standard approach is based on the notion of a repair, which is a database which satisfies the integrity constraints and is as similar as possible to the original database. Consistent answers are defined as those answers which hold in all repairs. A similar strategy can be used for description logics by replacing the integrity constraints with the ontology. Unfortunately, recent work on consistent query answering in description logics has shown this problem to be co-NP-hard in data complexity, even for instance queries and the simplest DL-Lite dialect. In light of this negative result, we considered the problem of identifying cases where consistent query answering is feasible, and in particular, can be done using query rewriting, with the aim of better understanding the cases in which query rewriting can be profitably used. In [51], we make some first steps towards this goal by formulating general conditions which can be used to prove that a consistent rewriting does or does not exist for a given DL-Lite TBox and instance query.

6.3.6. **Module-based data management in DL-lite**

The current trend for building an ontology-based data management system (DMS) is to capitalize on efforts made to design a preexisting well-established DMS (a reference system). The method amounts to extract from the reference DMS a piece of schema relevant to the new application needs – a module –, possibly to personalize it with extra-constraints w.r.t. the application under construction, and then to manage a dataset using the resulting schema. We have revisited the reuse of a reference ontology-based DMS in order to build a new DMS with specific needs. We go one step further by not only considering the design of a module-based DMS (i.e., how to extract a module from a ontological schema): we also study how a module-based DMS can benefit from the reference DMS to enhance its own data management skills. We consider the setting of the DL-LiteA dialect of DL-Lite, which encompasses the foundations of the QL profile of OWL2 (i.e., DL-LiteR): the W3C recommandation for managing efficiently large datasets. We introduce and study novel properties of robustness for modules that provide means for checking easily that a robust module-based DMS evolves safely w.r.t. both the schema and the data of the reference DMS. From a module robust to consistency checking, for any data update in a corresponding module-based DMS, we show how to query the reference DMS for checking whether the local update does not bring any inconsistency with the data and the constraints of the reference DMS. From a module robust to query answering, for any query asked to a module-based
DMS, we show how to query the reference DMS for obtaining additional answers by also exploiting the data stored in the reference DMS.

6.4. Data and Knowledge Integration

Participants: Julio Cesar Dos Reis, Fayçal Hamdi, Rania Khefifi, Yassine Mrabet, Nathalie Pernelle, Chantal Reynaud, Fatih Saïs, Brigitte Safar, Fabian Suchanek, Danai Symeonidou.

6.4.1. Reference Reconciliation

The reference reconciliation problem consists in deciding whether different data descriptions refer to the same real world entity (same person, same conference etc.) Some of existing approaches, such as LN2R, are declarative and knowledge-based. Different kinds of knowledge can be declared in a domain ontology, like disjointness between classes or key constraints. This knowledge can be exploited to infer reconciliation and non-reconciliation decisions.

Our reference reconciliation work pursues three directions:

- develop an automatic approach of key constraint discovery. We have proposed in [46] KD2R, a method which allows automatic discovery of key constraints associated to OWL2 classes. These keys are discovered from RDF data which can be incomplete. The proposed algorithm allows this discovery without having to scan all the data. KD2R has been tested on data sets of the international contest OAEI and obtains promising results.

- develop a reference reconciliation method for detecting redundant data in case of web data tables that are semantically annotated by an ontology. Each table cell values consists in numerical fuzzy set (NFS) or in symbolic fuzzy set (SFS). We have developed a method which uses ontology knowledge and computes similarity scores to decide the data redundancy. We have also proposed two similarity measures for numerical fuzzy set as well as symbolic fuzzy set. The proposed measures are more flexible than existing ones. This approach has been published in [36], [58]. We are working on its extension to be able to distinguish redundant data from similar ones by using provenance information.

- develop a new approach which addresses the problem of resource discovery in the Linked Open Data cloud (LOD) where data described by different schemas is not always linked. We have proposed an automatic approach in [42], [58] that allows discovery of new links between data. These links can help to match schemas that are conceptually relevant with respect to a given application domain. Furthermore, these links can be exploited during the querying process in order to combine data coming from different sources. In this approach we exploit the semantic knowledge declared in different schemas in order to model: (i) the influences between concept similarities, (ii) the influences between data similarities, and (iii) the influences between data and concept similarities. The similarity scores are computed by an iterative resolution of two non linear equation systems that express the concept similarity computation and the data similarity computation.

6.4.2. Context-aware Personal Information Management

Personal information management (PIM) is the practice and analysis of the activities performed by people to acquire, organize, maintain, and retrieve information for everyday use. PIM is a growing area of interest because, everyone is looking for better use of our limited personal resources of time, money and energy. Several research on the topic is being done in different disciplines, including human-computer interaction, database management, information retrieval and artificial intelligence.

The increasingly big amount of personal information (e.g., mails, contacts, appointments) managed by a user is characterized by their heterogeneity, their dispersion and their redundancy. The general goal of this work consists in designing a system, which allows providing the end-users personal data access with services that are relevant to his/her needs, and to access personal data both by mobile devices (smartphone) and Internet-connected Personal Computers. More specifically, we focus here on the problem of defining a common
meta-model for a flexible and homogeneous personal information management. The meta-model that we propose allows users creating personal information and organizing them according to different points of view (ontologies) and different contexts. Contextual queries are defined to allow users to retrieve its personal information using the geographical contexts. The semantic Web languages (OWL, RDF and SPARQL) are used to implement the approach.

6.4.3. Mapping between ontologies

We pursue our work on ontology alignment in the setting of the ANR GeOnto project by aiming to provide full life-cycle support for ontologies.

We investigated how alignment results generated by our alignment tool, TaxoMap, can be used to enrich one ontology with another. We shown that the enrichment process depends on characteristics of the ontology used for enrichment. Three enrichment contexts identified in the setting of the ANR project GeOnto have been studied and enrichment treatments performed. A first context considers ontologies of the same application domain and of a reasonable size. A second context considers small ontologies previously extracted from a generalist one. A third context considers enrichment from a huge, generalist ontology, such as Yago. Early results obtained in the setting of the ANR project GeOnto in the topographic domain have been published in [50], [25].

The module supporting our enrichment approach has been implemented in TaxoMap Framework using patterns. Initially, TaxoMap Framework was composed of our alignment tool, TaxoMap, we are working on for several years in the team and of a mapping refinement module. We extended it in order to obtain a broader framework and an interactive environment by including TaxoPart, a partitioning tool we developed to split two huge ontologies which could not be aligned into two sets of blocks of a limited size, and a module specific to ontology enrichment. Moreover, we re-implemented TaxoMap, our alignment tool, as a web service to make it easily accessible at: http://taxomap.lri.fr:8000/axis2/services/TaxoMapService?wsdl.

We also started a PhD work, joined with CRP Henri Tudor in Luxembourg, to investigate issues dealing with medical knowledge organizing systems evolution. We will define a formal framework to support medical knowledge organizing systems evolution in a consistent way and also to support the maintenance of mappings directly impacted by knowledge organizing systems local evolution.

On a related topic, we have developed a probabilistic framework, PARIS (Probabilistic Alignment of Relations, Instances and Schema), for matching ontologies holistically, thereby exploiting synergies between matches on the instance level and matches on the schema level [57]. The framework is parameter-free and does not require resource-specific tuning. PARIS is fully implemented and has been shown to match some of the largest ontologies on the Semantic Web with a precision of around 90%.

6.4.4. Integration of Web resources

We have pursued our work on integration of resources available on the Web in Adaptive Hypermedia Systems (AHS), allowing creators to define their own adaptation strategies based on their own domain models. The approach is based on a set of 22 adaptation patterns, independent of any application domain and independent of any adaptation engine, published in [59], [47]. These elementary adaptation patterns are organized in a typology in order to facilitate their understanding and their use in the EAP framework to define complex strategies. In [24], we described the whole process to generate complex adaptation strategies and how the generated strategies can be integrated into existing AHSs. The results of an experiment conducted in the e-learning domain is presented. It showed that the pattern-based approach for defining adaptation strategies is more suitable than those based on "traditional" AH languages.

We also pursued our work on the integration of the EAP framework and other AHSs. Our collaboration with A. Cristea from the University of Warwick (UK) led us to a very detailed study of adaptation languages. The first flexible generic adaptation language is the LAG adaptation language. We studied the expressivity of this initial adaptation language in comparison with our newly proposed language, in the EAP framework, and the pros and cons of various decisions in terms of the ideal way of defining an adaptation language. We proposed a unified vision of adaptation and adaptation language. The unified vision is not limited to the
two languages analyzed, and can be used to compare and extend other approaches in the future. Beside this theoretical qualitative study, we also made experimental evaluation and comparison of the two languages, and an article is currently being evaluated.

We have also investigated integration of Web services. The Search Computing project (“SeCo”) at the Polytechnic University of Milan aims to orchestrate Web services to answer user queries. Currently, the project represents Web services by so-called Service Marts. These are frame-like representations of the services, which follow the slot-value paradigm. This representation faces several challenges if more Web services get added to the system, because it is hard to ensure that Web services added by different users can still be joined. Therefore, we have explored a more ontological representation of Web services. In our proposal [55], Web services are represented as sub-graphs of an ontology. This allows users to add new Web services that re-use the vocabulary of existing Web services.

On related topics, together with researchers from the Max-Planck Institute in Saarbrucken, we have worked on extending the YAGO ontology. YAGO already contains dozens of millions of facts. With the present work, we aim to give these facts a temporal and a spatial dimension. For every event and every entity, we want to know where and when these objects existed. For this purpose, we have developed a methodology that extracts these types of facts from Wikipedia. We have also developed a logical reasoning framework that allows propagating these time and space annotations from some facts to others. This has grown YAGO to 80 million facts in total, making it an ontology that is anchored in time and space (Best demo award at the WWW 2011 conference [40]).

6.5. Reasoning over Distributed Systems

6.5.1. Distributed Diagnosis Problems

We pursued the work on distributed algorithms for diagnosing distributed systems. The general framework is consistency-based diagnosis for propositional-logic theories in a P2P setting with privacy constraints. It boils down to distributed implicant finding and is thus in some sense dual to the problem of consequence finding described in next paragraph. Vincent Armant is finishing his PhD and has extended his previous work on more general topics, i.e. focusing on the construction of a good decomposition of the network that will ensure an efficient reasoning mechanism. An important effort has been put in the design of a real-world sized experimentation on distributed systems.

Lina Ye defended her PhD on diagnosability analysis of distributed discrete-event systems, modeled as synchronized labeled automata. The aim of diagnosability is to ensure that a given partially observable system has the property that any fault (taken from a set of faults given a priori) will be detectable and identifiable without ambiguity in a finite time after its occurrence. Distributed diagnosability analysis is optimized by abstracting necessary and sufficient information from local objects to achieve global decision. After having addressed the distribution of the system’s model into local models, we focus in 2011 on the extension to systems where the observable information itself is distributed instead of centralized. Joint diagnosability definition has been provided and undecidability of deciding it has been proved in the general case where communication events are not observable, before proposing an algorithm to test its sufficient condition. In addition, decidability result and algorithm have been given when communications are observable.

Michel Batteux defended also his PhD (led in the framework of a CIFRE thesis with Sherpa Engineering) about diagnosability and diagnosis of technological systems. The work was led in the centralized case, focusing on defining, implementing, testing and validating on a real case study (a fuel cell system) an all-in-one tool to design a diagnosis system for technological systems by integrating representation of the system and its potential faults, off-line diagnosability analysis and automatic generation of the on-line embedded diagnoser.
6.5.2. Distributed Consequence Finding

A major reengineering of the SOMEWHERE platform, for decentralized consequence finding, has been initiated within the DISQUE project. Current efforts have focused on the rewriting of the communication layer, that now relies on the JXTA middleware. A new tool is also being developed, in order to facilitate large scale experimentations on a grid (Grid5000). This tool is designed in a fairly generic way, in order to be reusable for similar projects that require deploying sets of collaborating reasoners in a decentralized setting, and automating collaborative problem solving on various instances. We also expect this tool to be used for automating integration tests during further developments.

6.5.3. Towards distributed architectures for Modern SAT Solvers

If we aim at proposing a new architecture for distributed SAT Solvers, we pursued this year the improvements of Glucose, our centralized SAT solver. Glucose 2 won 3 medals at the SAT 2011 Competition, and one in the category Application SAT+UNSAT. We target to make a massively distributed version of Glucose, for very hard SAT problems.
6. New Results

6.1. Discrete logarithms

Participant: Andreas Enge.

In [10], we presented for the first time an algorithm for the discrete logarithm problem in certain algebraic curves that runs in subexponential time less than $L(1/2)$, namely, $L(1/3 + \varepsilon)$ for any $\varepsilon > 0$. In [13], we lower this complexity to $L(1/3)$, showing that the corresponding algebraic curves (essentially $C_{ab}$ curves of genus $g$ growing at least quadratically with the logarithmic size of the finite field of definition, $\log q$) result in cryptosystems that are as easily attacked as RSA or traditional cryptosystems based on discrete logarithms in finite fields. We provide a complete classification of all the curves to which the attack applies.

6.2. Class groups and other invariants of number fields

Participants: Jean-François Biasse, Jean-Paul Cerri, Pierre Lezowski.

J.-F. Biasse has determined a class of number fields for which the ideal class group, the regulator, and a system of fundamental units of the maximal order can be computed in subexponential time $L(1/3, O(1))$ (whereas the best previously known algorithms have complexity $L(1/2, O(1))$). This class of number fields is analogous to the class of curves described in [13], cf. ref sec:dlog. The article [18] has been submitted to Mathematics of Computation.

Using new theoretical ideas and his novel algorithmic approach, J.-P. Cerri has discovered examples of generalised Euclidean number fields and of 2-stage norm-Euclidean number fields in degree greater than 2 [11]. These notions, extending the link between usual Euclideanity and principality of the ring of integers of a number field had already received much attention before; however, examples were only known for quadratic fields.

P. Lezowski extended J.-P. Cerri’s algorithm, which was restricted to totally real number fields, to decide whether a generic number field is norm-Euclidean. His procedure allowed to find principal and non norm-Euclidean number fields of various signatures and degrees up to 8, but also to give further insight about the norm-Euclideanity of some cyclotomic fields. Besides, many new examples of generalised Euclidean and 2-stage Euclidean number fields were obtained. The article [25] has been submitted to Mathematics of Computation.

In another direction, norm-Euclidean ideal classes have been studied. They generalise the notion of norm-Euclideanity to non principal number fields. Very few such number fields were known before. A modification of the algorithm provided many new examples and allowed to complete the study of pure cubic fields equipped with a norm-Euclidean ideal class. The article [26] has been submitted to International Journal of Number Theory.

With E. Hallouin, J.-M. Couveignes has studied descent obstructions for varieties [21]. Such obstructions play an important role when one studies families of varieties (e.g. curves of a given genus). Obstructions are often measured by elements in groups like class groups. The theory of stacks provides a more general treatment for these obstructions. Couveignes and Hallouin give the first example of a global obstruction for a variety (that is an obstruction that vanishes locally at every place).

6.3. Number and function field enumeration

Participants: Henri Cohen, Anna Morra, Pieter Rozenhart.
In joint work with R. Scheidler and M. Jacobson, P. Rozenhart has generalized Belabas’s algorithm for tabulating cubic number fields to cubic function fields [30]. This generalization required function field analogues of the Davenport-Heilbronn Theorem and of the reduction theory of binary cubic and quadratic forms. As an additional application, they have modified the tabulation algorithm to compute 3-ranks of quadratic function fields by way of a generalisation of a theorem due to Hasse. The algorithm, whose complexity is quasi-linear in the number of reduced binary cubic forms up to some upper bound $X$, works very well in practice. A follow-up article [29] describes how to use these results to compute 3-ranks of quadratic function fields, in particular yielding examples of unusually high 3-rank.

H. Cohen and A. Morra [12] have obtained an explicit expression for the Dirichlet generating function associated to cubic extensions of an arbitrary number field with a fixed quadratic resolvent. As a corollary, they have proved refinements of Malle’s conjecture in this context.

6.4. Complex multiplication and modularity

Participants: Jean-Marc Couveignes, Andreas Enge, Damien Robert.

The book [16] edited by J.-M. Couveignes and B. Edixhoven, with contributions by J.-M. Couveignes, B. Edixhoven, R. de Jong, F. Merkl and J. Bosman, describes the first polynomial time algorithms for computing Galois representations and coefficients of modular forms. Modular forms are tremendously important in various areas of mathematics, from number theory and algebraic geometry to combinatorics and lattices. Their Fourier coefficients, with Ramanujan’s $\tau$-function as a typical example, have deep arithmetic significance. Prior to this book, the fastest known algorithms for computing these Fourier coefficients took exponential time, except in some special cases. The case of elliptic curves (Schoof’s algorithm) was at the birth of elliptic curve cryptography around 1985. This book gives an algorithm for computing coefficients of modular forms of level one in polynomial time. For example, Ramanujan’s $\tau$ of a prime number $p$ can be computed in time bounded by a fixed power of the logarithm of $p$. Such fast computation of Fourier coefficients is itself based on the main result of the book: the computation, in polynomial time, of Galois representations over finite fields attached to modular forms by the Langlands programme. Because these Galois representations typically have a nonsolvable image, this result is a major step forward from explicit class field theory, and it could be described as the start of the explicit Langlands programme.

The computation of the Galois representations uses their realisation, following Shimura and Deligne, in the torsion subgroup of Jacobian varieties of modular curves. The main challenge is then to perform the necessary computations in time polynomial in the dimension of these highly nonlinear algebraic varieties. Exact computations involving systems of polynomial equations in many variables take exponential time. This is avoided by numerical approximations with a precision that suffices to derive exact results from them. Bounds for the required precision – in other words, bounds for the height of the rational numbers that describe the Galois representation to be computed – are obtained from Arakelov theory. Two types of approximations are treated: one using complex uniformisation and another one using geometry over finite fields.

With F. Morain, A. Enge has determined exhaustively under which conditions “generalised Weber functions”, that is, simple quotients of $\eta$ functions of not necessarily prime transformation level and not necessarily of genus 1, yield class invariants [24]. The result is a new infinite family of generators for ring class fields, usable to determine complex multiplication curves. We examine in detail which lower powers of the functions are applicable, thus saving a factor of up to 12 in the size of the class polynomials, and describe the cases in which the polynomials have integral rational instead of integral quadratic coefficients.

With J.-C. Faugère and D. Lubicz, D. Robert has given an explicit construction for a modular correspondance between abelian varieties [14]. This correspondance describes the algebraic relations of ThetaNullWerte of different levels on isogenous abelian varieties. With R. Cosset, D. Robert has then given an algorithm explaining how to construct the corresponding isogeny, when we are given its (maximally isotropic) kernel [20]. This use a formula by Koizumi for changing the level of the ThetaNullWerte. This is the first algorithm allowing to compute in polynomial time an isogeny between abelian varieties, and a public implementation is available in AVISOGENIES.
With K. Lauter, D. Robert has worked on improving the computation of class polynomials in genus 2 by the CRT method. This involves some improvements to detect if the curve is maximal, a better sieving of the primes used, and the use of the CRT over the real quadratic field rather than over $\mathbb{Q}$ for the case of dihedral CM fields. The main improvements come from using the above isogeny computation, both in order to be able to find a maximal curve from a curve in the correct isogeny class, and in order to find all others maximal curves from one. A preprint describing these improvements is being written, some details are described in the talk http://www.normalesup.org/~robert/pro/publications/slides/2011-04-C2.pdf.

With Reynald Lercier, J.-M. Couveignes has given in [23] a quasi-linear time randomised algorithm that on input a finite field $\mathbb{F}_q$ with $q$ elements and a positive integer $d$ outputs a degree $d$ irreducible polynomial in $\mathbb{F}_q[x]$. The running time is $d^{1+o(1)} \times (\log q)^{5+o(1)}$ elementary operations. The $o(1)$ in $d^{1+o(1)}$ is a function of $d$ that tends to zero when $d$ tends to infinity. And the $o(1)$ in $(\log q)^{5+o(1)}$ is a function of $q$ that tends to zero when $q$ tends to infinity. The fastest previously known algorithm for this purpose was quadratic in the degree. The algorithm relies on the geometry of elliptic curves over finite fields (complex multiplication) and on a recent algorithm by Kedlaya and Umans for fast composition of polynomials.

6.5. Elliptic curve cryptology

Participants: Jean-Marc Couveignes, Vincent Verneuil.

In joint work with C. Clavier, B. Feix, G. Gagnerot and M. Roussellet, V. Verneuil has presented in [15] new side-channel analysis results on the AES. They propose improvements on collision-correlation attacks which require less power traces than classical second-order power analysis techniques. In particular, two new methods are presented and are shown to be efficient in practice on two first-order protected AES implementations. They also mention that other symmetric embedded algorithms can be targeted by these new techniques.

With the same coauthors, V. Verneuil has presented new exponentiation algorithms for embedded implementations in [19]. Embedded exponentiation techniques have become a key concern for security and efficiency in hardware devices using public key cryptography. An exponentiation is basically a sequence of multiplications and squarings, but this sequence may reveal exponent bits to an attacker on an unprotected implementation. Although this subject has been covered for years, they present new exponentiation algorithms based on trading multiplications for squarings. This method circumvents attacks aimed at distinguishing squarings from multiplications at a lower cost than other countermeasures. Finally, they present new algorithms using two parallel squaring blocks which provide one of the fastest exponentiation algorithms.

Together with D. Lubicz, D. Robert has extended their algorithm to compute pairings on abelian varieties using theta functions (published at ANTS 2010) to the case of the ate and optimal ate pairings. This involves a description of the Miller functions in term of theta coordinates and an extension of the addition law using more general Riemann relations in order to compute them. The case of theta functions of level 2 has been optimised by introducing a way to compute “compatible” additions without the need for a square roots. A preprint describing these results is being written, and some details can be found in the talk http://www.normalesup.org/~robert/pro/publications/slides/2011-06-Geocrypt.pdf.

With J.-G. Kammerer, J.-M. Couveignes has given in [22] an appropriate geometric method for studying and classifying encodings into elliptic curves in a cryptographic context. Such encodings were first proposed by Icart in 2009, and later on by Farashahi, Kammerer, Lercier, and Renault. But it was a little bit disappointing to see that it was no more than an application of Tartaglia’s result without any geometrical explanations for the existence of such “parameterisations” of elliptic curves. Couveignes and Kammerer have filled this gap by giving exactly what can be expected from geometry: a clear explanation. Moreover, they unify all the recent “parameterisations” of elliptic curves under the same geometric point of view. The approach described in this article uses dual curves with some results coming from intersection theory. The main originality of this work is that these geometrical tools are employed to explain symbolic computations used in cryptography, that is, encoding on elliptic curves.
LICT Exploratory Action

5. New Results

5.1. Liability issues in software engineering

Software contracts usually include strong liability limitations or even exemptions of the providers for damages caused by their products. This situation does not favour the development of high quality software because software editors do not have sufficient economic incentives to apply stringent development and verification methods. Indeed, experience shows that products tend to be of higher quality and more secure when the actors in position to influence their development are also the actors bearing the liability for their defects. The usual argument to justify this lack of liability is the fact that software products are too complex and versatile objects whose expected features (and potential defects) cannot be characterised precisely, and which thus cannot be treated as traditional (tangible) goods. Taking up this challenge is one of our objectives [12]: we study liability issues both from the legal and the technical points of view with the aim to put forward a formal framework to (1) define liability in a precise and unambiguous way and (2) establish such liability in case of incident.

Obviously, specifying all liabilities in a formal framework is neither possible nor desirable. Usually, the parties wish to express as precisely as possible certain aspects which are of prime importance for them and prefer to state other aspects less precisely (either because it is impossible to foresee at contracting time all the events that may occur or because they do not want to be bound by too precise commitments). Taking this requirement into account, we provide a set of tools and methods to be used on a need basis in the contract drafting process (as opposed to a monolithic, “all or nothing” approach). Our model is based on execution traces which are abstractions of the log files of the system. In a nutshell, liability is specified as a function taking as parameters a claim and an execution trace and returning a set of “responsible” actors. This set of actors (ideally a singleton) depends on the claim and the errors occurring in the trace. Both errors and claims are expressed as trace properties. The liability function can be made as precise or detailed as necessary by choosing the claims and errors relevant for a given situation [5].

In order to provide a more generic way to define liabilities, we have also introduced a concept of “logical causality” [11]. Causality has been studied for a long time in computer science, but with quite different perspectives and goals. In the distributed systems community, causality is seen essentially as a temporal property. We have defined several variants of logical causality allowing us to express the fact that an event $e_2$ (e.g. a failure) would not have occurred if another event $e_1$ had not occurred (“necessary causality”) or the fact that $e_2$ could not have been avoided as soon as $e_1$ had occurred (“sufficient causality”). We have applied these technical definitions of causality to real case studies and related them to the legal views of causality.

As far as legal issues are concerned, we have studied the legal validity of the technical solutions proposed in the project both in terms of legal evidence and allocation of liabilities [6]. Contract templates have been defined in collaboration with lawyers to allow the parties to effectively integrate our results in a legal contract [6].

5.2. Privacy

Despite apparently strong legal protections, many citizens feel that information technologies have invaded so much of their lives that they no longer have suitable guarantees about their privacy. As a matter of fact, many aspects of new information technologies render privacy protection difficult to put into practice. A lot of data communications already take place nowadays on the Internet without the users’ notice and the situation is going to get worse with the advent of “ambient intelligence” or “pervasive computing” [19]. One of the most challenging privacy issues in this context is to reconcile this continuous flow of data with privacy protection. One possible option to improve the situation when data has to be disclosed (or when it is practically impossible to object to its disclosure) is to enhance the obligations of the controllers and enforce more stringent rules on the use of personal data. We have followed this approach, considering both
• technical means to define and enforce obligations and
• possible evolutions of data protection regulations to avoid discriminations based on the use of personal data.

**Technical means: specification and a posteriori verification of obligations**

A major challenge for the formalization of privacy policies is the integration of deontic and temporal operators. Deontic operators are required because privacy policies are typically expressed in terms of obligations and interdictions. Temporal operators are necessary because obligations and interdictions usually come with deadlines: for example, the controller must inform the data subject before forwarding his data to a third party or must delete the data within a given period of time. On the theoretical side, the limitations of Standard Deontic Logic (SDL) have constantly been pointed out, almost since its introduction. However, no other unified mathematical formalization of this logic has been proposed so far. Instead, many specialized logics have been put forward, each aimed at addressing one particular issue. To adddress this challenge, we have proposed a language called FLAVOR (Formal Language for A posteriori Verification Of legal Rules) for the expression of privacy policies and, more generally, obligations to be fulfilled by organizations. Indeed, organizations have to comply with a growing number of legal rules stemming from law, regulations, corporate policies or contractual agreements. Generally speaking, the actions to be monitored can be checked either *a priori* or *a posteriori*. *A priori* checks are stronger in the sense that they make it possible to ensure that no breach will occur. However, they are too constraining, if not inapplicable, in many situations. Even when they could be implemented, *a priori* checks are not desirable in situations in which it could be legitimate to bypass the rules. For instance, it is necessary to provide emergency procedures to access personal health records when human lifes are at stake, even if the medical practitioner on duty does not have sufficient permissions. The essential features provided by FLAVOR are the possibility to express “contrary to duty” obligations (substitute obligations to be fulfilled in case of breach of the primary obligation), obligations with deadlines and contextual obligations. We have defined a strength ordering between obligations and illustrated the language with typical privacy policy rules [10]. We have also considered the delegation of obligations between actors in [8] and studied the impact of delegation on different types of responsibilities (causal, functional, legal).

**Legal means: privacy and non discrimination**

In order to address the new threats to individual rights that are made possible by the progress of information technologies, we have proposed to distinguish two very different types of data collection [9]:

1. The collection of data as part of formal procedures with clearly identified parties or in the course of clearly identified events, recognized as such by the subjects (e.g. when submitting a file, filling a questionnaire, using a smart card or providing one’s fingerprint to get access to a building).
2. The apparently insignificant and almost continuous collection of data that will become more and more common in the digital society (digital audit trails, audio and video recordings, etc.). This collection may be more or less perceived or suspected by the subject or remain completely invisible and unsuspected. Another worrying phenomenon is the automatic generation of new knowledge using data mining and knowledge inference techniques. In this kind of situation, the subject may ignore not only the process but also the generated knowledge itself, even if this knowledge is about him and could be used to take actions affecting him (e.g. not offering him a job or an insurance contract or adjusting the price of a service up to the level he would be prepared to pay).

The regulations on personal data protection were originally designed to address the first type of situation. Efforts are made to adapt them to the complex issues raised by the second type of data collection but they tend to be increasingly ineffective in these situations. The main cause of this ineffectiveness is their underlying philosophy of *a priori* and procedural controls. Starting from this observation, we have argued that a possible option is to strengthen *a posteriori* controls on the use of personal data and to ensure that the victims of data misuses can get compensations which are significant enough to represent a deterrence for data controllers. We have also argued that the consequences of such misuses of personal data often take the form of unfair discriminations and this trend is likely to increase with the generalization of the use of profiles. For this reason, we advocate the establishment of stronger connections between anti-discrimination and data protection laws,
in particular to ensure that any data processing resulting in unfair differences of treatments between individuals is prohibited and is subject to effective compensations and sanctions [9].
6. New Results

6.1. Modeling and estimation in biomechanics

6.1.1. Patient-Specific Electromechanical Models of the Heart for the Prediction of Pacing Acute Effects in CRT: a Preliminary Clinical Validation

In collaboration with Project-Team Asclepios from INRIA Sophia-Antipolis-Méditerranée and the Division of Imaging Sciences of St Thomas’ Hospital, King’s College London we demonstrated the benefits of using patient-specific electromechanical models of the heart for the prediction of pacing acute effects in CRT, see [5].

Cardiac resynchronisation therapy (CRT) is an effective treatment for patients with congestive heart failure and a wide QRS complex. However, up to 30% of patients are non-responders to therapy in terms of exercise capacity or left ventricular reverse remodelling. A number of controversies still remain surrounding patient selection, targeted lead implantation and optimisation of this important treatment. The development of biophysical models to predict the response to CRT represents a potential strategy to address these issues. We present how the personalisation of an electromechanical model of the myocardium can predict the acute haemodynamic changes associated with CRT. In order to introduce such an approach as a clinical application, we needed to design models that can be individualised from images and electrophysiological mapping of the left ventricle. We performed the personalisation of the anatomy, the electrophysiology, the kinematics and the mechanics. The acute effects of pacing on pressure development were predicted with the in silico model for several pacing conditions on two patients, achieving good agreement with invasive haemodynamic measurements: the mean error on dP/dtmax is $47.5 \pm 35$ mmHg.s$^{-1}$, less than 5% error.

6.1.2. Estimation of tissue contractility from cardiac MRI using a biomechanical heart model

Participants: Radomir Chabiniok, Dominique Chapelle, Alexandre Imperiale, Philippe Moireau.

In collaboration with P.-F. Lesault, A. Rahmouni and J.-F. Deux from Hospital H. Mondor, Créteil we proposed and assessed an estimation procedure – based on data assimilation principles – well-suited to obtain some regional values of key biophysical parameters in a beating heart model, using actual Cine-MR images, see [8], [1]. The motivation is twofold: (1) to provide an automatic tool for personalizing the characteristics of a cardiac model in order to achieve predictivity in patient-specific modeling, and (2) to obtain some useful information for diagnosis purposes in the estimated quantities themselves. In order to assess the global methodology we specifically devised an animal experiment in which a controlled infarct was produced and data acquired before and after infarction, with an estimation of regional tissue contractility – a key parameter directly affected by the pathology – performed for every measured stage. After performing a preliminary assessment of our proposed methodology using synthetic data, we then demonstrate a full-scale application by first estimating contractility values associated with 6 regions based on the AHA subdivision, before running a more detailed estimation using the actual AHA segments. The estimation results are assessed by comparison with the medical knowledge of the specific infarct, and with late enhancement MR images. We discuss their accuracy at the various subdivision levels, in the light of the inherent modeling limitations and of the intrinsic information contents featured in the data.

We are now working on improving these results by the use of Tagged-MRI, see [9]. The first approach consists in assuming that the image data is processed in the form of deforming tag planes, which we employ to obtain a discrepancy between the model and the data by computing distances to these surfaces. We assess our procedure using synthetic measurements produced with a model representing an infarcted heart as observed in an animal experiment, and the estimation results are found to be of superior accuracy compared to assimilation based on segmented endo- and epicardium surfaces. Then we extend this strategy to tagged lines instead of tagged planes or even directly with apparent displacements extracted from tagged images by optical flow methods.
6.1.3. Convergence of observers based on partial field measurements for the wave equation

**Participants:** Dominique Chapelle, Nicolae Cîndea, Maya de Buhan, Philippe Moireau.

We analyzed an observer strategy based on partial – i.e. in a subdomain – measurements of the solution of a wave equation, in order to compensate for unknown initial conditions, see [17], [18]. We proved the exponential convergence of this observer under a non-standard observability condition, whereas using measurements of the time-derivative of the solution would lead to a standard observability condition arising in stabilization and exact controllability. Nevertheless, we directly related our specific condition to the classical geometric control condition. This results justify in a linear framework the use of our observer-based filter in cardiac modeling.

6.1.4. Reduced nonlinear optimal filtering

**Participants:** Dominique Chapelle, Akos Matszangosz, Philippe Moireau.

We investigated some issues pertaining to reduced-order considerations in nonlinear optimal filtering. Classically, optimal filtering formulations lead to Hamilton-Jacobi-Bellman (HJB) equations posed in the complete “space of uncertainty”, namely, including the state space. This makes such methods generally untractable for PDE-based models. However, under certain assumptions pertaining to reduced uncertainties we can transform the HJB equations into a form posed in the reduced uncertainty space, and with only time derivatives involved. This form can be solved for – including with PDEs – provided this reduced space is of limited size, and then gives a reference “optimal” method to which other filtering procedures can be compared. The subject of Akos Matszangosz’ internship (from “Ecole des Mines de Paris”, duration 4 months) was to design and perform an adequate implementation of this reduced-order optimal filter, based on a sparse-grid discretization of the uncertainty space. In addition, we are currently working on discrete-time optimal filtering formulations, which are distinct – and preferable in principle – to discretizing the continuous forms.

6.2. Asymptotic and multiscale modeling

6.2.1. Modeling and simulation of multi-layers mechanical structures

**Participants:** Marina Vidrascu, Sofiene Hendili.

The collaboration with Françoise Krasucki (Montpellier University) and Giuseppe Geymonat (Ecole polytechnique) on the modeling of 3D materials connected by stiff interfaces continues within the Epsilon ANR project (Domain decomposition and multi-scale computations of singularities in mechanical structures 7.1.1). In the framework of matched asymptotic expansions we introduced a new effective and robust method to approximate the behavior of a structure containing a thin layer with periodically distributed heterogeneities (holes, rigid bodies...), see [3], [10], [11].

6.2.2. Multi-scale modeling and simulation of rubber

**Participants:** Maya de Buhan, Marina Vidrascu, Antoine Gloria [SIMPAF], François Lequeux [ESPCI], Patrick Le Tallec [Ecole Polytechnique].

In collaboration with A. Gloria (project-team SIMPAF) and P. Le Tallec (Ecole Polytechnique), we are currently working on a multiscale model for rubber based on the statistical physics description of a network of polymer chains. The numerical simulation of the model has been addressed within the ARC Disco using the Shelldon software. Comparisons with mechanical experiments are promising, and related inverse problems have been addressed in the post-doc of M. de Buhan. Two publications are in preparation.

This work is supported by the ARC DISCO (7.1.2).

6.3. Other topics

6.3.1. Numerical analysis of POD-based Galerkin approximations

**Participants:** Dominique Chapelle, Asven Gariah, Philippe Moireau, Jacques Sainte-Marie.
In [2], we proposed a numerical analysis of Proper Orthogonal Decomposition (POD) model reductions in which a priori error estimates are expressed in terms of the projection errors that are controlled in the construction of POD bases. These error estimates are derived for generic parabolic evolution PDEs, including with non-linear Lipschitz right-hand sides, and for wave-like equations. A specific projection continuity norm appears in the estimates and — whereas a general uniform continuity bound seems out of reach — we prove that such a bound holds in a variety of Galerkin bases choices. Furthermore, we directly numerically assess this bound — and the effectiveness of the POD approach altogether — for test problems of the type considered in the numerical analysis, and also for more complex equations. Namely, the numerical assessment includes a parabolic equation with super-linear reaction terms, inspired from the FitzHugh-Nagumo electrophysiology model, and a 3D biomechanical heart model. This shows that the effectiveness established for the simpler models is also achieved in the reduced-order simulation of these highly complex systems.

This work is now being continued in order to handle parameter-dependent models, and thence estimation problems.

6.3.2. Sail modeling

Participants: Dominique Chapelle, Daniele Trimarchi, Marina Vidrascu.

A dynamic Finite Element method – based on non-linear MITC shell finite elements implemented in the MITCNL software – has been proposed and assessed for the analysis of downwind sail-type structures, see [12]. The main purpose was here to investigate the development of wrinkling, a phenomenon commonly observed in practice for such structures. Considering the wrinkling in this type of analysis is of great interest, since wrinkling affects the stress distribution in the fabric. Further developments primarily regard various refinements of the model, in order to represent some even more realistic sail configurations such as with non-isotropic material models, corner reinforced zones, and cable boundary conditions. Of course, another very important perspective — and work in progress, indeed — concerns the use of such sail models coupled with the wind flow in a fluid-structure interaction framework.
6. New Results

6.1. Behavioral Fingerprinting

Participant: Olivier Festor [contact].

Device fingerprinting aims to automatically determine the types (name and version of software, brand name and series of hardware) of remote devices for a given protocol. Hence, keeping an up-to-date inventory database of devices in use on a network is possible and helpful as for example to check remotely if unauthorized applications have been installed. Some types of devices for which vulnerabilities are known can be easily detected in order to patch them or at least send alerts to the owners. From a security point of view, attackers use specific tools to perform their attack which may also be detected rapidly thanks to fingerprinting.

Most current systems rely only on signatures of differences in implementation of a given protocol stack and signatures are often outdated.

We have designed a new fingerprinting scheme that is accurate even on protocol stacks that are completely identical, but which run on hardware having different capabilities (CPU power, memory resources, etc). Our fingerprinting scheme can learn distinctive patterns in the state machine of a particular implementation. We see such a pattern as a restricted tree finite state machine that provides additional time-related information about the transitions performed [15]. The captured identification models were then used to automatically build attack prevention rules [19].

This work was done in cooperation with Jérôme Francois, Radu State and Thomas Engel from the University of Luxembourg.

6.2. Management and monitoring of P2P networks

Participants: Isabelle Chrisment [contact], Olivier Festor, Juan Pablo Timpanaro.

Content pollution is one of the major issues affecting P2P file sharing networks. However, since early studies on FastTrack and Overnet, no recent investigation has reported its impact on current P2P networks. In [21], we presented a method and the supporting architecture to quantify the pollution of contents in the KAD network. We first collected information on many popular files shared in this network. Then, we proposed a new way to detect content pollution by analyzing all filenames linked to a content with a metric based on the Tversky index and which gives very low error rates. By analyzing a large number of popular files, we showed that 2/3 of the contents are polluted, one part by index poisoning but the majority by a new, more dangerous, form of pollution that we call index falsification. This work was done, in collaboration with the University of Technology of Troyes, within the context of the ACDA-P2P3 Project funded by GIS-3SGS4.

BitTorrent is a widely deployed P2P file sharing protocol, extensively used to distribute digital content and software updates, among others. Recent actions against torrent and tracker repositories have fostered the move towards a fully distributed solution based on a distributed hash table to support both torrent search and tracker implementation. We conducted an analysis on one of the BitTorrent’s DHT (Mainline DHT) and developed a monitoring architecture, so as to measure and discover security flaws on the network. In [23] we compared KAD DHT against BitTorrent DHT in terms of security by deploying different attacks on the network. We showed that the lack of security in Mainline DHT allows very efficient attacks that can easily impact the operation of the whole network. We also provided a peer-ID distribution analysis of the network, so as to adapt previous protection schemes to the Mainline DHT. The mechanisms are assessed through large-scale experiments on the real DHT-based BitTorrent tracker.

3Apprnoch Collaborative pour la Détection d’Atttaques dans les réseaux Pair à Pair
4Groupement d’Intérêt Scientifique - Surveillance, Sureté et Sécurité des grands Systèmes
If BitTorrent’s Mainline DHT is exposed to several identified security issues, in parallel, the KAD DHT has been the core of intense research and was improved over years. We presented a study that motivates the integration of both worlds. We provided a performance comparison of both DHTs in terms of publishing efficiency. We investigated the security threats and showed that the current BitTorrent’s Mainline DHT is more vulnerable to attacks than KAD while the download service of BitTorrent has much better performance. Given the strengths and weaknesses of both DHTs, we designed a hybrid architecture [24], which is based on KAD’s indexation mechanism and BitTorrent download protocol. On the one hand, the client is able to index its files in the well-known KAD DHT, taking advantage of KAD’s security mechanism and its double-indexation scheme. On the other hand, the client uses the BitTorrent download protocol so as to download a given file, which has been proven to surpass KAD’s. We implemented this hybrid architecture, that we called hMule, as a unified KAD-BitTorrent file-sharing application, which is compatible with both P2P file sharing networks and provides the KAD advantages on indexation and the BitTorrent speed for transfer without losing backward compatibility.

We started our research about being anonymous when downloading from BitTorrent. We conducted a set of measurements from High Security Lab aiming to characterize the usage of the I2P network, a low-latency anonymous network based on garlic routing [35]. Our goal was to answer the following questions: what is the network used for? when is it used the most? which kind of applications the network designers should pay more attention to? We designed a distributed monitoring architecture for the I2P network and we showed that, through three one-week long experiments, we were able to identify 32% of all running applications, among web servers and file-sharing clients. Additionally, we identified 37% of published I2P applications, which turned out to be unreachable after their publication on the I2P distributed database.

In parallel, we built-up a model of I2P encryption/decryption approach and using the Avispa tool, we able to find a possible attack on the network. Further work will be focused on probing right and on developing a proof-of-concept of this.

### 6.3. Configuration security automation

**Participants:** Rémi Badonnel [contact], Martin Barrere, Olivier Festor.

The main research challenge addressed in this work has focused on enabling configuration security automation in autonomic networks and services. In particular our objective has been to increase vulnerability awareness in the autonomic management plane in order to prevent configuration vulnerabilities. The continuous growth of networking significantly increases the complexity of management. It requires autonomic networks and services, which are capable of taking in charge their own management by optimizing their parameters, adapting their configurations and ensuring their protection against security attacks. However, the operations and changes they execute during these management activities may generate vulnerable configurations. A first part of our work has therefore consisted in consolidating a security automation strategy for preventing vulnerabilities and maintaining safe configurations in autonomic infrastructures [7]. This solution relies on the integration of configuration vulnerability descriptions into the management plane [8]. The OVAL language, part of the SCAP protocol, has become the de-facto standard for specifying configuration vulnerabilities in a technical viewpoint. We have refined a mathematical modeling for mapping OVAL descriptions into policy rules which can be interpreted by the autonomic Cfengine configuration system. These policies enable the Cfengine system to assess and detect vulnerabilities. We have designed a functional architecture and formalized a translation algorithm for supporting this security automation. We have also prototyped an OVAL-to-Cfengine translation module, called Ovalyzer, and analyzed its interactions with the components of the Cfengine system. Based on vulnerability descriptions extracted from the official OVAL repository, we have performed an extensive set of experiments to quantify the performance and coverage of the Ovalyzer module. A second part of our work has consisted in investigating how our security automation solution can be extended to distributed configuration vulnerabilities. In SCAP-based traditional approaches, a distributed vulnerability is typically understood as the aggregation of individual configuration vulnerabilities which are spread in the network and might allow a multi-step attack. We have shown through the analysis of a case study that this definition does not offer a complete outlook of the problem. In particular, each network device can individually present a secure
configuration, but when combined across the network, a global vulnerable configuration may be produced. In that context, we have introduced in [27] a mathematical definition for distributed vulnerabilities and have specified the DOVAL language (Distributed OVAL), on top of OVAL, as a means for describing these vulnerabilities in a machine readable manner. A case study in the area of VoIP networks and services has been considered for demonstrating the instantiation of DOVAL main constructs. The DOVAL descriptions constitute useful security definitions that in turn can be exploited for security automation. We have built a framework for supporting these distributed configuration vulnerabilities based on the Cfengine system. In particular, we have proposed and evaluated collaborative strategies and optimized algorithms for performing the assessment of DOVAL descriptions.

6.4. Online Risk Management

Participants: Rémi Badonnel [contact], Oussema Dabbebi, Olivier Festor.

Telephony over IP has known a large scale deployment and has been supported by the standardization of dedicated signaling protocols. This service is however exposed to multiple attacks due to a lower confinement in comparison to traditional PSTN networks. While a large variety of methods and techniques has been proposed for protecting VoIP networks, their activation may seriously impact on the quality of such a critical service. Risk management provides new opportunities for addressing this challenge. In particular, our work aims at performing online risk management for VoIP networks and services. The purpose is to adapt the service exposure with respect to the threat potentiality, while maintaining a low security overhead. Based on the classification of VoIP attacks and the analysis of their properties, we have refined in [11] an extended risk modeling for IP telephony infrastructures. This modeling permits to cover a large spectrum of security attacks. It supports our online risk management strategy which is capable of dynamically activating or deactivating security safeguards in the VoIP infrastructure. The mitigation is based on the control of the service exposure using these safeguards. We have compared our solution to other traditional strategies, and have quantified the benefits and limits according to multiple performance criteria. We have also analyzed the impact of the risk model parameters on our mitigation, and showed to what extent the parameterization can be partially automated in [12]. An important part of our efforts has focused in the year 2011 on extending our online risk management strategy to more distributed configurations [32]. While our initial work was centered around Asterisk-based enterprise networks, we have taken a particular interest in P2PSIP networks. They constitute an open decentralized solution where the registration and location servers are implemented by a distributed hash table responsible for storing the bindings between the address-of-record SIP-URI and the contact SIP-URI. We have identified different attack sources and attack scenarios in these P2PSIP networks, considering the functional roles that are played by the SIP peers. The security threats are specific to the P2PSIP protocol or are the result of inheritance from the SIP layer and the peer-to-peer area. In that context, we have analyzed the instantiation of our online risk modeling by taking into account the properties and components of the P2PSIP architecture, and have established a portfolio of dedicated countermeasures, including replication-based and certification-based techniques. We have evaluated the strategy performance and scalability through an extensive set of experiments performed with the OMNET++ simulator. We also have quantified the complementarity of our solution with the RELOAD security framework which relies on a central certificate enrolment server.

6.5. VoIP Security

Participants: Laurent Andrey, Olivier Festor, Abdelkader Lahmadi [contact].

In previous work, we have proposed the prevention system SecSIP [5] for SIP-based networks which uses a rule-based approach to build prevention specifications on SIP protocol activities that stop attacks exploiting an existing vulnerability before reaching their targets. We have pursued our efforts in VoIP security which led to two new contributions:

- Building and maintaining prevention rules using the Veto language can become a time consuming and error prone task, especially when addressing an important number of vulnerabilities discovered
using a fuzzing tool. The discovered vulnerabilities using such process are usually based on a single
exploit message with a malformed field or sequence of vulnerable messages. To reduce this effort,
we have designed a generation method to produce VeTo specifications targeting those vulnerable
messages. The method mainly characterizes a malformed field within an exploit message or the
vulnerable sequence of messages and generates a set of VeTo rules specifications to prevent their
exploit. The generated VeTo rules are then deployed and maintained on the SecSIP engine to be
applied against the SIP traffic. The solution [19] relies on generating rules using genetic algorithms
operating on a a set of candidate regular expressions to match a malformed pattern within a SIP
message, and evaluate their quality using a well defined fitness function to ensure that their are
specific enough to only match exploit messages.

- SecSIP uses a plain text configuration file in which VeTo specifications are authored and managed
manually. While extending the deployment of the framework beyond our own lab, support for remote
configuration was required. Given the promise of Netconf, we naturally turned our investigations
towards this protocol and embraced the YANG data-modeling framework. In [20] we have presented
the Yang model built for VeTo policies and the Netconf framework put in place.

We have developed a flexible SIP honeypot. It is flexible in the sense that a behavior can be externally
and easily defined. The goal of such a honeypot is to be able to be quickly customized in response to an
observation made on a more generic and large scale honeypot. If the initial observation is likely to be an attack
the customized honeypot would eventually get deeper and more informative interactions with the attacker.
The realization is a module of the Dionaea general framework for honeypot (successor of the well-known
nepenthes framework) and we use the SIPP test tool as an engine to animate SIP interactions provided as
automata in some XML file. More detail on the implementation can be found in [26].

6.6. VoIP Fraud

Participants: Olivier Festor [Contact], Mohamed Nassar.

In the context of a cooperation with the University of Liege, we have addressed the problem of SPIT from
a new perspective [22]. Based on end-user feedback, we have proposed a scheme for generating SPIT
signatures from the SIP INVITE messages. Hence it is possible to filter the next SPIT calls before ringing
their destinations. The generated SPIT signatures are adaptive to the benign signaling traffic in the sense that
they do not conflict with it. The generation of signatures is based on supervised machine learning techniques.
We namely investigated decision trees with categorical at-tributes obtained by parsing the SIP messages.

Our system works in two modes: a batch and an online mode. The batch mode consists on training the decision
tree over a labeled (spit, normal) data-set and then trans- forming the tree into an if-else rule-set. In online
mode, the successive learnt signatures are aggregated and the possible conflicts are resolved. Experimenta-
tion on off-the-shelf SPIT tools showed the efficiency of our approach to find the good signatures. However,
experiments show that the J48 decision tree is easily defeated using some obfuscation techniques. We therefore
proposed a generalisation approach to translate the tree into an if-else rule-set shows instead good robust-
ness against such attacks. The overall framework provides suitable performance for operational deployment
in terms of learning time, required memory, size of the rule-set and the call setup delay. The different
parameters of the system (i.e. size of the different buffers and windows) are easily configurable. Different SPIT
signatures may imply different SPIT capabilities. For example, a spitter may break a Captcha test by brute-
forcing a DTMF guess. Another spitter may start talking by a human-like congratulation in order to bypass a
Turing test. One of the goals of our approach is to provide a framework for applying reinforcement learning
techniques and hence increasing the efficiency of the filtering process. The reinforcement learning aims at
selecting the best challenge to be used when a given SPIT signature is detected. Basically the re-inforcement
learning maintains a table matching each signature with the best challenge response discovered so far. The
table is continuously updated using a trial and error scheme.

We did validate the approach on multiple data-sets obtained from Voice over IP operators members of the
SCAMSTOP project.
6.7. Pervasive computing

Participants: Laurent Ciarletta [contact], Tom Leclerc, Julien Siebert, Olivier Fester, André Schaff.

Vincent Chevrier (MAIA Team)

In Pervasive or Ubiquitous Computing, a growing number of communicating/computing devices are collaborating to provide users with enhanced and ubiquitous services in a seamless way. Madynes is focusing on the networking aspects of ubiquitous systems. We cooperate with the Maia (and Trio) team(s) to be able to encompass issues and research questions that combine both networking and cognitive aspects.

Pervasive Computing is about interconnected and situated computing resources providing users with contextual services. These systems, embedded in the fabric of our daily lives, are complex: numerous interconnected and heterogeneous entities are exhibiting a global behavior impossible to forecast by merely observing individual properties. Firstly, users physical interactions and behaviors have to be considered. They are influenced and influence the environment. Secondly, the potential multiplicity and heterogeneity of devices, services, communication protocols, and the constant mobility and reorganization also need to be addressed. Our research on this field as detailed in [10] is going towards both closing the loop between humans and systems and taming the complexity, using multi-modeling (to combine the best of each domain specific model) and co-simulation (to design, develop and evaluate) as part of a global conceptual and practical toolbox.

In 2011 we worked on the following research topics:

- Multi-models of these Pervasive Computing environments (including the users in the modeling and the simulations). We have been focusing on the collaborative simulations of dynamic networks/elements, namely P2P and adhoc networks using agents to drive those simulations. This work is done in collaboration with the MAIA team. The results have been extensively described in the PhD thesis of Julien Siebert [3].

- Study of service discovery protocols, contextual metrics in adhoc networks, and Service Discovery in adhoc networks using an hybrid model between cluster-like (WCPD) and MPR-based (OLSR) broadcasting. The results have been extensively described in the PhD thesis (Contributions for Advanced Service Discovery in Ad hoc Networks) of Tom Leclerc [2]. In this thesis, we consider service discovery in MANETs, that are a collection of devices that communicate with each other over a wireless medium. Such networks are formed spontaneously whenever devices are in transmission range without any preexisting infrastructure. The main characteristic of MANETs is the high dynamics of nodes (induced by the users moving around), the volatile wireless transmissions, the user behavior, the services and their usage. We’ve proposed a complete solution for service discovery in ad hoc networks, from the underlying network up to the service discovery itself. A first contribution, is the Stable Linked Structure Flooding (SLSF) protocol that creates stable based cluster structure and thereby provides scalable and efficient message dissemination. The second contribution is the Stable Linked Structure Routing (SLSR) protocol that uses the SLSF dissemination structure to enable routing capabilities. Using those protocols as basis, we propose to improve service discovery by additionally considering context awareness and adaptation.

- Context awareness and mobility/usage models

We contributed on improving simulations by coupling simulators and models that, together, can model and simulate the variety and richness of ad hoc related usage scenarios and their human characteristic. A guideline for all of our contributions was to be able to integrate and/or consider context and context awareness in both the proposed protocols and the related research tools and models. On one hand, The proposed protocols all have the capacity to adapt their efforts according to certain metrics, that represent the context. The simulator coupling architecture, on the other hand, permits to model and design scenarios in which the context, such as the service usages or the human behavior, has an impact and matters.

- Energy-constraint geolocalization, addressing, routing and management of wireless devices: a research collaboration with Fireflies RTLS was started in March 2009 and is ongoing. The initial work
has been extended in a joint work with the TRIO Team and leads towards finding a global energy-cost function, and life expectancy of the wireless sensor system.

In the future work, we plan to apply those results to Cyber Physical Systems, within the Aetournos (Airborne Embedded auTonomOUs Robust Network of Objects and Sensors) platform at Loria. We aim at developing cross-layer solutions to robust routing between flying drones.

We are also working inside a CPER project towards management solutions of wireless network sensors (project ECOSUR) used to control Smart Spaces.

6.8. Co-Simulation and multi-modeling

Participants: Laurent Ciarletta [contact], Julien Siebert, Tom Leclerc.

Vincent Chevrier (MAIA team, LORIA) and Tomas Navarette are external collaborators.

Participants: Laurent Ciarletta [contact], Julien Siebert.

Vincent Chevrier (MAIA team, LORIA) is an external collaborator.

This work has been extensively detailed in Julien Siebert’s PhD thesis [3] and partially in Tom Leclerc’s, with an application to ubiquitous adhoc networks and services.

This work has been done between the fields of ubiquitous networks and multi-agent based simulation. The main context is to study mutual influences existing between ubiquitous network performances and their users behaviours. We have highlighted the need for reusing and coupling modelling and simulation softwares together in order to simultaneously integrate several abstraction levels in the study. We target those needs by a multiagent approach and we propose a metamodel: AA4MM. The core idea in AA4MM is to build a society of models, simulators and simulation softwares that solves the core challenges of multimodelling and simulation coupling in an homogeneous perspective. AA4MM major contributions are the possibility to easily reuse, to make interoperable and modular existing heterogeneous models and softwares, to manage scale changes and a simulation algorithm fully decentralized. We apply this metamodel to the field of ubiquitous networks in order to target the question of mutual influences between networks performances and users behaviours.

6.8.2. Adaptive control of a complex system based on its multi-agent model

Participants: Laurent Ciarletta [contact], Julien Siebert.

Vincent Chevrier (MAIA team, LORIA) and Tomas Navarette are external collaborators and main investigators of this theme.

As a starting point, we are exploring how the behavior and other factors such as spatial and temporal dimensions are mutually influencing and the impact of parameters variability of our models in environment where collective behaviors can emerge [6]. We did comparison of five different models. These models are built upon the same individual behavior hypothesis of a collective phenomenon present in peer-to-peer file exchange networks: "free-riding". We studied a global analytical model and four multi-agent models. Multi-agent models include the space and time dimensions rarely seen in the literature discussing aggregated models of the collective phenomenon in question. We have demonstrated that one individual decision algorithm can lead to contradictory information.

Using these results, we want to build a control mechanism for a complex/dynamic system. Specifically, we want to evaluate the effectiveness of creating a control mechanism based on a multi-agent model of the system.

Multi-agent models can be adapted to that purpose since usual approaches using analytical models as a basis can be intractable when dealing with such systems; and if we consider that the available control actions are meant to be applied locally, a multi-agent model is necessary. We are currently working on a case study within the dynamic networks domain, namely the free-riding phenomenon present in peer-to-peer networks.
We propose an architecture that gathers information from the system and uses it to parametrize and tune a set of multi-agent models. The outcome of simulations is used to decide which control actions have to be applied to the system, in order to achieve a predefined control objective. We consider that we do not have complete information to characterize the state of the system.

6.9. Sensor networks management

Participants: Cyril Auburtin, Alexandre Boeglin, Olivier Festor, Abdelkader Lahmadi, Emmanuel Nataf [contact].

6LowPAN networks denotes many embedded devices interconnected by a variety of links ranging from wireless technologies such as 802.15.4, bluetooth, Low Power Wifi to wired technologies such as low power PLC. The common property of such networks is the limited resources of their nodes in terms of power, computing, memory and communication. The network could be described with thousands of devices with very limited internal and external resources and their communication channels are low-bandwidth, high loss rate and volatile links subject to failure over time. These networks rely on the 6LowPAN protocol defined by the IETF as an adaptation layer for the IPv6 protocol to address their low power and lossy properties.

During the year 2011, we have started a research activity around the monitoring and security assessment of 6LowPAN networks. Our contributions are mainly as follows:

- We are developing a novel approach to assign monitoring roles in 6LowPAN networks using available local information provided by the routing layer. The resulting monitoring architecture is adaptive taking benefit from the reactivity of the routing protocol when dynamic changes occur due to connectivity or nodes mobility. Our first simulations results reveal that our assignment approach is more efficient, less aggressive and less resources consuming than its competitors.

- We have also designed and implemented a piggybacking technique to deliver monitoring report into existing packets traveling through 6LowPAN networks. In our solution, we have extended the IPv6 Hop-by-Hop extension header with a new option which contains status data of monitored nodes. This technique can reduce the number of packets and bytes sent across the network since there is no specific monitoring packets competing with existing traffic. Monitoring data shares the routing path of application data packets until it reaches a management node. We have applied our piggybacking technique to discover coap-enabled management agents. Each agent in the deployed wireless sensor network piggybacks its identifier into the RPL routing protocol messages until it reaches a manager node.

- Regarding security management of these networks, we have developed a stateless fuzzing tool for the 6LowPAN protocol [28]. The tool is build upon the Scapy packets manipulation library. It provides different mutation algorithms to be applied on 6LowPAN messages. These messages are defined by interaction scenarios described in an XML format.

- Related also to security, we have modelled an ontology for intrusion detection system in sensor networks [17]. The model exposes family of intrusions depending on their objectives. The service provided by the network, the communication channels and the security mechanisms are the main classes of the model.

6.10. High Security Lab

Participants: Alexandre Boeglin [contact], Olivier Festor, Mohamed Nassar.

The objective of the High Security Lab at INRIA Nancy Grant Est is to provide both the infrastructure and the legal envelope to researchers to perform sensitive security oriented experimentations. We do contribute to this laboratory by (1) designing and operating a large network telescope and (2) performing vulnerability assessment research, network data and malware collection and analysis.
During the year 2011, some maintenance tasks have been carried out on the High Security lab:

- the SDSL line, which previously had a capacity of 1Mbps, has been upgraded to a 2Mbps line, and traffic shaping rules have been added to the router, that allow honeypots to run alongside experiments, without impacting them,
- the storage capacity of our database server, which was starting to get full, has been multiplied by four, and existing data has been migrated to the new equipment.

A set of new experiments have also been deployed:

- a server has been dedicated to a new variant of SGNet, for the VAMPIRE project. This one specifically targets attacks on SIP services, which the other one cannot do,
- in collaboration with the INRIA Nancy Grant Est IT service, we started to log public (thus anonymous) DNS queries and responses made by the research center’s recursive DNS servers, to use the collected data as input set for experiments.

In 2011 we worked also on the automated analysis of malware traces to extract flow-level signatures of malware. We obtained early results regarding network flow-graphs and tested several clustering techniques to separate malware traffic.

6.11. Sensas

Participants: Cyril Auburtin, Alexandre Boeglin [contact], Olivier Festor.

The goal of the SensAS ADT, which started in 2011, is to propose applications based on wireless sensor networks, building upon work that has been done through the SensLab and SensTools projects.

The Madynes team is responsible of the SensMGT part of the SensAS project, which focuses on sensor network management and configuration applications.

First, we adapted the existing contiki-snmp implementation to the SensLab WSN430 nodes. We did so by (1) reducing the memory footprint of the code and (2) by implementing several SNMP MIBs.

To reduce the memory footprint, we had to disable some optional features and unused drivers of the Contiki OS.

The MIBs that we chose to implement were:

- the SNMPv2-MIB that provides generic system information,
- the IF-MIB that provides information and statistics about the network interface of the sensor,
- and the ENTITY-SENSOR-MIB, that provides access to the actual sensors data.

Then, we were facing a problem, as the Contiki versions provided by the SensTools project were only stable releases, and we found it difficult to track the development version of Contiki with them. We then decided to create our own WSN430 drivers and platform definition for Contiki, well integrated with the development repository, and reusing as much as possible of already existing code. Our next step in this direction will be to have our contribution officially integrated in the Contiki OS.

And finally, we devised and implemented a COAP server discovery protocol using the piggybacking technique, which allows every node that offers COAP resources to announce itself to the grounded root of the sensor network, without requiring the transmission of additional packets.
MAESTRO Project-Team

5. New Results

5.1. IP networks

Participants: Eitan Altman, Konstantin Avrachenkov.

5.1.1. Interdisciplinary study of the Internet access and of network neutrality

In our previous research we have identified large inefficiencies that occur when one allows one type of provider (e.g. access provider) to impose costs on another type of provider (e.g. content provider). This part in which E. Altman collaborated with P. Bernhard (INRIA project-team BIOCORE), S. Caron and G. Kesidis (both from Pennsylvania State Univ., USA), J. Rojas-Mora (Univ. of Barcelona, Spain), and S. Wong (Univ. of A Coruña, Spain) has now appeared in [96].

This investigation has been pursued in various directions. In [42], E. Altman, A. Legout (INRIA project-team PLANETE) and Y. Xu (Univ. Avignon/LIA) have studied a hierarchical structure of ISPs, the economic impact of some cashing placement policies, and more complex demand functions (the demands of users for content). In [33], E. Altman and the law specialist S. Wong (Univ. of A Coruña, Spain) analyze in cooperation with the economist J. Rojas-Mora (Univ. of Barcelona, Spain) the impact of legislation related to network neutrality on the quality of service for the end users.

5.1.2. Adaptive monitoring system for IP networks

The remarkable growth of the Internet infrastructure and the increasing heterogeneity of applications and users’ behavior make more complex the manageability and monitoring of ISP networks and raises the cost of any new deployment. The main consequence of this trend is an inherent disagreement between existing monitoring solutions and the increasing needs of management applications. In this context, in [62] K. Avrachenkov, I. Lassoued, A. Krifa and C. Barakat (all three from INRIA project-team PLANETE) present the design of an adaptive centralized architecture that provides visibility over the entire network through a network-wide cognitive monitoring system. Practically, given a measurement task and a constraint on the volume of collected information, the proposed architecture drives the sampling rates on the interface of network routers to achieve the maximum possible accuracy, while adapting itself to any change in network traffic conditions. The authors tune the system parameters with the help of FAST sensitivity test.

5.1.3. Size based scheduling

Size-based scheduling is a promising solution to improve the response time of small flows (mice) that have to share bandwidth with large flows (elephants). To do this, one important task is to track the size of the ongoing flows at the router. However, most of the proposed size-based schedulers either employ the trivial way of tracking the size information of all flows, or require changes at end-hosts. Hence, either they are not scalable or they increase complexity. In [55], E. Altman, D. Mon Divakaran (IIT Mandi, India) and P. Vicat-Blanc Primet (Lyatiss, France) have proposed a new way of performing size-based scheduling in a practical and scalable fashion, by identifying and ‘de-prioritizing’ elephants only at times of high load. They exploit TCP’s behavior by using a mechanism that detects a window of packets - called spikes - when the buffer length exceeds a certain threshold. This spike-detection is used to identify elephant flows and thereafter de-prioritize them. Two-level processor-sharing (TLPS) scheduling is employed to schedule flows in two queues, one with the high-priority flows, and the other with the de-prioritized flows. They show that the proposed mechanism not only improves the response time of mice flows in a scalable way, but also gives better response times to other flows by treating them preferentially as long as they do not overload the high-priority queue.
5.1.4. Accuracy of fluid models for bandwidth-sharing networks

Optimal control of stochastic bandwidth-sharing networks is typically difficult. In order to facilitate the analysis, deterministic analogues of stochastic bandwidth-sharing networks, the so-called fluid models, are often chosen for analysis, as their optimal control can be found more easily. The tracking policy translates the fluid optimal control policy back into a control policy for the stochastic model, so that the fluid optimality can be achieved asymptotically when the stochastic model is scaled properly. In [20] K. Avrachenkov, A. Piunovsky and Y. Zhang (both from the University of Liverpool, UK) study the efficiency of the tracking policy, that is, how fast the fluid optimality can be achieved in the stochastic model with respect to the scaling parameter. In particular, the result of [20] shows that, under certain conditions, the tracking policy can be as efficient as feedback policies.

5.1.5. Bootstrap method for simulating bandwidth sharing

In [71], E. Altman, T. Jimenez and J. Rojas-Mora (both from Univ. Avignon/LIA) identify difficulties in evaluating through simulations the expected transfer time of a file when several TCP connections share a common bottleneck buffer. The main difficulties are due to the fact that the file size over the Internet has been reported to have a Pareto distribution with parameter smaller than 1.5. This implies that the number of ongoing connections as well as the sojourn times have infinite variance. This has two implications: one cannot estimate the confidence intervals for simulation based on the CLT (central Limit Theory approach), and the duration of the simulations needed to get to steady state is very long. The authors show how to solve both problems by the use of the bootstrap approach.

5.2. Wireless communications

Participants: Sara Alouf, Eitan Altman, Konstantin Avrachenkov, Nicaise Choungmo Fofack, Mahmoud El Chamie, Majed Haddad, Manjesh Kumar Hanawal, Philippe Nain, Giovanni Neglia, Manoj Panda, Sreenath Ramanath.

5.2.1. Green networking

Green networking is a new trend in network design that is more aware of the impact of technology on the environment and on humans. Reducing energy has been so far the main concern in that approach, and much of the research has been devoted to understanding the tradeoffs between reducing energy and other performance measures such as coverage and delay.

For several years we have been contributing to this research effort, many of which have been summarized in the survey [67] by E. Altman in collaboration with G. S. Paschos (Center for Research and Technology, Hellas, Greece), P. Mannensal (VTT, Finland), S. Stanczak (HH-Fraunchofer, Berlin, Germany) and L. Tassiulas (Univ. of Thessaly, Greece). In particular, much of the work involving members of MAESTRO that had appeared in previous years in conferences concerning energy saving in WiMax has now appeared in a journal publication [21] by A. P. Azad, S. Alouf, E. Altman, in cooperation with V. Borkar (TATA Inst. of Fundamental Research, Mumbai, India) and G. S. Paschos (Center for Research and Technology, Hellas, Greece).

In 2011 we started investigating policies for switching off base stations using two new tools: multimodularity and stochastic geometry. The latter has been used by E. Altman and M. K. Hanawal (also with Univ. Avignon/LIA), in cooperation with R. El-Azouzi (Univ. Avignon/LIA) and S. Shamai (Technion, Israel) in [98] to study the tradeoffs related to the uplink, and by E. Altman in cooperation with C. Hasan and J. M. Gorce (both from INSA-Lyon and INRIA project-team SWING) in [89] for the downlink. Optimal policies were obtained within the class of policies that switch off base stations with some fixed probability but independently of each other. To relax this restriction of independence and thus obtain even better policies, S. Ramanath and E. Altman, in collaboration with V. Kavitha (Univ. Avignon/LIA), have used in [69] the theory of multimodularity, which is the discrete counterpart of convexity. Among the most striking points in this research has been the observation in [98] that the conventional energy saving approach can have the opposite effect on the humans in the uplink: when the base station closest to a mobile phone is switched off (for energy
saving) then the mobile phone has to transmit with a larger power so as to reach a more remote base station. It turns out that the main source of radiation to the human brain is indeed the uplink transmission, which implies that switching off base stations could cause more exposure to radiation. This is of particular concern in view of the announcement by the World Health Organization (May 31, 2011) that cell phones cause cancer.

5.2.2. Cellular networks with continuous connectivity

In [65], S. Alouf and V. Mancuso (Institute IMDEA Networks, Madrid, Spain) analyze the power save and its impact on web traffic performance when customers adopt the continuous connectivity paradigm. Considering realistic http traffic, they evaluate the user access delay, the download time and the expected economy of energy in the cell. The model, validated through packet-level simulations, shows that dramatic energy save can be achieved by both mobile users and base stations. In case of Poisson arrivals, the aggregate behavior of a base station’s users is studied by means of a processor-shared queueing system [105]. The model can be used to maximize the base station energy savings under a given set of QoS performance constraints. With the participation of N. Choungmo Fofack, the work in [65] has been complemented with a sensitivity analysis [95]. The impact of model parameters on the performance and cost metrics is thoroughly assessed.

5.2.3. Power allocation in multicell networks

Power allocation to satisfy user demands in the presence of large number of interferers in a multicellular network is a challenging task. Further, power to be allocated depends upon the system architecture, for example, upon components like coding, modulation, transmit precoder, rate allocation algorithms, available knowledge of the interfering channels, etc. This calls for an algorithm via which each base station in the network can simultaneously allocate power to their respective users so as to meet their demands (when they are within the achievable limits), using whatever information regarding the other users is available. In [70], S. Ramanath, V. Kavitha (Univ. Avignon/LIA) and M. Debbah (SUPELEC) devise such an algorithm which is in fact universal: the proposed algorithm works from a fully cooperative setting to almost no cooperation and for any configuration of modulation, rate allocation, etc. schemes. The algorithm asymptotically satisfies the user demands, running simultaneously and independently within a given total power budget at each base station. Further, it requires minimal information to achieve this: every base station needs to know its own users demands, its total power constraint and the transmission rates allocated to its users in every time slot. The authors formulate the power allocation problem in a system specific game theoretic setting, define system specific capacity region and analyze the proposed algorithm using ordinary differential equation (ODE) framework. Simulations confirm the effectiveness of the proposed algorithm.

5.2.4. Small cell networks

In [28], S. Ramanath and E. Altman, in collaboration with V. Kavitha (Univ. Avignon/LIA), characterize the performance of Picocell networks in the presence of moving users. They model various traffic types between base-stations and mobiles as different types of queues. They derive explicit expressions for the expected waiting time, service time and drop/block probabilities for both fixed and random velocity of mobiles. They obtain (approximate) closed-form expressions for optimal cell size when the velocity variations of the mobiles is small for both non-elastic and elastic traffic. They conclude from the study that, if the expected call duration is long enough, the optimal cell size depends mainly on the velocity profile of the mobiles, its mean and variance. It is independent of the traffic type or duration of the calls. Further, for any fixed power of transmission, there exists a maximum velocity beyond which successful communication is not possible. This maximum possible velocity increases with the power of transmission. Also, for any given power, the optimal cell size increases when either the mean or the variance of the mobile velocity increases.

5.2.5. New concepts in fair resource allocation

Fair resource allocation is usually studied in a static context, in which a fixed amount of resources is to be shared. In dynamic resource allocation one usually tries to assign resources instantaneously so that the average share of each user is split fairly. The exact definition of the average share may depend on the application, as different applications may require averaging over different time periods or time scales. Our main contribution is to introduce new refined definitions of fairness that take into account the time over which one averages the
performance measures. In [39] E. Altman, K. Avrachenkov and S. Ramanath examine how the constraints on the averaging durations impact the amount of resources that each user gets. The authors apply this new concept in [68] to spectrum allocation and indoor-outdoor femtocells.

5.2.6. Self organization in cellular networks

Time-slots and frequencies are contended in cellular networks and their allocation is determined by base stations. For scalability purposes the resource allocation is decentralized, so that base stations do not share their information with each other. Actions are often taken based on partial information on the system. In particular, the statistics of the channels are often not available. Scheduling decisions of a base station concerning mobiles in its cell cause interference in other cells and there is thus a need to dynamically adjust to interference and to converge to a satisfactory operation point. This has motivated a large amount of work on self-organization in cellular networks based on OFDMA. E. Altman, Z. Altman, R. Combes (both from Orange Labs, Issy les Moulineaux) and M. Haddad have written a series of papers on self-organization. In [53] and [51] self-organization in interference coordination is studied. In [50], R. Combes, Z. Altman and E. Altman, further propose and analyze a self-optimization method for coverage-capacity optimization in OFDMA networks with MIMO. Moreover, they study in [52] self-organization when adding relays so as to increase coverage. Static and dynamic resource sharing mechanisms are investigated. In the static case they use a queuing model to calculate the optimal resource sharing strategy and the maximal capacity of the network analytically. The influence of relay planning and number of deployed relays is investigated, and gains resulting from good planning are evaluated analytically. Self-optimizing dynamic resource allocation is tackled using a Markov Decision Process (MDP) model. [52] received the Best Paper Award of the 7th International Conference on Network and Service Management, Paris, Oct. 24-28, 2011.

Self-organization has also been used in the past to obtain opportunistic scheduling in a way that achieves proportional fair resource sharing. In [23], R. Combes, Z. Altman (both from Orange Labs, Issy les Moulineaux) and E. Altman, have extended this to the general $\alpha$-fair concept. A dynamic choice of the factor $\alpha$ is proposed, which has the interpretation of trading optimality with fairness in a dynamic way.

5.2.7. Dynamic networks

In source routing, a complete path is chosen for a packet to travel from source to destination. While computing the time to traverse such a path may be straightforward in a fixed, static graph, doing so becomes much more challenging in dynamic graphs, in which the state of an edge in one timeslot (i.e., its presence or absence) is random, and may depend on its state in the previous time step. The traversal time is due to both time spent waiting for edges to appear and time spent crossing them once they become available. In [99], P. Nain in collaboration with A. Bar-Noy (City University of New York), P. Basu (Raytheon BBN Technologies), M. P. Johnson (Pennsylvania State University), F. Yu (City University of New York) and D. Towsley (University of Massachusetts at Amherst) computes the expected traversal time (ETT) for a routing path in a number of special cases of stochastic edge dynamics models, and for three edge failure models, culminating in a surprisingly challenging yet realistic setting in which the initial configuration of edge states for the entire path is known. We show that the ETT for this “initial configuration” setting can be computed in quadratic time, by an algorithm based on probability generating functions. The authors also give several linear-time upper and lower bounds on the ETT.

5.2.8. Sensor networks

In many application scenarios sensors need to calculate the average of some local values, e.g. of local measurements. A possible solution is to rely on consensus algorithms. In this case each sensor maintains a local estimate of the global average, and keeps improving it by performing a weighted sum of the estimates of all its neighbors. The number of iterations needed to reach an accurate estimate depends on the weights used at each sensor. K. Avrachenkov, G. Neglia and M. El Chamie have proposed a new average consensus algorithm, where each sensor selects its own weights on the basis of some local information about its neighborhood [45]. In realistic sensor network topologies, the algorithm shows faster convergence than other existing consensus protocols.
5.2.9. Delay and disruption-tolerant networks (DTNs)

5.2.9.1. Applying risk sensitive control to delay tolerant networks

When controlling the propagation of a message in DTNs, the objective is often to maximize the successful delivery probability of a message within a given deadline. It takes often the form of the expectation of the exponent of some integral cost. So far, models involving such costs have been solved by interchanging the order of expectation and the exponential function. While reducing the problem to a standard optimal control problem, this interchange is only tight in the mean-field limit obtained as the population tends to infinity. In [41] E. Altman, V. Kavitha (Univ. Avignon/LIA), F. De Pellegrini (Create-Net, Trento, Italy), V. Kamble (UC Berkeley, CA, USA) and V. Borkar (TATA Inst., Mumbai, India), identify a general framework from optimal control in finance, known as risk sensitive control, which allows handling the original (multiplicative) cost and obtaining solutions to several novel control problems in DTNs. New optimal control problems which consider the effect of wireless propagation path loss factor and the power constraints at the source and or the destination are proposed for DTNs within this framework. Optimal policies of non-threshold type are found.

5.2.9.2. Multiple destinations

In [73], C. Singh, A. Kumar and R. Sundaresan (all three from IISC Bangalore, India) in collaboration with E. Altman, use Markov Decision Processes to study optimal policies for propagation of contents in DTNs to multiple destinations. They obtain structural properties for a discretized system which allows them to derive the structure of optimal policies to the original problem.

5.2.9.3. Reliable unicast and multicast

In case the DTN does not deliver a packet within some time $T$, it has to be retransmitted. In [36] E. Altman and M. Panda, in collaboration with T. Chahed and A. Ali, (both from Telecom SudParis) and L. Sassatelli (Univ. Nice Sophia Antipolis/I3S), propose protocols for unicast and for multicast that render the connection reliable. These protocols include ACKs and retransmissions. The authors compute the value of $T$ that optimizes the throughput and address energy consumptions aspects.

5.2.9.4. Network coding

In [18], E. Altman studies, in cooperation with F. De Pellegrini (Create-Net, Trento, Italy), how to improve the performance of DTNs by adding network coding. The latter has the effect of efficiently adding spatial redundancy to the network. They identify the structure of optimal policies, which are shown not always to be of a threshold type.

G. Neglia, in collaboration with X. Zhang (Fordham University, New York) and J. Kurose (University of Massachusetts at Amherst), has published a survey on the application of network coding to DTNs [78].

5.2.9.5. Ferry based local area networks

Polling systems are used to model the Ferry assisted Wireless LANs and thereby to obtain the stationary workload performance. Not much theory is available for calculating the stationary workload of polling systems with arrivals in a continuum. In [103], V. Kavitha (Univ. Avignon/LIA) and E. Altman propose a discretization approach, by which the so-called “pseudo conservation law” of the discrete polling systems is utilized to derive the stationary performance of continuous polling systems. The continuous polling results are used in deriving optimal ferry routes.

5.2.9.6. Adaptive epidemic routing in DTNs

G. Neglia and R. Masiero (University of Padua, Italy) have explored a recently proposed optimization framework that relies on local sub-gradient methods and consensus algorithms. The research is described in MAESTRO 2010 activity report and has appeared in [66].

5.2.9.7. Routing in quasi-deterministic networks

G. Neglia, U. Acer (Bell labs Antwerp), P. Giaccone and S. Tarapiah (both from Politecnico di Torino, Italy) and D. Hay (Hebrew University of Jerusalem), have investigated routing in DTNs where the underlying node mobility is known in advance but can be modified by random effects. The research is described in MAESTRO 2010 activity report and has appeared in [35] and [94].
5.3. Information systems

Participants: Eitan Altman, Konstantin Avrachenkov, Nicaise Choungmo Fofack, Majed Haddad, Alain Jean-Marie, Dorian Mazauric, Philippe Nain, Marina Sokol.

5.3.1. Web crawler optimization

A typical web search engine consists of three principal parts: crawling engine, indexing engine, and searching engine. The work [19] by K. Avrachenkov and P. Nain, together with A. Dudin, V. Klimenok, and O. Semenova (all three from Belarusian State University, Belarus), aims to optimize the performance of the crawling engine. The crawling engine finds new web pages and updates existing web pages in the database of the web search engine. The crawling engine has several robots collecting information from the Internet. The authors first calculate various performance measures of the system (e.g., probability of arbitrary page loss due to the buffer overflow, probability of starvation of the system, average time waiting in the buffer). Intuitively, one would like to avoid system starvation and at the same time to minimize the information loss. The authors formulate the problem as a multi-criteria optimization problem and solve it in the class of threshold policies. The authors consider a very general web page arrival process modeled by Batch Marked Markov Arrival Process and a very general service time modeled by Phase-type distribution. The model has been applied to the performance evaluation and optimization of the crawler designed by INRIA MAESTRO team in the framework of the RIAM INRIA-Canon research project (see MAESTRO 2006 and 2007 activity reports).

5.3.2. PageRank node centrality

In [48] K. Avrachenkov and M. Sokol, together with D. Nemirovsky (former MAESTRO team member), E. Smirnova (INRIA project-team AXIS) and N. Litvak (University of Twente, The Netherlands), study a problem of quick detection of top-k Personalized PageRank (PPR) lists. This problem has a number of important applications such as finding local cuts in large graphs, estimation of similarity distance and person name disambiguation. The authors suggest that two observations are important when finding top-k PPR lists. Firstly, it is crucial that one detects fast the top-k most important neighbors of a node, while the exact order in the top-k list and the exact values of PPR are by far not so crucial. Secondly, by allowing a small number of “wrong” elements in top-k lists, one achieves great computational savings, in fact, without degrading the quality of the results. Based on these ideas, the authors propose Monte Carlo methods for quick detection of top-k PPR lists. We demonstrate the effectiveness of these methods on the Web and Wikipedia graphs, provide performance evaluation and supply stopping criteria.

5.3.3. Analysis of YouTube

E. Altman and M. Haddad, in collaboration with S.-E. Elayoubi (Orange Labs, Issy les Moulineaux), R. El-Azouzi, T. Jimenez and Y. Xu (all three from Univ. Avignon/LIA) have been investigating streaming protocols similar to the one used by YouTube. After preparing a survey on the state-of-the-art in [57], they used Ballot theorems in [106] in order to compute the starvation probabilities (these are the probability that the queue empties before completing to send a streaming application).

This work is carried out in the framework of the Grant with Orange Labs (see Section 6.3) on “Quality of Service and Quality of Experience”.

5.3.4. Peer-to-peer networks

5.3.4.1. Real-time control of contents download

In the course of the VOODDO project, the question of assessing the theoretical limits of prefetching information in real-time arose. Given a network bandwidth and a graph of documents, is it possible to download documents in advance, so that the document surfer is never blocked because of missing information? The problem is modeled using a “cops-and-robbers” game and some of its algorithmic properties are derived. This work of A. Jean-Marie and D. Mazauric is joint with F. Fomin (Univ. Bergen) and F. Giroire and N. Nisse (both from INRIA project-team MASCOTTE) [86].
5.3.4.2. P2P traffic classification

P2P downloads still represent a large portion of today's Internet traffic. More than 100 million users operate BitTorrent and generate more than 30% of the total Internet traffic. According to the Wikipedia article about BitTorrent, the traffic generated by BitTorrent is greater than the traffic generated by Netflix and Hulu combined. Recently, a significant research effort has been done to develop tools for automatic classification of Internet traffic by application. The purpose of the work [47] by K. Avrachenkov and M. Sokol, together with A. Legout (INRIA project-team PLANETE) and P. Gonçalves (INRIA project-team RESO), is to provide a framework for subclassification of P2P traffic generated by the BitTorrent protocol. The general intuition is that users with similar interests download similar contents. This intuition can be rigorously formalized with the help of graph based semi-supervised learning approach. In particular, the authors propose to work with PageRank based semi-supervised learning method, which scales well with very large volumes of data.

5.3.4.3. BitTyrant

The success of BitTorrent has fostered the development of variants to its basic components. Some of the variants adopt greedy approaches aiming at exploiting the intrinsic altruism of the original version of BitTorrent in order to maximize the benefit of participating to a torrent. G. Neglia, D. Carra (University of Verona, Italy), P. Michiardi and F. Albanese (both from INSTITUT EURECOM) have studied BitTyrant, a recently proposed strategic client. The research is described in MAESTRO 2008 activity report. Results have been extended and supported by PlanetLab experiments in [22].

5.3.5. Content-centric networks

In [100] N. Choungmo Fofack, P. Nain and G. Neglia, together with D. Towsley (University of Massachusetts at Amherst), provide building blocks for the performance evaluation of Content Centric-like Networks (CCNs). In CCNs if a cache receives a request for a content it does not store, it forwards the request to a higher-level cache, if any, or to the server. When located, the document is routed on the reverse-path and a copy is placed in each cache along the path. In this work the authors consider a cache replacement policy based on Time-to-Lives (TTLs) like in a DNS network. A local TTL is set when the content is first stored at the cache and is renewed every time the cache can satisfy a request for this content (at each hit). The content is removed when the TTL expires. Under the assumption that requests follow a renewal process and the TTLs are exponential random variables, we determine exact formulas for the performance metrics of interest (average cache occupancy, hit and miss probabilities/rates) for some specific architectures (a linear network and a tree network with one root node and $N$ leaf nodes). For more general topologies and general TTL distributions, an approximate solution is proposed. Numerical results show the approximations to be accurate, with relative errors smaller than $10^{-3}$ and $10^{-2}$ respectively for exponentially distributed and constant TTLs.

This work is carried out in the framework of the Grant with Orange Labs on “Content-centric networks” (Section 6.2).

5.4. Game theory applied to networking

Participants: Eitan Altman, Konstantin Avrachenkov, Majed Haddad, Manoj Panda, Giovanni Neglia.

5.4.1. Resource allocation in wireless networks

5.4.1.1. Power control

In [14] E. Altman, K. Avrachenkov and A. Garnaev (St. Petersburg State University, Russia), study power control for Gaussian interference channel in optimization and game frameworks. In the optimization framework there is a single decision maker who assigns network resources and in the game framework users share the network resources according to Nash equilibrium. The authors enhance the water-filling technique with explicit analytic solutions. The authors also provide an alternative simple proof of the convergence of the Iterative Water Filling Algorithm. Finally, the authors compare the non-cooperative approach with the cooperative approach and show that the non-cooperative approach results in a more fair resource distribution.
There has been a debate between those proposing protocols based on a centralized controller and those favoring decentralized protocols based on non-cooperative game theory. In [26] E. Altman and M. Haddad, together with S.-E. Elayoubi and Z. Altman (both from Orange Labs, Issy les Moulineaux), consider a situation where a base station lets mobiles take power control decisions in some system states and imposes actions in other states. The authors study how best to choose what information to make available and how mobiles should react.

5.4.1.2. Joint power and rate allocation

In [63] X. Lei and L. Cottatellucci (both from INSTITUT EURECOM) and K. Avrachenkov consider a block fading interference channels with partial channel state information and address the issue of joint power and rate allocation in a game theoretic framework. Resource allocation algorithms based on Bayesian games are proposed. The existence, uniqueness, and some stability properties of Nash equilibria are analyzed. For some asymptotic setting, closed-form expressions of Nash equilibria are also provided.

5.4.1.3. Jamming in wireless networks

Jamming is a form of a denial of service attack in which an adversary can degrade the quality of the reception by creating interference. One can study jamming both in the purpose of protecting a wireless network against such attack or, on the contrary, in order to efficiently disrupt the communications of some adversary. In both cases jamming is part of a conflict for which game theory is an appropriate tool. In [15] E. Altman, K. Avrachenkov and A. Garnaev (St. Petersburg State University), investigate the effect of partially available information in which the user does not even know whether or not the jammer is indeed present. The problem is formulated as a zero-sum game. The authors find the equilibrium strategies in closed-form and specify the range of sub-carriers where the user can expect the jamming attack.

5.4.1.4. Channel access

In WiFi networks, mobile nodes compete for accessing the shared channel by means of a random access protocol called Distributed Coordination Function (DCF), which is long term fair. Selfish nodes could benefit from violating the protocol and increasing their transmission probability. G. Neglia, I. Tinnirello and L. Giarré (University of Palermo, Italy) have been studying the interaction of selfish nodes in the last two years (the research activity is described in MAESTRO 2009 and MAESTRO 2010 activity reports). [31], [74] further extend the results to a heterogeneous scenario, where nodes have different requirements in terms of uplink/downlink ratios.

5.4.2. Network formation games

The continued growth of computer networks such as the Internet has raised the interest in understanding how networks get formed. The design of such networks is generally carried out by a large number of self-interested actors (users, Internet Service Providers ...), all of whom seek to optimize the quality and cost of their own operation. Previous works have addressed the “Network Formation” problem considering almost exclusively networks designed by selfish users, which can be consistently suboptimal. In [46] K. Avrachenkov and G. Neglia, together with J. Elias (University Paris Descartes), F. Martignon (University Paris-Sud 11), and L. Petrosyan (St. Petersburg State University, Russia), address the network formation issue using cooperative game theory, which permits to study ways to enforce and sustain cooperation among agents. Both the Nash bargaining solution and the Shapley value are investigated. After the comparison of these two approaches, the authors conclude that the Nash bargaining solution is more suitable to enforce cooperation in the network formation game in terms of cost allocation to users and computation time to get the solution.

5.4.2.1. Network design with socially-aware users

In many scenarios network design is not enforced by a central authority, but arises from the interactions of several self-interested agents. This is the case of the Internet itself. K. Avrachenkov and G. Neglia, in collaboration with J. Elias (University Paris Descartes) and F. Martignon (University Paris-Sud 11), have proposed two novel socially-aware network design games. The research has been described in MAESTRO 2010 activity reports. [24] extends the results for the case when users’ utility functions incorporate a socially-aware component.
5.4.2.2. Stochastic games for cooperative network routing

In [64] K. Avrachenkov, L. Magni and L. Cottatellucci (both from INSTITUT EURECOM) consider a system where several providers share the same network and control the routing in disjoint sets of nodes. They provide connection toward a unique server (destination) to their customers. The objective is to facilitate the design of the available network links and their costs such that all network providers are interested in cooperating and none of them withdraw from the coalition. More specifically, the authors establish the framework of a coalition game by providing an algorithm to compute the transferable coalition values. As by-product, the authors apply the proposed algorithm to two-player games both in networks subject to hacker attacks and in epidemic networks.

5.4.2.3. Association games

Using tools from coalition game theory, E. Altman, in cooperation with C. Singh (IISc Bangalore, India), considers in [72] a wireless framework in which several mobile terminals can receive and decode the same signal of the base station, and where the cost for broadcasting is taken to be the transmission power. They begin by proposing various schemes to share the cost and study their properties. Then, they study the association with partial information: an arriving user knowing its location has to decide without knowledge of the location of the other users and their number whether to join the multicast tree and pay according to a given cost sharing scheme, or to have a unicast connection at a given cost. The unicast alternative that each mobile has, results in a limitation on the coverage (area covered by the multicast session) and on the capacity (number of mobiles connected to the multicast session). The authors derive the expected capacity and coverage as a function of the cost sharing policy. This work is extended in [58] to the case of several base stations by E. Altman in collaboration with C. Hasan and J. M. Gorce (both from INSA Lyon and INRIA project-team SWING).

5.4.3. Routing games

In [40], E. Altman, M. Panda and A. Estanisla (Master student at UPMC) study ring networks extensively used in both road traffic and telecommunications (in local area networks) in which each source with a given origin and destination on the ring, can split its traffic and send some part in one direction of the ring and some other part in the other direction. They compute the equilibria and find out that due to non-cooperation, much traffic is sent at equilibrium along long paths.

In [16], E. Altman, O. Pourtallier (INRIA project-team COPRIN), T. Jimenez (Univ. Avignon/LIA) and H. Kameda (Univ. Tsukuba, Japan) study a load balancing processor sharing problem. The classical framework of routing games turned out not to apply here. Indeed, it had been used to model situations where the flow from each class of users is split among paths without any information on the realization of the sizes of each packet. In contrast, in this paper, each individual knows its size. The authors have succeeded in computing the equilibrium within the new setting.

Collusion is the situation where several players decide to cooperate and to choose their actions as if they were a single player - each player maximizes the sum of utilities of that group instead of only its own utility. In [90], E. Altman in collaboration with Y. Hayel (Univ. Avignon/LIA) and H. Kameda (Univ. Tsukuba, Japan), has proposed various concepts that evaluate the impact of collisions. The authors have further studied collisions in routing games and identified situations where collisions are bad for all players: both those that collide loose in performance as well as those who remain independent.

5.5. Stochastic processes, queueing, control theory and game theory

Participants: Eitan Altman, Julien Gaillard, Majed Haddad, Alain Jean-Marie.

5.5.1. Convergence of rolling horizon control

In collaboration with E. Della Vecchia and S. Di Marco (both from National Univ. Rosario, Argentina), A. Jean-Marie has investigated the performance (convergence and error bounds) of the Rolling Horizon heuristic for optimal stochastic control and stochastic games in different modeling situations.
In the case of the long-term average expected gain, they have shown [85] that convergence occurs whenever the value iteration algorithm converges. They have then considered zero-sum semi-Markov games with discounted payoff [54], [76], for which they have proved geometric convergence under the usual assumptions of the literature.

5.5.2. Impulse control versus continuous control

Impulse control is a modeling framework of optimal control theory, in which the control actions can provoke instantaneous changes in the value of the state. For modelers, it has the features of both continuous-time and discrete-time models, and it can help understand which one to choose in a given optimization situation. A. Jean-Marie has studied the question in conjunction with K. Erdlenbruch (CEMAGREF), M. Tidball (INRA) and M. Moreaux (Univ. Toulouse 1). In a quite generic single-dimensional model, they show that the optimality of impulse policies with respect to “smooth” control policies is strongly related to a submodularity property of the instantaneous cost function [101].

5.5.3. Routing games

Several fundamental results have been obtained in routing games that model finite number of sources of traffic (players) who decide how to split the traffic among various paths. When the number of players is large, the Wardrop equilibrium concept is often used, where the problem is modeled as one with a continuum of decision makers where each has a negligible impact (non atomic game) on other’s performance. E. Altman and his co-workers have studied the question of whether Wardrop equilibrium is a good approximation for a problem with finitely many players for which the Nash equilibrium is the solution concept. In [38], E. Altman, in collaboration with Z. Altman, R. Combes (both from Orange Labs, Issy les Moulineaux) and S. Sorin (Univ. Pierre and Marie Curie (UPMC)) establishes the convergence under mild convexity assumptions on the link costs (or delays). The proof is based on yet another fundamental result derived in that reference and that was later extended in [44] by E. Altman in collaboration with O. Pourtallier (INRIA project-team COPRIN), T. Jimenez (Univ. Avignon/LIA) and H. Kameda (Univ. Tsukuba, Japan), that states that if there is some symmetry in a network then any Nash equilibrium will inherit the symmetric properties (for example, if two users have the same source and destination and the same demand then at equilibrium, they will send the same amount of traffic over each link).

In all the above work there is an assumption that the link cost (or delay) per packet is class independent (it depends on the flows through the link only through their sum). In the case of Wardrop equilibrium this assumption implies that the game has an equivalent global optimization problem whose solution coincides with the equilibrium. The link cost evaluated at some $x$ in the equivalent problem is the integral of the original link cost (from 0 to $x$) and is in fact a potential. In the case of class dependent cost, that is, when the cost depends in other ways on the traffic of each class then the result of the integration may depend on the path and one cannot transform the problem to an equivalent optimization one. H. Kameda and J. Li (both from Univ. Tsukuba, Japan) in collaboration with E. Altman, identify in [27] other class-dependent cost that have the property of a field, that is, it can be expressed as the gradient of a potential. They obtain the Wardrop equilibrium and study its properties.

Another difficulty occurs in rouging games when the paths available are not the same for all users. This is the case, in particular, when there are priorities. This problem is addressed in [25] by J. Elias (University Paris Descartes), F. Martignon (University Paris-Sud 11), A. Capone (Politecnico di Milano, Italy) and E. Altman within an application to non-cooperative spectrum access in cognitive radio networks.

5.5.4. Bio-inspired paradigms

5.5.4.1. Epidemiology

For several years now, E. Altman has been developing techniques for dynamic optimal control and games in cooperation with with S. Sarkar’s group from the University of Pennsylvania (which used to be part of the DAWN associated team with MAESTRO). This year this collaboration has resulted in three additional publications co-authored by M.H.R. Khouzani and S. Sarkar (both from Univ. of Pennsylvania, PA, USA) and E. Altman [61], [60], [104]. All three papers use the Pontriagin maximal principle to derive the structure
of optimal policies applied to a mean-field approximation of the problem. The first two papers do that in a context of optimal control theory while the third one does it in the context of a dynamic game.

5.5.4.2. Sequential anonymous games (SAG)

Sequential Anonymous Games (SAG) can be viewed as an extension of Markov Decision evolutionary games. In both formalisms there are many players modeled as a continuum number of players. A Markov chain is associated with each player. There are several types of players. The fraction of players in each class is called a global state and the state of the Markov chain of an individual is called the individual state. An individual chooses at some sequential decision opportunities actions. It earns some immediate reward (fitness) at each slot and moves with some probability to another individual state. In SAG, both the transition probabilities and the immediate fitness of an individual depend on its current state and action as well as on the current global system state. The latter evolves according to some function averaged over the fitness of the individuals in each class (the fraction of individuals in a class grows if they do better than those in the other classes). In [75] E. Altman investigates, in collaboration with P. Wieccek (Wroclaw Univ. of Technology, Poland), the case where the objective of an individual is to maximize either its total expected fitness during its life time or its expected average fitness. The authors establish the existence of equilibria and study its properties. Applications to power control have appeared in [32] by E. Altman, in collaboration with P. Wieccek (Wroclaw Univ. of Technology, Poland) and Y. Hayel (Univ. Avignon/LIA).

5.5.4.3. Markov decision evolutionary games (MDEGs)

Since his 2004 Infocom paper, E. Altman has been working on this novel paradigm. The model is similar to that of the previous paragraph (SAG) except that in MDEG both immediate fitness and transition probabilities depend linearly on the global state. This reflects a scenario where the interaction between a player and the rest of the population occurs through pairwise interactions: each player encounters from time to time a randomly chosen other player and it finds itself playing a matrix game with that player. The entries of the matrix corresponding to each player as well as the transition probabilities for each player depend on the individual states of the players. E. Altman has applied this model to the dynamic Hawk and Dove game, in which individuals have to choose the degree of aggressiveness in their behavior as a function of their energy state.

Below are three publications both with biological applications and applications to wireless communications (where depending on one’s remaining battery energy, one has to decide at what power to transmit). The first publication in [30], by E. Altman, H. Tembine (SUPELEC), R. El-Azouzi and Y. Hayel (both from Univ. Avignon/LIA), lays the foundations of MDEGs and presents the application to power control in which the individual state is the battery level of energy. The second publication in [59], by Y. Hayel (Univ. Avignon/LIA), E. V. Belmega (SUPELEC) and E. Altman, studies theoretical aspects that arise in case that the global state cannot represent the fractions of different populations but rather their actual size. The third publication in [97] by E. Altman, J. Gaillard, M. Haddad and P. Wieccek (Wroclaw Univ. of Technology, Poland) again studies MDEGs (as in the first paper), but restricts to policies that use static policies: the same mixed strategy is taken by a player at each state. The authors manage to compute explicitly the equilibrium in this game within this class of policies.

5.5.4.4. Delayed evolutionary games

Evolutionary game theory includes much theory on the description of the global system state as a function of the fitness of individuals. The models are often described through differential equations (e.g. the “replicator dynamics”). In many scenarios it is realistic to consider delays between the moment that one receives a given fitness till this is translated to a change in the population size. For example, if the lifetime of a computer is three years then an application that performs better with one computer may take more than a year till it is adopted by other users who do not have the same computer. In [30], H. Tembine (SUPELEC), E. Altman, R. El-Azouzi and Y. Hayel (both from Univ. Avignon/LIA) investigate instability phenomena that are introduced by the delay and derive necessary stability conditions.
6. New Results

6.1. Inverse Problems

6.1.1. Reconstruction of an elastic scatterer immersed in a homogeneous fluid

Participants: Hélène Barucq, Rabia Djellouli, Élodie Estecahandy.

The determination of the shape of an obstacle from its effects on known acoustic or electromagnetic waves is an important problem in many technologies such as sonar, radar, geophysical exploration, medical imaging and nondestructive testing. This inverse obstacle problem (IOP) is difficult to solve, especially from a numerical viewpoint, because it is ill-posed and nonlinear. Its investigation requires as a prerequisite the fundamental understanding of the theory for the associated direct scattering problem, and the mastery of the corresponding numerical solution methods.

In this work, we are interested in retrieving the shape of an elastic obstacle from the knowledge of some scattered far-field patterns, and assuming certain characteristics of the surface of the obstacle. The corresponding direct elasto-acoustic scattering problem consists in the scattering of time-harmonic acoustic waves by an elastic obstacle \( \Omega^s \) embedded in a homogeneous medium \( \Omega^f \), that can be formulated as follows:

\[
\begin{align*}
\Delta p + (\omega^2/c_f^2) p &= 0 & \text{in } \Omega^f \\
\nabla \cdot \sigma(u) + \omega^2 \rho_s u &= 0 & \text{in } \Omega^s \\
\omega^2 \rho_f u \cdot n &= \partial p/\partial n + \partial e^{i(\omega/c_f) x \cdot d}/\partial n & \text{on } \Gamma^s \\
\sigma(u)n &= -\rho_m e^{i(\omega/c_f) x \cdot d} n & \text{on } \Gamma^s \\
\lim_{r \to +\infty} r (\partial p/\partial r - i (\omega/c_f) p) &= 0 & \text{on } \Gamma^s
\end{align*}
\]

(7)

where \( p \) is the fluid pressure in \( \Omega^f \) whereas \( u \) is the displacement field in \( \Omega^s \), and \( \sigma(u) \) represents the stress tensor of the elastic material.

This boundary value problem has been investigated mathematically and results pertaining to the existence, uniqueness and regularity can be found in \[ 65 \] and the references therein, among others. We propose a solution methodology based on a regularized Newton-type method for solving the IOP. The proposed method is an extension of the regularized Newton algorithm developed for solving the case where only Helmholtz equation is involved, that is the acoustic case by impenetrable scatterers \[ 55 \]. The direct elasto-acoustic scattering problem defines an operator \( F : \Gamma^s \to p_{\infty} \) which maps the boundary \( \Gamma^s \) of the scatterer \( \Omega^s \) onto the far-field pattern \( p_{\infty} \). Hence, given one or several measured far-field patterns \( p_{\infty}(\tilde{x}) \), corresponding to one or several given directions \( d \) and wavenumbers \( k \), one can formulate IOPs as follows:

Find a shape \( \Gamma^s \) such that \( F(\Gamma^s)(\tilde{x}) = p_{\infty}(\tilde{x}) \); \( \tilde{x} \in S^1 \).

We propose a solution methodology based on a regularized Newton-type method to solve this inverse obstacle problem. At each Newton iteration, we solve the forward problem using a finite element solver based on discontinuous Galerkin approximations, and equipped with high-order absorbing boundary conditions. We have first characterized the Fréchet derivatives of the scattered field. They are solution to the same boundary value problem as the direct problem with other transmission conditions. This work has been presented both in FACM11 and in WAVES 2011. A paper has been submitted.
6.1.2. Seismic data interpretation using the Hough transform and principal component analysis

Participants: M.-G Orozco-del-Castillo, Carlos Ortiz-Aleman, Roland Martin, Rafael Avila-Carrera, Alejandro Rodriguez-Castellanos.

In [29], two novel image processing techniques are applied to detect and delineate complex salt bodies from seismic exploration profiles: Hough transform and principal component analysis (PCA). It is well recognized by the geophysical community that the lack of resolution and poor structural identification in seismic data recorded at sub-salt plays represent severe technical and economical problems. Under such circumstances, seismic interpretation based only on the human-eye is inaccurate. Additionally, petroleum field development decisions and production planning depend on good-quality seismic images that generally are not feasible in salt tectonics areas. In spite of this, morphological erosion, region growing and, especially, a generalization of the Hough transform (closely related to the Radon transform) are applied to build parabolic shapes that are useful in the idealization and recognition of salt domes from 2D seismic profiles. In a similar way, PCA is also used to identify shapes associated with complex salt bodies in seismic profiles extracted from 3D seismic data. To show the validity of the new set of seismic results, comparisons between both image processing techniques are exhibited. It is remarkable that the main contribution of this work is oriented in providing the seismic interpreters with new semi-automatic computational tools. The novel image processing approaches presented here may be helpful in the identification of diapirs and other complex geological features from seismic images. Conceivably, in the near future, a new branch of seismic attributes could be recognized by geoscientists and engineers based on the encouraging results reported here.

6.1.3. Gravimetry Inversion

Participants: Roland Martin, Dimitri Komatitsch, Mark Jessel, Stéphane Perrouty, Vadim Monteiller.

In order to improve the subsoil images in regions which are not well covered by a dense seismic array or can not be well retrieved by using seismic imaging techniques alone (salty dome regions like in the Gulf of Mexico for instance), we have been developing new gravity imaging techniques using supercomputing. In regions like Ghana or the Chicxulub crater located in Yucatan plate (Mexico), 3D sensitivity kernels are calculated for gravity potential data sets measured over 2000 up to 10000 locations randomly distributed in space. The density anomaly computational domain covers a 250 km × 250 km × 20 km volume in these two regions. For instance for the Ghana region two resolutions are taken: 1 point each 2 kms in the horizontal plane and 200 m in the vertical direction in the less accurate configuration and one point each 500 m in the horizontal plane and one point each 100 m in the vertical direction for the most accurate configuration. The gravity anomalies are inverted using an optimized least-square method applied to a sensitivity kernel of $10^{10}$ up to $4 \times 10^{11}$ elements. The least-square method using a $L^2$-norm or $L^1$-norm has been implemented on hybrid multi-CPU/multi-GPU Titan machines at CCRT of the French Nuclear Energy Agency. $L^1$ norm gives us sharper boundaries of the density structures when compared to $L^2$-norm solutions but these $L^1$ solutions are obtained at the expense of one order of magnitude in the number of iterations necessary to the inversion. The $L^2$-norm gives slightly smoother solutions but is much more faster than $L^1$ norm by at least one order of magnitude in terms of acceleration. The optimized CPU version has allowed us to reduce drastically the computation time form 5 hours on 512 processors to 25 minutes. Furthemore the multi-GPU version has decreased this computational time around 15 minutes. Our collaboration with geologists of IRD (Mark Jessell and Stephane Perrouty) has allowed us to determine a realistic a priori model of Ghana with different resolutions in order to obtain more realistic models after inversion. We are still optimizing the multi-GPU code, with the challenging goal of obtaining results lower than 10 minutes and then obtaining an acceleration factor of at least 4 when compared to the optimized multi-CPU inversion code. By now the code is further optimized and more improvements are already in the pipeline in terms of better preconditioning, automatic multi-resolution procedure implementation, gravimetry-seismic joint inversion and extension to the global earth imaging. An international article in a scientific peer-reviewed journal is in preparation.
6.2. Modeling

6.2.1. Local approximate DtN exterior boundary condition

Participants: Hélène Barucq, Rabia Djellouli, Anne-Gaëlle Saint-Guirons.

We investigate analytically the asymptotic behavior of high-order spurious prolate spheroidal modes induced by a second-order local approximate DtN absorbing boundary condition (DtN2) when employed for solving high-frequency acoustic scattering problems. We prove that these reflected modes decay exponentially in the high frequency regime. This theoretical result demonstrates the great potential of the considered absorbing boundary condition for solving efficiently exterior high-frequency Helmholtz problems. In addition, this exponential decay proves the superiority of DtN2 over the widely used Bayliss-Gunburger-Turkel absorbing boundary condition. This work has been accepted for publication in Progress In Electromagnetics Research B. [ 19 ].

6.2.2. Non-reflecting boundary condition on ellipsoidal boundary

Participants: Hélène Barucq, Anne-Gaëlle Saint-Guirons, Sébastien Tordeux.

The modeling of wave propagation problems using finite element methods usually requires the truncation of the computational domain around the scatterer of interest. Absorbing boundary condition are classically considered in order to avoid spurious reflections. In this paper, we investigate some properties of the Dirichlet to Neumann map posed on a spheroidal boundary in the context of the Helmholtz equation. We focus on the impedance coefficients defining the DtN condition and we aim at establishing suitable properties in order to propose an accurate numerical method for their computation. Then, we state the well-posedness of the corresponding mixed problem and propose a variational formulation adapted to a finite element discretization. This work has been submitted.

6.2.3. A new modified equation approach for solving the wave equation

Participants: Cyril Agut, Hélène Barucq, Julien Diaz, Florent Ventimiglia, Roland Martin, Dimitri Komatitsch.

The new method involving $p$-harmonic operator described in section 3.2 has been presented in [ 13 ]. We have proved the convergence of the scheme and its stability under a CFL condition. Numerical results in one, two and three-dimensional configurations show that this CFL condition is slightly greater than the CFL condition of the second-order Leap-Frog scheme. We have also studied the penalization parameters involved in the new schemes and their influence of the CFL condition. These results are presented in the PhD. thesis of Cyril Agut [ 11 ]. In the framework of the PhD thesis of Florent Ventimiglia, we are now considering the extension of this technique to the first order formulation of the elastodynamic equations.

6.2.4. Stability Analysis of an Interior Penalty Discontinuous Galerkin Method for the Wave equation

Participants: Cyril Agut, Hélène Barucq, Julien Diaz.

The Interior Penalty Discontinuous Galerkin Method [ 42 ], [ 38 ], [ 61 ] we use in the IPDGFE code requires the introduction of a penalty parameter. Except for regular quadrilateral or cubic meshes, the optimal value of this parameter is not explicitly known. Moreover, the condition number of the resulting stiffness matrix is an increasing function of this parameter, but the precise behaviour has not been explicit before. We have carried out a theoretical and numerical study of the CFL condition for quadrilateral and cubic meshes, which is presented in the PhD thesis of Cyril Agut [ 11 ]. These results were also presented at the peer-reviewed conference Waves 2011 (Vancouver, Canada, July 2011).

6.2.5. Higher Order Absorbing Boundary Conditions for the Wave Equation

Participants: Hélène Barucq, Julien Diaz, Véronique Duprat.
The numerical simulation of wave propagation is generally performed by truncating the propagation medium. Absorbing boundary conditions are then needed. We construct a new family of absorbing boundary conditions from the factorization of the wave equation formulated as a first order system. Using the method of M.E. Taylor, we show that we can generate an infinite number of boundary conditions which can not be obtained via the Niremberg’s factorization method. The conditions can be applied on arbitrarily-shaped surfaces and involve second-order derivatives. We then propose a reduced formulation of the wave equation using an auxiliary unknown which is defined on the regular surface only. The reduced problem allows one to easily include the boundary conditions inside the variational formulation. The corresponding boundary value problem remains well-posed in suitable Hilbert spaces and we give a demonstration in a framework that is suitable to applications. We then study the long-time behavior of the wave field and we show that it tends to 0 as time tends to infinity. This provides a weak stability result that should be completed in the second part of this work. We have then decided to improve the stability result by performing a quantitative study of the energy. We have then shown that the energy is exponentially decaying if the obstacle is star-shaped and the external boundary is convex. This work has been published as INRIA Research Reports [34], [35] and two papers are submitted. We have next addressed the issue of enriching these ABCs by representing evanescent and damping waves. This has given rise to a work for the Helmholtz equation and we have shown that the enriched ABCs performed better than standard ABCs. The extension to the acoustic wave has led to new conditions involving fractional derivatives. To the best of our knowledge, it is the first time that fractional derivatives have been used for optimizing the performance of ABCs. These new results have been presented in two seminars (University of Bordeaux I and University of Genova) and in two conferences (FACM11 and WAVES 2011). A paper has been published [17] for the case of evanescent waves and two papers are in preparation. All these results are presented in the PhD thesis of Véronique Duprat [12].

6.2.6. Numerical methods combining local time stepping and mixed hybrid elements for the terrestrial migration

Participants: Caroline Baldassari, Hélène Barucq, Henri Calandra [Expert Engineer, TOTAL], Bertrand Denel [Research Engineer, TOTAL], Julien Diaz, Florent Ventimiglia.

In order to justify the use of our code IPDGFEM for the Reverse Time Migration, we have carried out a performance analysis of the Interior Penalty Discontinuous Galerkin method and of the Spectral Element Method. This analysis, which shows that IPDG performs as well as SEM, has been presented in [14].

Another aspect of the work concerns the design of local time-stepping algorithms. The local-time stepping strategy proposed in [5] allows for high-order time schemes where the time scheme is adapted to the various space step of the mesh. However, when the mesh contains both low-order and high-order cells, this method not allows for the adaptation of the order of the time-scheme to the order of the cells. We have then presented a new local time-stepping algorithm where both the order of the scheme and the time step vary in the different parts of the mesh. This method has been presented in [14] and at the peer-reviewed conferences Waves 2011 (Vancouver, Canada, July 2011) and DD20 (Domain Decompostion, San Diego, USA, February 2011).

The local-time stepping algorithm is not adapted to handle dissipation terms. A method has been proposed in [59], but it is based on an Adams-Bashworth scheme and it requires the storage of additional unknowns. We can not use this scheme for the simulation of seismic waves in very large heterogeneous domains due to memory limitation. We are now working on the design of alternative schemes which would not require the introduction of the auxiliary unknowns. This one of the topics of the PhD. thesis of Florent Ventimiglia.

6.2.7. Perfectly Matched Layers for the Shallow Water equations

Participants: Hélène Barucq, Julien Diaz, Mounir Tlemcani [Assistant Professor, University of Oran, Algeria].

In [45], we have proposed a new Perfectly Matched Layer for Shallow Water equations. This layer required the computation of an auxiliary variable in the whole computational domain. We are now considering a new strategy, which only requires the computation of the auxiliary variable inside the layer. Moreover, the new methodology seems to be well-adapted to the non-linear shallow water equations. We are now performing numerical tests to confirm this point.
6.2.8. **Multiperforated plates in linear acoustics**  
**Participants:** Abderrahmane Bendali, M'Barek Fares, Sophie Laurens, Estelle Piot, Sébastien Tordeux.

Acoustic engineers use approximate heuristic models to deal with multiperforated plates in liners and in combustion chambers of turbo-engines. These models were suffering from a lack of mathematical justifications and were consequently difficult to improve. Performing an asymptotic analysis (the small parameter is the radius of the perforations), we have justified these models and proposed some improvement. Our theoretical results have been compared to numerical simulations performed at CERFACS (M'Barek Fares) and to acoustical experiments realized at ONERA (Estelle Piot). Two papers are in preparation.

6.2.9. **Asymptotic modeling in electromagnetism**  
**Participants:** François Buret, Gabriel Caloz, Monique Dauge, Patrick Dular, Marc Duruflé, Erwan Faou, Laurent Krähenbühl, Victor Péron, Ronan Perrussel, Clair Poignard, Damien Voyer.

The following results rely on several problematics developed in section 3.2, item Asymptotic modeling.

We consider in [21] the equations of electromagnetism set on a domain made of a dielectric and a conductor subdomain in a regime where the conductivity is large. Assuming smoothness for the dielectric–conductor interface, relying on recent works we prove that the solution of the Maxwell equations admits a multiscale asymptotic expansion with profile terms rapidly decaying inside the conductor. This skin effect is measured by introducing a skin depth function that turns out to depend on the mean curvature of the boundary of the conductor. We then confirm these asymptotic results by numerical experiments in various axisymmetric configurations. We also investigate numerically the case of a nonsmooth interface, namely a cylindrical conductor.

We derive new thin layer models in electromagnetism, in [22]. We study the behavior of the electromagnetic field in a biological cell modeled by a medium surrounded by a thin layer and embedded in an ambient medium. We derive approximate transmission conditions in order to replace the membrane by these conditions on the boundary of the interior domain. Our approach is essentially geometric and based on a suitable change of variables in the thin layer. Few notions of differential calculus are given in order to obtain the first-order conditions in a simple way, and numerical simulations validate the theoretical results. Asymptotic transmission conditions at any order are given.

We present a numerical treatment of rounded and sharp corners in the modeling of 2D electrostatic fields in [36]. This work deals with numerical techniques to compute electrostatic fields in devices with rounded corners in 2D situations. The approach leads to the solution of two problems: one on the device where rounded corners are replaced by sharp corners and the other on an unbounded domain representing the shape of the rounded corner after an appropriate rescaling. Both problems are solved using different techniques and numerical results are provided to assess the efficiency and the accuracy of the techniques.

6.2.10. **Operator Based Upscaling for Discontinuous Galerkin Methods**  
**Participants:** Hélène Barucq, Théophile Chaumont, Julien Diaz, Victor Péron.

Realistic numerical simulations of seismic wave propagation are complicated to handle because they must be performed in strongly heterogeneous media. Two different scales must then be taken into account. Indeed, the medium heterogeneities are very small compared to the characteristic dimensions of the propagation medium. To get accurate numerical solutions, engineers are then forced to use meshes that match the finest scale representing the heterogeneities. Meshing the whole domain with the fine grid leads then to huge linear systems and the computational cost of the numerical method is then very high. It would be thus very interesting to dispose of a numerical method allowing to represent the heterogeneities of the medium accurately while computing on a coarse grid. This is the challenge of multiscale approaches like homogenization or upscaling. In this work, we use an operator-based upscaling method. Operator-based upscaling methods were first developed for elliptic flow problems (see [41]) and then extended to hyperbolic problems (see [62], [73], [72]). Operator-based upscaling method consists in splitting the solution into a coarse and a fine part. The coarse part is defined on a coarse mesh while the fine part is computed on a fine mesh. In order to speed up
calculations, artificial boundary conditions (ABC) are imposed. By enforcing suitable ABCs on the boundary of every cells of the coarse mesh, calculations on the fine grid can be carried out locally. The coarse part is next computed globally on the coarse mesh. Operator-based upscaling methods were so far developed in joint with standard finite element discretisation strategy. In this work, we investigate the idea of combining an operator based upscaling method with discontinuous Galerkin finite element methods (DG-FEM). To begin with, we have used the interior penalty method as presented in [42] for elliptic problems and in [61], [60] for the wave equation. This is a quite natural way of addressing this issue because we can use a software package that has been already developed in the team. The first results that we have obtained seem to indicate that an DG operator based upscaling method could be interesting essentially in case of stationary problems. Nevertheless, the numerical analysis of the discretized problem must be continued. This work has been initiated during the internship of Theophile Chaumont-Frelet who was a fourth year engineer student at Rouen INSA. A paper dealing with the case of the Laplace operator will be submitted soon.

6.2.11. Discontinuous Galerkin Methods for Seismic Wave Propagation

Participants: Hélène Barucq, Caroline Baldassari, Lionel Boillot, Marie Bonnasse, Julien Diaz, Jérôme Luquel, Vanessa Mattesi, Florent Ventimiglia.

In the framework of our collaboration with Total, we are implementing a Discontinuous Galerkin formulation of the first order elastodynamic wave equations in the platform Diva which is developed by Total. We consider the formulation proposed in [54] for isotropic media. During her post-doc, Caroline Baldassi has implemented a three dimensional code with Perfectly Matched Layers for this formulation. Jérôme Luquel has implemented the 2D version of this code during his internship. In the framework of the internship of Marie Bonnasse and the PhD thesis of Lionel Boillot, we have extended the formulation to Vertical Transverse Isotropic and Tilted Transverse Isotropic media in both 2D and 3D. The introduction of Absorbing Boundary Conditions or of PML is still an open problem for these types of media. It is one of the topics of the PhD thesis of Lionel Boillot.

The version of the code that we are using assumed that the properties of the media (density, velocity,...) are constant on each cells of the mesh. Discontinuous Galerkin methods allow for considering more general configurations, where these properties vary as polynomial functions inside each cells. Hence, it is not necessary to define the interfaces between the different media before constructing the mesh. The discontinuities are taken into account directly inside each cells. Moreover, we are able to consider smoothly varying media.

In the framework of the internship of Vanessa Mattesi, we have implemented polynomial velocities in a Discontinuous Galerkin formulation. We have compared the results obtained with this method to the one obtained with piecewise constant properties. We have observed that the new formulation was more accurate and that it allowed for a simpler construction of the mesh. However, these gains do not counterbalance the increase of the computational induced by the new method. We have then concluded that considering piecewise constant properties was more appropriate to model seismic wave propagation.

6.2.12. Elastic surface waves in crystals

Participants: José Carcione, Fabio Cavallini, Dimitri Komatitsch, Nathalie Favretto-Cristini.

In [25], we present a review of wave propagation at the surface of anisotropic media (crystal symmetries). The physics for media of cubic and hexagonal symmetries has been extensively studied based on analytical and semi-analytical methods. However, some controversies regarding surfaces waves and the use of different notations for the same modes require a review of the research done and a clarification of the terminology. In a companion paper we obtain the full-wave solution for the wave propagation at the surface of media with arbitrary symmetry (including cubic and hexagonal symmetries) using two spectral numerical modeling algorithms.

In [27], we obtain the full-wave solution for the wave propagation at the surface of anisotropic media using two spectral numerical modeling algorithms. The simulations focus on media of cubic and hexagonal symmetries, for which the physics has been reviewed and clarified in a companion paper. Even in the case of homogeneous media, the solution requires the use of numerical methods because the analytical Green’s
function cannot be obtained in the whole space. The algorithms proposed here allow for a general material variability and the description of arbitrary crystal symmetry at each grid point of the numerical mesh. They are based on high-order spectral approximations of the wave field for computing the spatial derivatives. We test the algorithms by comparison to the analytical solution and obtain the wave field at different faces (stress-free surfaces) of apatite, zinc and copper. Finally, we perform simulations in heterogeneous media, where no analytical solution exists in general, showing that the modeling algorithms can handle large impedance variations at the interface.

6.2.13. Application of an elastoplastic spectral-element method to 3D slope stability analysis

Participants: Hom Nath Gharti, Dimitri Komatitsch, Oye Volker, Roland Martin, Jeroen Tromp.

In [26], we implement a spectral-element method for 3D time-independent elastoplastic problems in geomechanics. As a first application, we use the method for slope stability analyses ranging from small to large scales. The implementation employs an element-by-element preconditioned conjugate gradient solver for efficient storage. The program accommodates material heterogeneity and complex topography. Either simple or complex water table profiles may be used to assess effects of hydrostatic pressure. Both surface loading and pseudostatic seismic loading are implemented. In order to simulate elastoplastic behavior of slopes, a Mohr-Coulomb yield criterion is employed using an initial strain method (i.e., a viscoplastic algorithm). For large-scale problems, the software is parallelized based on domain decomposition using MPI (Message Passing Interface). Strong-scaling measurements demonstrate that the parallelized software performs efficiently. We validate our spectral-element results against several other methods, and apply the technique to simulate failure of an earthen embankment and a mountain slope.

6.2.14. Indirect Boundary Element Method applied to Fluid-Solid Interfaces

In [31], scattering of elastic waves in fluid-solid interfaces is investigated. We use the Indirect Boundary Element Method to study this wave propagation phenomenon in 20 models. Three models are analyzed: a first one with an interface between two half-spaces, one fluid on the top part and the other solid in the bottom; a second model including a fluid half-space above a layered solid; and finally, a third model with a fluid layer bounded by two solid half-spaces. The source, represented by Hankel’s function of the second kind, is always applied in the fluid. This indirect formulation can give to the analyst a deep physical insight on the generated diffracted waves because it is closer to the physical reality and can be regarded as a realization of Huygens’ principle. In any event, mathematically it is fully equivalent to the classical Somigliana’s representation theorem. In order to gauge accuracy we test our method by comparing with an analytical solution known as Discrete Wave Number. A near interface pulse generates scattered waves that can be registered by receivers located in the fluid and it is possible to infer wave velocities of solids. Results are presented in both time and frequency domain, where several aspects related to the different wave types that emerge from this kind of problems are pointed out.

6.2.15. Multiperforated plates in linear acoustics

Participants: Mohamed Amara, Sharang Chaudhry, Julien Diaz, Rabia Djellouli, Magdalena Grigoroscuta-Strugaru.

We have designed a new and efficient solution methodology for solving high-frequency Helmholtz problems. The proposed method is a least-squares based technique that employs variable bases of plane waves at the element level of the domain partition. A local wave tracking strategy is adopted for the selection of the basis at the regional/element level. More specifically, for each element of the mesh partition, a basis of plane waves is chosen so that one of the plane waves in the basis is oriented in the direction of the propagation of the field inside the considered element. The determination of the direction of the field inside the mesh partition is formulated as a minimization problem. Since the problem is nonlinear, we apply Newton’s method to determine the minimum. The computation of Jacobians and Hessians that arise in the iterations of the Newtonâs method is based on the exact characterization of the Fréchet derivatives of the field with
respect to the propagation directions. Such a characterization is crucial for the stability, fast convergence, and computational efficiency of the Newton algorithm. These results are part of the Master thesis of Sharang Chaudhry (student at CSUN).

6.3. High Performance methods for solving wave equations

6.3.1. Forward and adjoint simulations of seismic wave propagation on fully unstructured hexahedral meshes

Participants: Daniel Peter, Dimitri Komatitsch, Yang Luo, Roland Martin, Nicolas Le Goff, Emanuelle Casarotti, Feyre Le Loher, Federica Magnoni, Qinya Liu, Céline Blitz, Tarje Nissen-Meyer, Piero Basini, Jeroen Tromp.

In [30], we present forward and adjoint spectral-element simulations of coupled acoustic and (an)elastic seismic wave propagation on fully unstructured hexahedral meshes. Simulations benefit from recent advances in hexahedral meshing, load balancing and software optimization. Meshing may be accomplished using a mesh generation tool kit such as CUBIT, and load balancing is facilitated by graph partitioning based on the SCOTCH library. Coupling between fluid and solid regions is incorporated in a straightforward fashion using domain decomposition. Topography, bathymetry and Moho undulations may be readily included in the mesh, and physical dispersion and attenuation associated with anelasticity are accounted for using a series of standard linear solids. Finite-frequency Fréchet derivatives are calculated using adjoint methods in both fluid and solid domains. The software is benchmarked for a layercake model. We present various examples of fully unstructured meshes, snapshots of wavefields and finite-frequency kernels generated by Version 2.0 ‘Sesame’ of our widely used open source spectral-element package SPECFEM3D.

6.3.2. Fluid-solid coupling on a cluster of GPU graphics cards for seismic wave propagation

Participant: Dimitri Komatitsch.

In [28], we develop a hybrid multiGPUs and CPUs version of an algorithm to model seismic wave propagation based on the spectral-element method in the case of models of the Earth containing both fluid and solid layers. Thanks to the overlapping of communications between processing nodes on the computer with calculation by means of non-blocking message passing, we obtain excellent weak scalability of this finite-element code on a cluster of 192 GPUs and speedup factors of more than one order of magnitude compared to the same code run on a cluster of traditional CPUs. This enables us to show a new geophysical phenomenon concerning wave propagation of diffracted shear waves in a layer called D” located at the base of the Earth’s mantle, namely that in this layer the transverse and radial components of these waves can undergo a relative shift even in an isotropic Earth model, whereas this observation in real seismological data was interpreted until now as an indication of the presence of anisotropy in this layer.
6. New Results

6.1. Yeast comparative genomics

Participants: David James Sherman, Pascal Durrens [correspondant], Tiphaine Martin, Nicolás Loira.

By using the MAGNOME software developments, including the MAGUS system and YAGA software, we have successfully realized a full annotation and analysis of seven new genomes, provided to the Génolevures Consortium by the CEA–Génoscope (Évry). Two distant genomes from the Debaryomycetaceae and mitosporic Saccharomycetales clades of the Saccharomycetales were annotated using previously published Génolevures genomes [5], [9], [10] as references. A further group of five species, comprised of pathogenic and nonpathogenic species, was analyzed with the goal of identifying virulence determinants[13]. By choosing species that are highly related but which differ in the particular traits that are targeted, in this case pathogenicity, we are able to focus on a few hundred genes related to the trait. The approximately 40,000 new genes from these studies were classified into existing Génolevures families as well as branch-specific families. The results from these two studies will be published in the coming year.

6.2. Assembly, annotation and comparison of Oenococcus strains

Participants: David James Sherman, Pascal Durrens, Elisabeth Bon [correspondant], Tiphaine Martin, Aurélie Goulielmakis.

*Oenococcus oeni* is part of the natural microflora of wine and related environments, and is the main agent of the malolactic fermentation (MLF), a step of wine making that generally follows alcoholic fermentation (AF) and contributes to wine deacidification, improvement of sensorial properties and microbial stability. The start, duration and achievement of MLF are unpredictable since they depend both on the wine characteristics and on the properties of the *O. oeni* strains. In collaboration with Patrick Lucas’s lab of the ISVV Bordeaux that is currently proceeding with genome sequencing, explorative and, and comparative genomics, Elisabeth Bon coordinates our efforts into the OENIKITA project (since 2009), a scale switching challenge including high throughput exploratory and comparative genomics for oenological bacterial starters, and the development of an online web-collaborative multigenomic comparative platform (under development) based on the the Génolevures database architecture and MAGUS / YAGA systems.

**OENI-Genomics axis:** In comparative genomics, we investigated gene repertoire and genomic organization conservation through intra- and inter-species genomic comparisons, which clearly show that the *O. oeni* genome is highly plastic and fast-evolving. Results reveal that the optimal adaptation to wine of a strain mostly depends on the presence of key adaptive loops and polymorphic genes. They also point up the role of horizontal gene transfer and mobile genetic elements in *O. oeni* genome plasticity, and give the first clues of the genetic origin of its oenological aptitudes. As a result of the scaling out challenge, we completed the assembly of 19 fully sequenced *O. oeni* genome variants.

**KITA-Genomics (E. Bon, D. Sherman):** This project that is focused on the sequencing, assembly, exploration and comparison of the *O. kitaharae* genome, has benefited to an international collaboration involving Dr V. Makeev. MAGNOME contributed to the assembly of the genome. The comparison against the *O. oeni* genomic architecture will contribute to shed light on the evolutionary mechanisms which are responsible for the atypically long branch of the genus Oenococcus in phylogenetic trees.
Transcriptomic axis (E. Bon, A. Goulielmakis): Under the supervision of E. Bon, Aurélie Goulielmakis has completed for the ANR DIVOENI a detailed manual annotation of a new reference strain of O. oeni and performed comparative transcriptome analysis to identify genes differentially expressed under different culture conditions. We explored and compared how the expression system is solicited when O. oeni strains adapted to growth in some niches are placed under stress-exposure conditions. The monitoring of gene expression status between strains, through the definition of a global expression pattern proper to each gene, partially lift the veil on how O. oeni genome adapts function to its environment. The weight of genetic background and ecological niche pressure on gene expression flexibility was evaluated, and the O. oeni pan-transcriptome architecture characterized. The first guidelines revealed a supra-spatial organization of stress response into activated and repressed larger macro-domains defining functional landmarks and intra-chromosomal territories [16]. Decryption of stress-sensitive gene repertoires promises to be an efficient tool in the conquest of O. oeni “domestication” through the identification of molecular markers responsible for different physiological capabilities, and the selection of the best adapted strains.

Gene plasticity modelisation (E. Bon, A. Goulielmakis): A novel axis of research recently emerged under the initiative of E. Bon (pseudOE project) around the detection, characterization and conservation of pseudogenes populations in Oenococcus bacteria. Such topic presents a double interest: phylogenetic at first because it should allow to better estimate the degree of genic/genomic plasticity of these bacteria, and algorithmic then because the pseudogenes are a source of confusion for the automatic prediction of genes. Through a transversal collaboration and a cooperative supervision with the Algorithms for Analysis of Biological Structures Group (P. Ferraro, J. Allali) at LaBRI, Laetitia Bourgeade (PhD, Univ. Bordeaux1) was recruited to develop dedicated methods to improve pseudogenes automatic detection, and therefore gene predictions, and to reconstruct fossil and modern genes evolutionary history.

6.3. Scaling-out

Participants: David James Sherman [correspondant], Pascal Durrens, Tiphaine Martin, Natalia Golenetskaya, Florian Lajus.

The Tsvetok project in MAGNONE targets “scaling out” for data and computation, both to improve capacity for handling large volumes of data and to permit more automatic analysis of projects of the “comparative genomics of related species” type, where a set of genomes is sequenced and analyzed as part of the same process. Natalia Golenetskaya has designed and implemented a NoSQL schema through the identification of standard queries, definition of the appropriate query-oriented storage schema, and mapping of structured values to this schema. This prototype is being tested on an Apache Cassandra ring deployed in MAGNONE’s dedicated computing cluster.

Large-scale data-mining such as that required for comparative genomics is fundamentally data-parallel: an initial transformation is applied to every data object of a given type (such as genes or even individual nucleotides), then a statistical machine learning procedure is applied to the transformed data to produce a summary or to learn a classification function. Analyses of this kind are the design goal of the MapReduce paradigm [31]. Using Tsvetok as a generator for Apache Hadoop, Natalia is designing MapReduce solutions for the principal whole-genome and data-mining analyses used by MAGNONE for eukaryote and prokaryote comparative genomics.

6.4. Affinity Proteomics: Standards for affinity binders

Participants: David James Sherman [correspondant], Natalia Golenetskaya.

Last year we successfully completed and released the MIAPAR and PSI-PAR international standards for knowledge representation and data exchange of affinity binder properties, a five-year effort organized as part of the ProteomeBinders and HUPO-PSI consortia. These standards were reported in Nature Biotechnology and Molecular and Cellular Proteomics to the research community [3] [37], [52] and extend previous work [38], [43]. One long-standing issue is the adoption of these standards by individual researchers in the lab: initial data entry must be simple enough that standards-based reporting can be integrated into the process
of writing the paper. We used an extensive dataset of affinity proteomics data to evaluate “last mile” tools for data entry and initial reporting of affinity proteomics data, and identified places where existing tools need to be adapted to meet these specific needs[21].

6.5. Inferring metabolic models

Participants: David James Sherman [correspondant], Pascal Durrens, Tiphaine Martin, Nicolás Loira, Anna Zhukova.

In collaboration with Prof Jean-Marc Nicaud’s lab at the INRA Grignon, we developed the first functional genome-scale metabolic model of an oleaginous yeast. Most work in producing genome-scale metabolic models has focused on model organisms, in part due to the cost of obtaining well-annotated genome sequences and sufficiently complete experimental data for refining and verifying the models. However, for many fungal genomes of biotechnological interest, the combination of large-scale sequencing projects and in-depth experimental studies has made it feasible to undertake metabolic network reconstruction for a wider range of organisms.

An excellent representative of this new class of organisms is *Yarrowia lipolytica*, an oleaginous yeast studied experimentally for its role as a food contaminant and its use in bioremediation and cell factory applications. As one of the hemiascomycetous yeasts completely sequenced in the Génolevures program it enjoys a high quality manual annotation by a network of experts. It is also an ideal subject for studying the role of species-specific expansion of paralogous families, a considerable challenge for eukaryotes in genome-scale metabolic construction. To these ends, we undertook a complete reconstruction of the *Y. lipolytica* metabolic network.

Methods: A draft model was extrapolated from the *S. cerevisiae* model iIN800, using *in silico* methods including enzyme conservation predicted using Génolevures and reaction mapping maintaining compartments. This draft was curated by a group of experts in *Y. lipolytica* metabolism, and iteratively improved and validated through comparison with experimental data by flux balance analysis. Gap filling, species-specific reactions, and the addition of compartments with the corresponding transport reactions were among the improvements that most affected accuracy.

Results: We produced an accurate functional model for *Y. lipolytica*, MODEL1111190000 in Biomodels.net, that has been qualitatively validated against gene knockouts.

6.6. Hierarchical modeling with BioRica

Participants: David James Sherman [correspondant], Tiphaine Martin, Alice Garcia, Rodrigo Assar-Cuevas, Nicolás Loira.

A recurring challenge for *in silico* modeling of cell behavior is that experimentally validated models are so focused in scope that it is difficult to repurpose them. Hierarchical modeling is one way of combining specific models into networks. Effective use of hierarchical models requires both formal definition of the semantics of such composition, and efficient simulation tools for exploring the large space of complex behaviors.

BioRica is a high-level hierarchical modeling framework for models combining continuous and discrete components. By providing a reliable and functional software tool backed by a rigorous semantics, we hope to advance real adoption of hierarchical modeling by the systems biology community. By providing an understandable and mathematically rigorous semantics, this will make is easier for practicing scientists to build practical and functional models of the systems they are studying, and concentrate their efforts on the system rather than on the tool.

Rodrigo Assar formalized two strategies for integrating discrete control with continuous models, coefficient switches that control the parameters of the continuous model, and strong switches that choose different models. This was translated by Alice Garcia into a BioRica specification for hybrid systems that assures integrity of models, allowing composition, reconciliation, and reuse of models with SBML specifications. Rodrigo used this approach to describe two systems: wine fermentation kinetics, and cell fate decisions leading to bone and fat formation[11]. In the first, known models that describe the responses of yeast cells to different
temperatures, resources and toxins, were reconciled using coefficient switches that gave the best adjustment of the model depending on the initial conditions and fermentation variable. In the second, a combination of accurate models to predict the bone and fat formation in response to activation of pathways such as the Wnt pathway, and changes of conditions affecting these functions such as increments in Homocysteine, were used to analyze the responses to treatments for osteoporosis and other bone mass disorders. Our hope is that this is a first step in obtaining *in silico* evaluations of medical treatments before testing them *in vivo* or *in vitro*.

Maria Lluberes of the University of Puerto Rico visited MAGNOME and we established formal relationships between BioRica models and probabilistic boolean networks.
6. New Results

6.1. Scene and camera reconstruction

Participants: Marie-Odile Berger, Srikrishna Bhat, Nicolas Noury, Gilles Simon, Frédéric Sur.

6.1.1. Image point correspondences and repeated patterns

Matching or tracking interest points between several views is one of the keystones of many computer vision applications, especially when considering structure and motion estimation. The procedure generally consists in several independent steps: interest point extraction, then interest point matching by keeping only the “best correspondences” with respect to the similarity between some local descriptors, and final correspondence pruning to keep those that are consistent with a realistic camera motion (here, consistent with epipolar constraints or homography transformation.) Each step in itself is a delicate task which may endanger the whole process. In particular, repeated patterns give rise to lots of false correspondences in descriptor-based matching. Actual correspondences are thus hardly, if ever, recovered by the final pruning step. Dealing with repeated patterns is of crucial importance in man-made environments. Starting from a statistical model by Moisan and Stival [25], we have proposed a one-stage approach for matching interest points based on simultaneous descriptor similarity and geometric constraint. The resulting algorithm has adaptive matching thresholds and is able to pick up point correspondences beyond the nearest neighbour. We have also shown how to improve ASIFT [26], an effective point matching algorithm to make it more robust to the presence of repeated patterns [5], [23], [8].

6.1.2. Visual words for pose computation

Visual vocabularies are standard tools in the object/image classification literature, and are emerging as a new tool for building point correspondences for pose estimation. Within S. Bhat’s PhD thesis, we have proposed several methods for visual word construction dedicated to point matching, with structure from motion and pose estimation applications in view. The three dimensional geometry of a scene is first extracted with bundle adjustment techniques based on keypoint correspondences. These correspondences are obtained by grouping the set of all SIFT descriptors from the training images into visual words using transitive closure (TC) techniques. We obtain a more accurate 3D geometry than with classical image-to-image point matching. In a second on-line step, these visual words serve as 3D point descriptors that are robust to viewpoint change, and are used for building 2D-3D correspondences on-line during application, yielding the pose of the camera by solving the PnP problem. Several visual word formation techniques have been compared with respect to robustness to viewpoint change between the learning and the test images. Our experiments showed that the adaptive TC visual words are better in many ways when compared to other classical techniques such as K-means [12].

6.1.3. Tracking by synthesis using point features and pyramidal blurring

Tracking-by-synthesis is a promising method for markerless vision-based camera tracking, particularly suitable for Augmented Reality applications. In particular, it is drift-free, viewpoint invariant and easy-to-combine with physical sensors such as GPS and inertial sensors. While edge features have been used successfully within the tracking-by-synthesis framework, point features have, to our knowledge, still never been used. This is probably due to the fact that real-time corner detectors are weakly repeatable between a camera image and a rendered texture.
We compared the repeatability of commonly used FAST, Harris and SURF interest point detectors across view synthesis [17]. We showed that adding depth blur to the rendered texture can drastically improve the repeatability of FAST and Harris corner detectors (up to 100% in our experiments), which can be very helpful, e.g., to make tracking-by-synthesis running on mobile phones. We proposed a method for simulating depth blur on the rendered images using a pre-calibrated depth response curve. In order to fulfil the performance requirements, a pyramidal approach was used based on the well-known MIP mapping technique. We also proposed an original method for calibrating the depth response curve, which is suitable for any kind of focus lenses and comes for free in terms of programming effort, once the tracking-by-synthesis algorithm has been implemented.

**6.1.4. Acquisition of 3D calibrated data**

Christel Leonet joined the team in October 2010 as an INRIA assistant engineer with the aim to build an integrated 3D acquisition system. More specifically, the objective of her work is to combine an IMU (Inertial Measurement Unit), a GPS receiver, a laser rangefinder and a video camera for ground truth data acquisitions of camera movements and scene structures. These data will be useful to validate several algorithms developed in our team. This year she dealt with the hand-eye coordination between the different devices. Moreover, a 3D laser pointer has been built, which allows to acquire textured 3D polygons by pointing them with the laser attached to the camera and the IMU put on a tripod.

**6.2. Medical imaging**

**Participants:** René Anxionnat, Marie-Odile Berger, Abdulkadir Eryildirim, Erwan Kerrien, Pierre-Frédéric Villard, Brigitte Wrobel-Dautcourt, Ahmed Yureidini.

**6.2.1. Vessel reconstruction with implicit surfaces**

Our research activity is led in collaboration with Shacra project-team from INRIA Lille-Nord Europe and the Department of Interventional Neuroradiology from Nancy University Hospital. It was pursued this year in the context of the SOFA-InterMedS INRIA Large-Scale Initiative.

Our objective is the implicit modeling of blood vessels from 3DRA data, with the aim to use these models for real-time simulation of interventional procedures. Within A. Yureidini’s PhD thesis, a new model was developed consisting of a tree of local implicit blobby models. This model was implemented in Sofa simulation platform, enabling interactive simulation time (60 fps) and thereby showing an impressive realism during tool navigation [20]. We focused this year on the extensive validation of our RANSAC-based vessel tracking algorithm, by comparison with state of the art Multiple Hypothesis Testing [24] on 10 patient data [18].

Our initial mechanism to fit the implicit model to patient data relies on the minimization of a multi-termed energy. This energy was put under scrutiny, assessing the contribution of each energy term [19]. Our current goal is to reintroduce the raw image data for a more accurate energy computation, with the aim to design a blobby deformable model.

**6.2.2. A variational framework for automatic modeling of the vocal tract**

Segmenting the vocal tract in MRI is difficult especially because the tongue may move near other edges in the oral cavity, such as the palate or the teeth, which may disturb the segmentation process. The idea explored in our past work was to guide the segmentation with shape priors learnt on a reference speaker within a shape-based variational framework.

Shape priors were incorporated into segmentation via a PCA model with a relatively large number of components to enable the adaptation of the model to strong morphological differences. During this year, this work was continued with the aim to detect tongue contours in physical correspondences, thus allowing us to build a model of the vocal tract. An automatic method for the identification of the end points as well as an improved variational framework to obtain curves in physical correspondences was described in [15]. Second, we extensively assessed the segmentation process. We experimentally showed that the reference model is able to cope with strong morphological differences between speakers with a limited numbers of modes.
6.2.3. Medical simulators based on task analysis

We present here two works done within a collaboration with Imperial College of London. In order to validate a virtual reality ultrasound-guided targeted liver biopsy procedure simulators previously designed \[ 22 \], we have worked on task analysis to deconstruct individual procedural tasks followed by metric definition and critical performance indicator identification. Consultant and trainee scores on the performance metrics were compared. Independent t-tests revealed significant differences between trainees and consultants on 3 performance metrics: targeting, probe usage time and mean needle length in beam. ANOVA reported significant differences across years of experience on seven performance metrics: no-go area touched, targeting, length of session, probe usage time, total needle distance moved, number of skin contacts, total time in no-go area. More experienced participants consistently received better performance scores on all 19 performance metrics \[ 9 \].

We used the same task analysis technique to design an inguinal hernia repair simulator \[ 16 \]. The task analysis allowed to break down the complex operation into sub-tasks and it also provided the foundation for useful and productive discussions between clinical staff and developers. We deployed our system as an e-learning application, allowing surgeons to easily access the application.

6.3. National Initiatives

- SOFA-InterMedS (2009–) Participants: R. Anxionnat, M.O. Berger, E. Kerrien, A. Yureidini. The SOFA-InterMedS large-scale INRIA initiative is a research-oriented collaboration across several INRIA project-teams, international research groups and clinical partners. Its main objective is to leverage specific competences available in each team to further develop the multidisciplinary field of Medical Simulation research. Our action within the initiative takes place in close collaboration with both Shacra INRIA project-team in Lille and the Department of diagnostic and therapeutic interventional neuroradiology of Nancy University Hospital. We aim at providing in-vivo models of the patient’s organs, and in particular a precise geometric model of the arterial wall. Such a model is used by Shacra team to simulate the coil deployment within an intracranial aneurysm. The associated medical team in Nancy, and in particular our external collaborator René Anxionnat, is in charge of validating our results.

- ANR ARTIS (2009-2012) Participants: M.O. Berger, A. Eryildirim, E. Kerrien. The main objective of this fundamental research project is to develop inversion tools and to design and implement methods that allow for the production of augmented speech from the speech sound signal alone or with video images of the speaker’s face. The Magrit team is especially concerned with the development of procedures allowing for the automatic construction of a speaker’s model from various imaging modalities.

- ANR Visac (2009-2012) Participants: M.O. Berger, B. Wrobel-Dautcourt. The ANR Visac is about acoustic-visual speech synthesis by bimodal concatenation. The major challenge of this project is to perform speech synthesis with its acoustic and visible components simultaneously. Within this project, the role of the Magrit team is twofold. One of them is to build a stereovision system able to record synchronized audio-visual sequences at a high frame rate. Second, a highly realistic dense animation of the head must be produced.

6.4. European Initiatives

6.4.1. Major European Organizations with which you have followed Collaborations

Partner 1: Imperial College, London.
Pierre-Frédéric Villard has a Honorary Research Fellow contract with Imperial College. The research focusing on medical simulators based on task analysis have been done within this link. The collaboration has involved 2 research visits in London to mainly incorporate work done in Lorraine both at the LORIA and with Nancy University intern students. There was also a participation as an activity leader in a one-week summer school on Haptic Technology (to give the basics of computer haptics, including visual and haptics rendering, force feedback, haptic interfaces, collision detection, collision response and deformation modelling).
5. New Results

5.1. Decision Making

5.1.1. Optimizing Automated Service Discovery

Participant: Jörg Hoffmann.

Michael Stollberg (SAP Research, Germany) and Dieter Fensel (University of Innsbruck, Austria) are external collaborators.

We completed earlier work, done while all authors were employed at the University of Innsbruck, and published it in the International Journal of Semantic Computing [10]. In a nutshell, the work proposes to use first-order logic for annotating web services to accomplish better precision and recall in service discovery; its core contribution is a technique making such discovery more effective – discovery here involves first-order logical reasoning – by designing a caching technique storing known relationships between available services and possible discovery queries.

5.1.2. Overview of Semantic Web Service Technologies

Participant: Jörg Hoffmann.

Stijn Heymans (SemanticBits, USA), Annapaola Marconi (Fondazione Bruno Kessler, Trento, Italy), Joshua Phillips (SemanticBits, USA), and Ingo Weber (University of New South Wales, Sydney, Australia) are external collaborators.

We were invited to write a book chapter about the basic AI technologies underlying semantic Web service discovery and composition. The chapter has been published as part of a book entitled “Handbook of Service Description – USDL and its Methods” in Springer-Verlag [46].

5.1.3. Analyzing Planning Domains to Predict Heuristic Function Quality

Participant: Jörg Hoffmann.

The heuristic search approach to planning (cf. the above) rises and falls with the quality of the heuristic estimates. The dominant method, especially in satisficing (non-optimal) planning, is to approximate a heuristic function called $h^+$ – this is used in almost every state of the art satisficing planning system. In earlier work, Jörg Hoffmann showed that $h^+$ has some amazing qualities, in many traditional planning benchmarks, in particular pertaining to the complete absence of local minima. [62] His proofs of this are hand-made, raising the question whether such proofs can be lead automatically by domain analysis techniques. The possible uses of such analysis are manifold, e.g., for automatic configuration of hybrid planners or for giving hints how to improve the domain design. The question has been open since 2002. A serious attempt of Jörg Hoffmann resulted in disappointing results – his analysis method has exponential runtime and succeeds only in two extremely simple benchmark domains. In contrast to this, in our work here we answer the question in the affirmative. We establish connections between certain easily testable syntactical structures, called “causal graphs”, and $h^+$ topology. This results in low-order polynomial time analysis methods, implemented in the Torchlight tool, cf. Section 4.2. Of the 12 domains where Hoffmann proved the absence of local minima, TorchLight gives strong success guarantees in 8 domains. Empirically, its analysis exhibits strong performance in a further 2 of these domains, plus in 4 more domains where local minima may exist but are rare. We show that, in this way, TorchLight can distinguish Hoffmann’s “easy” domains from the “hard” ones. By summarizing structural reasons for analysis failure, TorchLight also provides diagnostic output pin-pointing potentially problematic aspects of the domain. A conference paper on this work was published at ICAPS 2011 [25], and nominated for the best paper award there. A journal paper was published in the Journal of AI Research (JAIR) [9].
5.1.4. Relaxing Bisimulation for State Aggregation in the Computation of Lower Bounds

Participant: Jörg Hoffmann.

Raz Nissim (Ben-Gurion University, Beer-Sheva, Israel) and Malte Helmert (University of Freiburg, Germany) are external collaborators.

Like the previous line of work, this addresses planning as heuristic search, specifically the automatic generation of heuristic estimates. This is also the core question investigated in the BARQ project, see below. In preparation of this project, we are conducting this line of research, which explores some of the most basic ideas behind BARQ. The basic technique under consideration was developed in prior work outside INRIA. [61] The heuristic estimates are lower bounds generated from a quotient graph in which sets of states are aggregated into equivalence classes. A major difficulty in designing such classes is that there are exponentially many states. Despite this, our technique allows explicit selection of individual states to aggregate, via an incremental process interleaving it with state space re-construction steps. We have shown previously that, if the aggregation decisions are perfect, then this technique dominates the other known related techniques, and sometimes produces perfect estimates in polynomial time. But how to take these decisions? Little is known about this as yet. In the present work, we start from the notion of a “bisimulation”, which is a well-known criterion from model checking implying that the quotient system is behaviorally indistinguishable from the original system— in particular, the cost estimates based on a bisimulation are perfect. However, bisimulations are exponential even in trivial planning benchmarks. We observe that bisimulation can be relaxed without losing any information as far as the cost estimates are concerned. Namely, we can ignore the “content of the messages sent”, i.e., the state transition labels. Such relaxed bisimulations are often exponentially smaller than the original ones. We show to what extent such relaxation can be applied also within our incremental construction process. As a result, in several benchmarks we obtain perfect estimates in polynomial time, and we significantly increase the set of benchmark instances that can be solved with this approach. Indeed, the approach obtained a 2nd place in the optimal track of the 2011 International Planning Competition, and was part of the 1st-prize winning portfolio. A conference paper was published at IJCAI 2011 [28], and a journal paper is under preparation for submission to the Journal of the ACM.

5.1.5. Relaxing Bisimulation by Choosing Transition Subsets

Participants: Michael Katz, Jörg Hoffmann.

Malte Helmert (University of Freiburg, Germany) is an external collaborator.

This line of work builds on the previous one by designing new methods for relaxing bisimulations. The key idea is to apply the bisimulation property to only a subset of the transitions in the system under consideration. We showed that one can ignore large subsets of transitions without losing any information, i.e., while still guaranteeing to obtain a perfect heuristic. At the same time, such a relaxed bisimulation makes less distinctions and may thus be exponentially smaller. For practical purposes, we designed several approximate strategies relaxing more, obtaining smaller abstractions at the expense of information loss. The techniques are currently being evaluated empirically, and a paper submission is in preparation for ICAPS’12.

5.1.6. Improving \( h^+ \) by Taking Into Account (Some) Negative Effects

Participants: Emil Keyder, Jörg Hoffmann.

Patrik Haslum (NICTA, Australia) is an external collaborator.

Like the previous lines, this is on planning as heuristic search. As mentioned above in Section 5.1.3, approximating the \( h^+ \) heuristic is the dominant approach to obtain estimates in satisficing (non-optimal) planning. That notwithstanding, \( h^+ \) is obtained by ignoring all negative effects, which of course leads to very bad estimates in domains where these domains play a key role, for example puzzle-like domains, e.g. Rubic’s cube, where actions interfere intensively with each other. It has long (for almost 10 years) been an active research issue how to take at least some of the negative effects into account when computing \( h^+ \). All attempts, however, remained at rather ad-hoc methods, like, counting the number of violated binary constraints (pairs of facts that cannot be true at the same time) within the relaxed plan underlying the estimate. In the present work,
for the first time we provide a well-founded formal approach to the issue. As was suggested in prior work, [60], we design a compiled planning task which introduces constructs allowing $h^+$ to correctly handle a subset $C$ of fact conjunctions. Whereas this prior work requires a compilation exponential in $|C|$ – and thus allows only to introduce very few conjunctions – in our work we designed a compilation that is linear in $|C|$. We proved that one can always choose $C$ so that $h^+$ in the compiled task is a perfect heuristic. Of course, in general $C$ might have to be exponentially large to achieve this. We designed practical methods selecting $C$ in a way so that the overhead (the size of $C$) is kept at bay, while the quality of the heuristic is sufficiently improved to boost search performance. The techniques are currently being evaluated empirically, and a paper submission is in preparation for ICAPS’12.

5.1.7. Accounting for Uncertainty in Penetration Testing  
Participants: Olivier Buffet, Jörg Hoffmann.

Carlos Sarraute (Core Security Technologies) is an external collaborator.

Core Security Technologies is an U.S.-American/Argentinian company providing, amongst other things, tools for (semi-)automated security checking of computer networks against outside hacking attacks. For automation of such checks, a module is needed that automatically generates potential attack paths. Since the application domain is highly dynamic, a module allowing to declaratively specify the environment (the network and its configuration) is highly advantageous. For that reason, Core Security Technologies have been looking into using AI Planning techniques for this purpose. After consulting by Jörg Hoffmann (see also Section 6.1.1 below), they are now using a variant of Jörg Hoffmann’s FF planner (cf. Section 4.1) in their product. While that solution is satisfactory in many respects, it also has weaknesses. The main weakness is that it does not handle the incomplete knowledge in this domain – figuratively speaking, the attacker is assumed to have perfect information about the network. This results in high costs in terms of runtime and network traffic, for extensive scanning activities prior to planning. We are currently working with Core Security’s research department to overcome this issue, by modeling and solving the attack planning problem as a POMDP instead. A workshop paper detailing the POMDP model has been published at SecArt’11 [29]. While such a model yields much higher quality attacks, solving an entire network as a POMDP is not feasible. We have designed a decomposition method making use of network structure and approximations to overcome this problem, by using the POMDP model only to find good-quality attacks on single machines, and propagating the results through the network in an appropriate manner. A conference paper is in preparation for submission to ICAPS’12.

5.1.8. Searching for Information with MDPs  
Participants: Mauricio Araya, Olivier Buffet, Vincent Thomas, François Charpillet.

In the context of Mauricio Araya’s PhD, we are working on how MDPs —or related models— can search for information. This has led to various research directions that we describe now.

A POMDP Extension with Belief-dependent Rewards — A limitation of Partially Observable Markov Decision Processes (POMDPs) is that they only model problems where the performance criterion depends on the state-action history. This excludes for example scenarios where one wants to maximize the knowledge with respect to some random variables.

To overcome this limitation, we have proposed $\rho$-POMDPs, an extension of POMDPs in which the reward function depends on the belief state rather than on the state. In this framework, and under the hypothesis that the reward function is convex, we have proved that:

- the value function itself is convex; and
- if the reward function is $\alpha$-Hölder, then the value function can be approximated arbitrarily well with a piecewise linear and convex function.

These results allow for adapting a number of solution algorithms relying on approximating the value function.
This theoretical work has been first published in an international conference in December 2010, then in [36], where it has received a best paper award.

We are currently pursuing experimental work about the proposed algorithm.

**Active Learning of MDP Models** — Reinforcement Learning is about learning how to perform a task by trial and error (no model of the system to control being available). Model-based Bayesian RL (BRL) consists in all RL algorithms that maintain a belief (in the Bayesian sense) about the model of the system to control. In fact, this is a way to turn an RL problem into a POMDP—the unknown model becoming an unobservable part of the state—, thus replacing the exploration-exploitation dilemma by the definition of a prior belief over possible models.

A particular BRL task we have been considering is to actively learn the dynamical model itself, i.e., to act so as to improve the knowledge about the transition function. In a way this means solving a ρ-POMDP since the reward depends on a belief, not on a state. To that end, we have proposed several optimization criteria, and derived the corresponding reward functions, making sure that their computational complexity allows for their use in a BRL algorithm. We have also proved that a non-optimistic BRL algorithm—EXPLOIT—could be used in this particular case.

This work, along with experiments, has been published in [36] and [35] (french version).

**PAC-BAMDP Algorithms** — Exact or approximate solutions to Model-based Bayesian RL are impractical, so that a number of heuristic approaches have been considered, most of them relying on the principle of “optimism in the face of uncertainty”. Some of these algorithms have properties that guarantee the quality of their outcome, inspired by the PAC-learning (Probably Approximately Correct) framework. For example, some algorithms provably make in most cases the same decision as would be made if the true model were known (PAC-MDP property).

We have proposed a novel optimistic algorithm, BOUH, that is

- appealing in that it is (i) optimistic about the uncertainty in the model and (ii) deterministic (thus easier to study); and
- provably PAC-BAMDP, i.e., makes in most cases the same decision as a perfect BRL algorithm would.

First results about this algorithm are currently under review.

### 5.1.9. Scheduling for Probabilistic Realtime Systems

**Participant:** Olivier Buffet.

*Maxim Dorin, Luca Santinelli, Liliana Cucu-Grosjean (INRIA, TRIO team), and Rob Davies (U. of York) are external collaborators.*

In this collaborative research work (mainly with the TRIO team), we look at the problem of scheduling periodic tasks on a single processor, in the case where each task’s period is a (known) random variable. In this setting, some job will necessarily be missed, so that one will try to satisfy some criteria depending on the number of deadline misses.

We have proposed three criteria: (1) satisfying pre-defined deadline miss ratios, (2) minimizing the worst deadline miss ratio, and (3) minimizing the average deadline miss ratio. For each criterion we propose an algorithm that computes a provably optimal fixed priority assignment, i.e., a solution obtained by assigning priorities to tasks and executing jobs by order of priority.

This work has been presented in [26].

We also collaborate on other topics linked to real-time scheduling, as (i) on search algorithms for deterministic, but multiprocessor, problems [38], and (ii) on the problem of which jobs to drop (on-going work).

### 5.1.10. Adaptive Management with POMDPs

**Participant:** Olivier Buffet.
Iadine Chadès, Josie Carwardine, Tara G. Martin (CSIRO), Samuel Nicol (U. of Alaska Fairbanks) and Régis Sabbadin (INRA) are external collaborators.

In the field of conservation biology, adaptive management is about managing a system, e.g., performing actions so as to protect some endangered species, while learning how it behaves. This is a typical reinforcement learning task that could for example be addressed through BRL.

Here, we consider that a number of experts provide us with one possible model each, assuming that one of them is the true model. This allows making decisions by solving a mixed observability MDP (MOMDPs), where the hidden part of the state corresponds to the model (in cases where all other variables are fully observable).

We have conducted preliminary studies of this approach, using the scenario of the protection of the Gouldian finch, and focusing on the particular characteristics that could be exploited to more efficiently solve this problem. First results have been presented in [39].

5.1.11. Information Gathering with Sensor Systems

Participant: Olivier Buffet.

Elodie Chanthery, Matthieu Godichaud (LAAS-CNRS) and Marc Contat (EADS) are external collaborators.

The DOPEC project was a DGA PEA (upstream studies project) on the optimization of the use of sensor systems. In collaboration with EADS (project leader) and the LAAS, we have worked on autonomous sequential decision making problems. We were more particularly interested, on the one hand, in multi-agent problems and, on the other hand, in taking uncertainties into account.

The overall architecture that has been developed in the context of this project was presented in a national and an international conference [40], [23].

5.1.12. How do real rats solve non-stationary (PO)MDPs?

Participant: Alain Dutech.

Etienne Coutureau and Alain Marchand (Centre de Neurosciences Intégratives et Cognitives (CNIC), UMR 5228, Bordeaux) are external collaborators.

For a living entity, using simultaneously various ways for learning models or representations of its environment can be very useful to adapt itself to non-stationary environments in a Reinforcement Learning setting. In the rats and in the monkey, two different action control systems lie in specific regions of the prefrontal cortex. Neurobiologists and computer scientists find here a common ground to identify and model these systems and the selection mechanisms between them, selection that could depend on uncertainty or error signals. Using real data collected on rats with or without prefrontal lesions, reinforcement learning models are used and evaluated in order to better understand this behavioral flexibility. MAIA is more particularly involved as a reinforcement learning expert in order to suggest and build models of the various learning mechanisms. In particular, we have used an on-policy learning scheme (SARSA) to investigate how well the use of simple or complex representations (with or without memory of the immediate past) can best model the learning behavior of rats in instrumental contingency degradation tasks [7].

This work has led us to investigate in more details the relations between the prefrontal cortex and the basal ganglia and their respective role when rats learn to solve non-stationary tasks. The research is conducted through the PEPII project IMAVO (see 7.2.7).

5.1.13. Developmental Reinforcement Learning

Participants: Alain Dutech, Olivier Buffet.

Luc Sarzyniec and Joël Legrand (M2R Student of UHP Nancy 1) are external collaborators.
The goal of this work is to investigate how reinforcement learning can benefit from a developmental approach in the field of robotics. Instead of having a robot directly learn a difficult task using appropriate but rich (in the number of dimensions) sensory and motor spaces, we have followed an incremental approach. Both the number of perception and action dimensions increase only when the performance of the learned behavior increases. At the core of the algorithm lies a neuronal approximator used to compute the value function of the current policy of the robot. When the perception or action space grow, neurons or networks, initialized from existing neurons and networks, are added to the control architecture.

Thus far, our research focussed on the approximation architecture used to evaluate the $Q$-function. In simple robotic task, we investigated the use of Multi-Layer Perceptrons, either one approximation for every possible action ([41]) or one unique global approximator with as many outputs as the number of actions (Master Thesis of Joël Legrand). Currently, a reservoir computing architecture is under study as depicted in [16].

5.1.14. Classification-based Policy Iteration with a Critic

Participant: Bruno Scherrer.

Victor Gabillon, Alessandro Lazaric and Mohammad Ghavamzadeh (from Sequel INRIA-Lille) are external collaborators.

We study the effect of adding a value function approximation component (critic) to rollout classification-based policy iteration (RCPI) algorithms. The idea is to use the critic to approximate the return after we truncate the rollout trajectories. This allows us to control the bias and variance of the rollout estimates of the action-value function that are strongly related to the length of the rollout trajectories. Therefore, the introduction of a critic can improve the accuracy of the rollout estimates, and as a result, enhance the performance of the RCPI algorithm. We present in [49], [20] a new RCPI algorithm, called direct policy iteration with critic (DPI-Critic), and provide its finite-sample analysis when the critic is based on LSTD and BRM methods. We empirically evaluate the performance of DPI-Critic and compare it with DPI and LSPI in two benchmark reinforcement learning problems.

5.1.15. Linear Approximation of Value Functions

Participant: Bruno Scherrer.

Matthieu Geist (Supélec, Metz) is an external collaborator

In the framework of Markov Decision Processes, we consider the problem of learning a linear approximation of the value function of some fixed policy from one trajectory possibly generated by some other policy.

In [30], [42], [51], we describe a systematic approach for adapting on-policy learning least squares algorithms of the literature (LSTD, LSPE, FPKF and GPTD/KTD) to off-policy learning with eligibility traces. This leads to two known algorithms, LSTD(\(\lambda\))/LSPE(\(\lambda\)) and suggests new extensions of FPKF and GPTD/KTD. We describe their recursive implementation, discuss their convergence properties, and illustrate their behavior experimentally. Overall, our study suggests that the state-of-art LSTD(\(\lambda\)) remains the best least-squares algorithm.

We also consider the task of feature selection. A promising approach consists in combining the Least-Squares Temporal Difference (LSTD) algorithm with \(\ell_1\)-regularization, which has proven to be effective in the supervised learning community. This has been done recently with the LARS-TD algorithm, which replaces the projection operator of LSTD with an \(\ell_1\)-penalized projection and solves the corresponding fixed-point problem. However, this approach is not guaranteed to be correct in the general off-policy setting. In [21], we take a different route by adding an \(\ell_1\)-penalty term to the projected Bellman residual, which requires weaker assumptions while offering a comparable performance. This comes at the cost of a higher computational complexity if only a part of the regularization path is computed. Nevertheless, our approach ends up to a supervised learning problem, which let envision easy extensions to other penalties.
5.2. Understanding and mastering complex systems

5.2.1. Complex systems: simulation, control and definition

5.2.1.1. Adaptive control of a complex system based on its multi-agent model

Participants: Vincent Chevrier, Tomas Navarrete.

Laurent Ciarletta (Madynes team, LORIA) is an external collaborator.

We are interested in how to build a control mechanism for a complex/dynamic system. Specifically, we want to evaluate the effectiveness of creating a control mechanism based on a multi-agent model of the system[12]. Multi-agent models can be adapted to that purpose since usual approaches using analytical models as basis can be untractable when dealing with such systems; and because if we consider that the available control actions are meant to be applied locally, a multi-agent model is necessary. We are currently working on a case study within the dynamic networks domain, namely the free-riding phenomenon present in peer-to-peer networks.

We propose an architecture that gathers information from the system and uses it to parametrize and tune a set of multi-agent models. The outcome of simulations is used to decide which control actions have to be applied to the system, in order to achieve a predefined control objective. We consider that we do not have complete information to characterize the state of the system and hence would like to focus on the following two issues of the control problem that we have identified:

1. How to build a multi-agent model that represents the evolution of a dynamic network. That is, what to do when the information given by the simulation of the multi-agent is in contradiction with the information gathered from the system
2. How to build an adaptive control mechanism based on the multi-agent model of a dynamic network. That is, how to use the information given by the multi-agent model to achieve the control objective.

The architecture we proposed, is designed as a control loop composed of the following steps: estimate the state of the system and instantiate multi-agent models accordingly, simulate different control actions, choose a control action and apply it. From one cycle to another of the control loop, each step can be tuned (in terms of model parameters, control action selection process, sampling strategy, etc.) to overcome the previously mentioned issues of the control problem.

The architecture is currently specified in terms of a formal notation. We have already implemented the architecture within the context of the free-riding problem where we use the PeerSim simulator as the target system to control.

Within our case study, we have conducted two different sets of experiments to investigate under which conditions our control architecture can achieve its goal and to investigate the efficiency of different sampling methods to estimate the state of the network. We have effectively managed to drive the system to a state where the majority of the peers share, when the initial conditions, without intervention from our architecture, would drive the system to a state where no peer would share.

The elements of the architecture having an impact on the performance of the control obtained have been identified. These are: the initialization of the parameters of the models used to estimate the state of the system, predict the evolution of the system and test the possible control actions, as well as the strategy used to observe the system and the different time horizons to consider within the architecture.

The next steps are to better identify the advantages and limits of the proposed architecture and to widen the problem family in the free-riding problem.

5.2.1.2. Multi Modeling and multi-simulation

Participants: Vincent Chevrier, Julien Siebert.

This work is undertaken in a joint PhD Thesis between MAIA and Madynes Team. Laurent Ciarletta (Madynes team, LORIA) is co-advisor of this PhD.
Complex systems generally require to use different points of view (abstraction levels) at the same time on the system in order to capture and to understand all the dynamics and the complexity. Being made of different interacting parts, a model of a complex system also requires simultaneously modeling and simulation (M&S) tools from different scientific fields.

Building a model and a simulation of a complex system from the interaction of the different existing M&S tools present in each scientific field involved, is also a complex task. To represent a complex system, we need to couple several models (multi-modeling) that each represents a part of the whole system. Each model could have been designed by and for a specific scientific domain. Making different models interact raises hard issues on model interoperability (semantic coherence, formalism compatibility). As many simulators exist in the scientific fields involved, a possible approach to make a simulation of a complex system is to reuse and to make interact these existing simulators. Since each simulator has been developed for specific purposes, making them interact (multi-simulation) raises simulation issues (interoperability, synchronization).

The multi-agent paradigm is an homogeneous solution both for multi-modeling and multi-simulation of complex systems. On the one hand, a multi-agent model per se is a multi-model: a multi-agent model is made of interacting agent models and environment models. On the other hand, agent oriented software engineering (AOSE) allows designers to create complex softwares as a set of autonomous, heterogeneous and interacting softwares (i.e. as a multiagent system). Robustness, scalability, openness, modularity and interoperability are some of the properties that AOSE allows to achieve.

This work explores the contribution of multiagent paradigm to the fields of multi-modeling and multi-simulation of complex systems.

The first contribution of this work is to propose an homogeneous multiagent meta-model (called AA4MM[44]) that provides solutions both for multi-modeling and multi-simulation of complex systems by reusing existing and heterogeneous M&S tools. The core idea in AA4MM is to build a society of models, simulators and simulation softwares that solves the core challenges of multimodelling and simulation coupling in an homogeneous perspective. AA4MM has been implemented and used both for proof of concept and for a real case study. A proof of concept has been made by coupling different models together to develop a multi-model of a prey-predator model. This has permitted us to show both conceptual and operational properties of AA4MM such as interaction of heterogeneous models, modularity, interoperability.

This multiagent meta-model has been applied to model complex systems that are ubiquitous networks. Ubiquitous networks are highly dynamic computer networks that are composed of a great number of interacting and sometimes mobile nodes which can join or leave the system, interact together and where the environment plays a significant role either on radio communications or on the behavior of users. Modeling and simulation is the approach to evaluate these technologies or to build new ones.

5.2.1.3. Robustness of Cellular Automata and Reactive Multi-Agent Systems

Participants: Olivier Bouré, Vincent Chevrier, Nazim Fatès.

Our research on emergent collective behaviours focuses on robustness analysis, that is the behavioural resistance to perturbations in collective systems. We progressed in the knowledge of how to tackle this issue in the case of cellular automata (CA) and multi-agent systems (MAS).

We focused on the specific case of a perturbation of the updating scheme in CA, that is, changing the way cells are updated. Using similar ideas to the Influence-Reaction principle developed to resolve conflicts related to simultaneous actions, we created a new type of asynchronism, called beta-synchronism, which aims at disrupting the transmission of information about states between cells. We found out that the different types of asynchronism may induce radical change of behaviour for particular a value range of the synchrony rate [15].

More recently, our interest focused on a bio-inspired discrete dynamical system. Using the formalism of a subclass of cellular automata, lattice-gas CA, we study a model of swarming which displays qualitatively different behaviours under certain experimental conditions. We discussed these observations by relating them to the potential links with certain attributes of the model [48].
We studied a phase transition that occurs in the Greenberg-Hastings CA reaction-diffusion \[ 5 \].

The density classification problem was taken as a typical framework for studying how decentralised computations can be carried out with simple cells. Although it is known that this problem can not be solved perfectly, we showed that using randomness provides a solution with an arbitrarily high success rate \[ 17 \]. We also studied how to extend this result to the infinite-space case \cite{Papier ????}.

We studied the behaviour of the amoebae aggregation model \[ 33 \] and applied the aggregation scheme on a robotic case (ALICE robots and Khepera III with Romea interactive table).

5.2.4. Ant algorithms for multi-agent patrolling

**Participants:** Olivier Simonin, François Charpillet, Olivier Buffet, Arnaud Glad.

We proposed in 2007 an ant algorithm, called EVAP, to deal with multi-agent patrolling, which is based on the marking and the evaporation of a digital pheromone. During the simulations carried out to measure the performances of EVAP, we identified that the system can self-organize towards stationary cycles (a periodic attractor). These cycles correspond to an Hamiltonian or quasi-Hamiltonian covering of the environment, which is an optimal or quasi-optimal solution to the multi-agent patrolling problem. We then established the mathematical proof that the system can stabilize only in cycles, one per agent, having the same length (cf. publication in ECAI’2008). Moreover, we introduced new heuristics in the agent behavior that improve dramatically the time for convergence, and we proved that under deterministic hypotheses the system always converges to stable cycles (these results have been published in SASO 2009, AAMAS’10). Results of 2011 are:

- Defense of Arnaud Glad’s PhD. thesis (November 15th) synthesising theoretical and experimental studies of the EVAP algorithm. The writing of a journal article is also in progress.
- EVAP has been adapted to continuous space in the context of the SUSIE project, which consider the surveillance of an area with a set of autonomous aerial robots.

5.2.2. Multi-robot systems: swarm intelligence, cooperation, navigation

5.2.2.1. Multi-robot exploration and mapping

**Participants:** Olivier Simonin, François Charpillet, Antoine Bautin.

In the context of the ANR Cartomatic project, introduced in Sec. 7.2.3, we study multi-agent models for multi-robot deployment and mapping. This work is in line with the PhD thesis of Antoine Bautin, started in November 2009. New results of 2011 are:

- A new frontier assignment algorithm for multi-robot exploration has been proposed. It relies on counting the number of robots towards a frontier rather than considering only distances between robots and frontiers. We measured on benchmarks that the approach outperforms the two classical algorithms **closest frontier** and **Greedy approach**. Results are presented in \cite{37}, \cite{43} and are submitted to ICRA’2012.
- We implemented and experimented the approach with autonomous mobile robots in the context of the ANR Carotte challenge (June 2011, Bourges). Our team “cartomatic” obtained one of the best map of the contest, while deploying several robots.

5.2.2.2. New experimental device: the Interactive Table

**Participants:** Olivier Simonin, François Charpillet, Nicolas Beaufort.

*Olivier Rochel (INRIA research engineer, SED Nancy) is an external collaborator.*

During 2010 we developed with the Nancy INRIA SED\(^6\) (Olivier Rochel) a new experimental device dedicated to swarm robotics study. It is composed of two independent components: an interactive table able to display and to compute any active environment and a set of autonomous mobile robots able to read and write information on the environment.

\(^6\)Service d’Expérimentation et Développement
Studies using the Table in 2011 are:

- We revisited the Drogoul & Ferber Foraging model, inspired by ants and also called “robot dockers” as the agents exchange the transported resources when they meet. From this simulated model we examined how it can be implemented with real mobile robots on an interactive environment, by considering that robots drop pheromones as ants. We defined a model extending the docker model with the robots on the Table, and studied its robustness to perception failure/mistakes. This work, done with Thomas Huraux (Master 2 Recherche internship), has been published in ICTAI 2011 Int. Conference [31].

- Several students (from Science Cog. Nancy 2 Master) implemented and explored pheromone-based foraging behaviors and flocking-based navigation models (supervised by François Charpillet and Christine Bourjot).

5.2.2.3. Local control based platooning

**Participants:** Alexis Scheuer, Olivier Simonin, François Charpillet, Jano Yazbeck.

We consider decentralised control methods to operate autonomous vehicles at close spacings to form a platoon. We study models inspired by the flocking approach, where each vehicle computes its control from its local perceptions. We investigate different decentralised models in order to provide robust and scalable solutions. Open questions concern collision avoidance, stability and multi-platoon navigation.

- **Coupling lateral and longitudinal controls.** A first work [67] focused on longitudinal control, which aims at computing velocities to avoid collision when all the vehicles are moving along a fixed path. When vehicles move in a two dimensional space, a lateral controller is needed to steer the vehicles. While lateral and longitudinal controls can be considered separately, the longitudinal control should be done after the lateral control: while turning, a higher inter-vehicle distance is needed to avoid collisions.

An innovative approach to improve the quality of lateral control has been proposed during Jano Yazbeck’s internship at LORIA (03/10–07/10), entitled “Decentralised local approach for lateral control of platoons” and supervised by A. Scheuer and O. Simonin. This allows to reduce the distance between each vehicle’s path and the path of the previous vehicle, by using only embedded sensors such as a laser rangefinder. It relies on memorizing and computing in real time the previous vehicle relative trajectory. This work has been published in 2011 IEEE-RSJ International Conference on Intelligent Robots and Systems (IROS’2011) [34].

- **Finding an efficient lateral control.** To obtain an even better lateral control, and to drive each vehicle exactly in the trace of the previous one, we are developing a more efficient lateral control law. This law is defined in order to reduce exponentially the tracking error (which is more or less the distance between each vehicle’s path and the path of the previous vehicle). Once again, as for the longitudinal control [67], the formula of the control law is obtained through the proof of its property: necessary conditions are simplified in order to get the final result.

5.2.2.4. Adaptation of autonomous vehicle traffic to perturbations

**Participants:** Mohamed Tlig, Olivier Simonin, Olivier Buffet.

In the context of the European InTraDE project, one problem is to handle the displacements of numerous IAVs in a seaport. Here we assume a supervisor planning the routes of the vehicles in the port. However, in such a large and complex system, different unexpected events can arise and damage the traffic: failure of a vehicle, human mistake while driving, obstacle on roads, local re-planning, and so on.

We started focusing on a first important sub-problem of space resource sharing among multiple agents: how to ensure the crossing of two opposed flows of vehicles on a road when one of the two paths is blocked by an obstacle, e.g., a disabled vehicle. To overcome this problem, blocked vehicles have to coordinate with vehicles of the other side to share the road and manage delays. The objective is to improve traffic flow and reduce the emergence of traffic jam.

---

7 Intelligent Autonomous Vehicle
Solving this problem with reactive coordination methods is a major challenge of the PhD thesis of Mohamed Tlig (started in December 2010).

- We started by formalizing the problem and the possible actions of agents (vehicles) following a STRIPS formalism. We adapted this model dedicated to planning to the description of local rules in reactive coordination.
- We then defined and studied in simulation two decision rules that produce two different strategies: the first one alternates between two vehicles from each side of the road, and the second one gives priority to the vehicle with the highest delay. We are preparing a publication of these first results.

### 5.2.3. Ambient intelligence and Actimetry

#### 5.2.3.1. Robotics and spatial computing : the iTiles - intelligent tiles - model

**Participants:** Olivier Simonin, François Charpillet, Lionel Havet.

Olivier Rochel (INRIA research engineer, SED Nancy) is an external collaborator.

In the context of intelligent home and assistant robots, we explore the definition and use of an active floor based on a cellular network approach. We aim at exploring spatial calculus models when considering physical cells augmented with sensors where robots and humans can evolve. Since 2009, we study a model consisting in paving the floor with interconnected tiles. Each tile can communicate with its neighbors and can sense the presence of a robot or a human. A first Tile model has been defined and evaluated using a tiles emulator and real mobile robots (Kheperas III), which validated the interest of the approach. See CAR’2010 publication [68].

In 2011 we designed with the help of INRIA Grenoble SED a prototype of 9 physical tiles embedding a WSN node able of computation and communication with other tiles. From this experimental device we explored several questions:

- How to follow a person walking on such a discrete and sensitive floor? We proposed a set of distributed algorithms allowing tiles to track a person or a robot (cooperation between neighboring tiles).
- How to make communications between a robot and the tile(s) it occupies? We developed a set of functions using the wifi communication of the tiles and the robot.
- From the work mentioned in the previous items we propose the definition of a new tile network based on the SensLab technology (wire connections between tiles and wireless communications between tiles and robots/humans). This prototype has been ordered and will be installed in the beginning of 2012.

#### 5.2.3.2. Bayesian 3D Human Motion Capture Using Factored Particle Filtering

**Participants:** Abdallah Dib, Cédric Rose, Amandine Dubois, François Charpillet.

The gait deterioration of elderly people is an important factor in loss of autonomy and it increases the risk of falls. In order to evaluate this risk the MAIA team has been developing since 2003 a markerless human motion capture system that estimates the 3D positions of the body joints over time. The system uses a dynamic Bayesian network and a factored particle filtering algorithm. This year, we have evaluated the impact of using different observation functions for the Bayesian state estimation: chamfer distance, a pixel intersection and finally a pseudo-observation of the subject direction calculated from the previous output of the system. We also compared two methods for the factored generation of the particles. The first one uses a deterministic interval exploration strategy whereas the second one is based on an adaptive diffusion. The capacity of the system to recover after occlusion by obstacles was tested on simulated movements in a virtual scene [57].
An other achievement of the year has been the assessment of the accuracy and precision of this system, especially for measuring the step length of a walking human. This has been realized by Amandine Dubois during her research master [58]. An experiment with young subjects has been designed and realized. Measures of the markerless motion capture system were then compared with real values. These values were obtained through the footprints left by the subjects. Ink swabs placed at the front and rear of the shoes of each subject make it possible to mark a paper strip positioned on the ground. A statistical analysis of the results has been done by Amandine. Thus we were able to determine if the real and measured lengths were significantly different or not.

5.2.3.3. Automatic Evaluation of Vascular Access in Hemodialysis Patients

Participants: Cédric Rose, François Charpillet.

The vascular access that allows to perform the extra-corporeal circulation, is usually a vein of the arm that has been enlarged by a surgical creation of a fistula. The prevention of complications such as stenosis or thrombosis of the vascular access is a key issue in hemodialysis treatment. Many dialysis machines measure ionic dialysance by conductivity measures on the dialysate fluid. Ionic dialysance is an indicator of small molecules transfers through the dialysis membrane. Previous works have shown that the follow-up of the dialysance and the pressures along the extra corporeal circuit can help to detect at an early stage a potential complication on the vascular access. The difficulty of automating the follow-up is the large variability of the measures and the need to detect tendencies. Dynamic Bayesian networks (DBN) allow to formalize expert knowledge as a graphical stochastic model adapted to reasoning under uncertainty. In a DBN the state of the patient and the measurements are represented by interconnected temporal random variables. The relations between those variables are described using probability distributions. The proposed approach [64] is based on a supervised learning of a DBN for classifying the dialysis sessions according to a risk score describing the medical situation (0: no risk, 1: mild risk, 2: severe risk). The training of the system was performed using a dataset labeled by a medical expert. The evaluation of the results was done by performing a double-blind analysis of real data. The result was an 85% agreement rate between the human expert and the automated analysis. The purpose of the system is to assist the human expert by reporting abnormalities. The results show that a score 2 reported by the human is rarely missed by the automated analysis (only 1 case) whereas the opposite is more frequent (8 cases). The final decision to further investigate a case is taken by the human expert.
6. New Results

6.1. Type theory and formalization of mathematics

6.1.1. Foundational aspects of mechanized proofs

Participants: José Grimm, Loïc Pottier.

We attempt to prove all theorems in the “Theory of Sets” of Bourbaki. The first chapter describes Formal Mathematics, and we show that it can be interpreted in the Coq language, thanks to a bunch of axioms introduced by Carlos Simpson (CNRS, Nice), modulo some modifications. This work that was started in 2009, when J. Grimm was in the Apics project-team. A new formulation of this work using ssreflect has proved more efficient than the initial formulation relying on standard Coq.

The second chapter of Bourbaki covers the theory of sets, per se. It defines ordered pairs, correspondences, unions, intersections and products of a family of sets, as well as equivalence relations. The work of formalizing this chapter comprises 15000 lines of Coq script and is described in a technical report and a paper for the journal of formal reasoning published in 2010.

The third chapter of Bourbaki covers the theory of ordered sets, well-ordered sets, equipotent sets, cardinals, natural integers, and infinite sets; its implementation in Coq is described in [21]. This chapter is longer (22000 lines of code), and there are more exercises (18000 lines of code for about half of the exercises currently implemented).

We also looked at the univalent foundation proposed by V. Voevodsky to provide a new model for equality in type theory and simplified the proof that he proposed to derive extensionality from the univalence axiom.

6.1.2. Group theory (Character theory)

Participants: Georges Gonthier [Microsoft Research], Laurence Rideau, Laurent Théry.

We participate in the collaborative research agreement “Mathematical Components” with Microsoft Research. This project aims at evaluating the applicability of a new approach to mathematical proofs called “small-scale reflection”, especially in the domain of finite group theory [4].

This year, we have initiated the formalisation of the second book of the proof of Feit-Thompson’s theorem. The basic properties of character theories are now covered. This lets us formalised the first 4 chapters of the second book, “Character theory for the Odd Order Theorem” by Peterfalvi.

6.1.3. Proofs in geometry

Participants: Tuan Minh Pham, Yves Bertot.

The work on elementary (synthetic) geometry has been completed. A publication on the topic has also been presented at a conference [19]. This work was also the main content of Tuan Minh Pham’s thesis which was defended in November [5].

6.1.4. Towards constructive algebraic topology

Participants: Laurence Rideau, Maxime Dénès, Yves Bertot.

We have participated in the formalization of a complete chain of computation from an image (as a bitmap) to the corresponding Betti numbers and homology groups. In particular, we improved the formalization of “incidence simplicial matrices” in ssreflect. This work was described in conference article [17].

6.1.5. Computing with polynomials and matrices

Participants: Maxime Dénès, Yves Bertot.
The libraries of the project "Mathematical Components" propose a rather complete formalisation of polynomials and matrices. Unfortunately, these objects cannot be used directly for computing.

We have continued our study of executable algorithms to compute with matrices and polynomials inside Coq. In collaboration with other members of the European project Formath, we have looked at implementation of Strassen-Winograd and Karatsuba for fast matrix multiplication and other algorithms for various kinds of matrix normal forms: Smith normal form, Frobenius, and Jordan normal forms. This work is described in an article that has been submitted for publication.

6.1.6. Regularity of interval matrices

Participants: Guillaume Cano, Yves Bertot.

As part of our work on the regularity of interval matrices, we still needed to formalize the Perron-Frobenius theorem. This year we concentrated on an important lemma for this formalization, the Bolzano-Weierstrass theorem, which requires a usable formalization of general topology, in particular the concept of compact.

6.1.7. Type-based termination

Participants: Jorge Luis Sacchini, Benjamin Grégoire.

The work on this topic has been completed and is described in Jorge-Luis Sacchini’s Ph.D thesis, which was defended in June 2011 [6].

6.1.8. Native compilation of terms with primitive structures

Participants: Mathieu Boespflug [McGill University, Canada], Maxime Dénès, Benjamin Grégoire.

We kept working on the integration of the native compiler of the Ocaml language into a scheme for the efficient reduction of terms in the calculus of inductive constructions. This work is described in a publication at the conference CPP11 in Taiwan [14].

6.2. Proving tools

6.2.1. Connecting an SMT prover and Coq

Participants: Michaël Armand, Germain Faure [project-team Typical], Benjamin Grégoire, Chantal Keller [project-team Typical], Laurent Théry.

Our previous work on integrating SAT technology has been used as a basis to obtain SMT automation within Coq. We are now capable of replaying traces produced by the SMT prover VERRIT that deal with conjunctive normal forms, congruence closures, and linear arithmetic. We are actively working on adding quantified formulae. This work is supported by the ANR Decert project. A preliminary version [10] of this work has been presented at the workshop PSATTT’11, a full version [9] at the conference CPP11. The generic exchange proof format [13] for SMT has been presented at the workshop PXTP’11.

6.2.2. Geometric Algebras and Automatic Theorem Proving

Participants: Laurent Fuchs [Université de Poitiers], Laurent Théry.

We have completed our work on Grassman-Cayley algebras. This has been published in the post-proceedings of the ADG’10 conference. We are now working on the natural continuation of this work: Clifford’s algebras. We have very encouraging preliminary results.

6.2.3. Taylor models in Coq

Participants: Erik Martin-Dorel [project-team Arénaire], Ioana Paşca [project-team Arénaire], Micaela Mayero [Université Paris XIII], Laurence Rideau, Laurent Théry.
Taylor models are a very effective way to approximate real functions with polynomials. We have started a formalisation of these models in the Coq prover. In a first step, we have concentrated our efforts in having a computational version of these models within Coq using native computations, certified floating point and interval arithmetics. Since our first evaluations show that they behave well computationally, we are now working on completing this work with the corresponding correctness proofs. This work is supported by the ANR Tamadi.

6.2.4. Tactics on polynomial equalities: nsatz

Participant: Loïc Pottier.

We started describing in the Coq programming language an efficient algorithm to compute Gröbner bases, similar to the one written in ocaml for the nsatz tactic. We hope to prove it correct and to use it for proofs by reflexion in commutative algebra.

6.2.5. D-Modules

Participant: Loïc Pottier.

We studied normalization of non-commutative polynomials ad exponentials in the Weyl algebra. The normal forms we found are similar with the one described found by Blasiak and Flajolet for graph models.

6.3. Formal study of cryptography

6.3.1. Certicrypt

Participants: Gilles Barthe, Benjamin Grégoire, Sylvain Heraud, Santiago Zanella.

CertiCrypt is a general framework to certify the security of cryptographic primitives in the Coq proof assistant. We completed a machine-checked proof of the security of OAEP (a widely public-key encryption scheme based on trapdoor permutations) against adaptive chosen ciphertext attacks under the assumption that the underlying permutation is partial-domain one-way. This work has been described in a publication at the conference CT-RSA 2011 in San Francisco [12].

6.3.1.1. Easycrypt

Participants: Gilles Barthe [IMDEA], Benjamin Grégoire, Sylvain Heraud, Anne Pacalet, Santiago Zanella.

Based on our experience with Certicrypt, we started last year the development of the tool Easycrypt. The goal of this work is to provide a friendly tool easily usable by cryptographers without knowledge of formal proof assistants. The idea is to use the techniques formally proved in Certicrypt and to call SMT-provers instead of using Coq. We have applied Easycrypt on a variety of academic examples and one bigger example: the proof of IND-CCA security of the Cramer-Shoup cryptosystem. The drawback of this tool is that it provide less guarantees than Certicrypt for the correctness of the proof. To fill this gap we are now able to generate Coq files (based on Certicrypt) allowing to check the validity of Easycrypt proofs. This work has been described in a publication at the conference CRYPTO 2011 in Santa Barbara and has obtained the best paper Award [11].
5. New Results

5.1. Metapopulation

In the framework of metapopulation models we have obtained some new results. We have studied a metapopulation model with \( n \) patches. The migration model is with residents and travelers and the epidemic model is of SIS type. In particular, we have proved analytically the conjecture of Arino and van den Driessche [12]. The global behavior of the system is addressed in [10].

We are also currently studying, with our brazilian partners in the framework of the CAPES-COFECUB project (see international program), a metapopulation model for studying the propagation of dengue in the state of Rio. We use data provided by the foundation FIOCRUZ. These data concern different epidemics in RIO between 1986 to 2006. The effects of transportation system are taken into account.

We have considered a reduced system represented by Figure 2. The outputs of the model compare favorably with the actual data (Figure 3).

5.2. Identification and state estimation

We identify some unknown parameters using the framework of observers.

We have used numerical observers to identify the transmission parameters of bilharzia.

We also have used observers for models with unknown inputs to identify the transmission parameters for intra-host models of malaria. We have developed a method for estimating total parasite load in *falciparum* malaria patients using the clinical observations of peripheral parasitaemia. We have applied this method using the data from malariatherapy. The results are illustrated in Figure 4.
Figure 2. Reduced metapopulation model

Figure 3. Model vs data
Figure 4. Estimated total parasite load (red) and parasitaemia measures (blue)
6. New Results

6.1. Network Design and Optimization

Participants: Jean-Claude Bermond, Nathann Cohen, David Coudert, Frédéric Giroire, Dorian Mazauric, Joanna Moulierac, Nicolas Nisse, Ronan Pardo Soares, Issam Tahiri.

6.1.1. Backbone and Broadband Networks

Network design is a very wide subject that concerns all kinds of networks. We mainly study telecommunications networks which can be either physical networks (backbone, access, wireless, ...) or virtual (logical) ones. The objective is to design a network able to route a (given, estimated, dynamic, ...) traffic under some constraints (e.g. capacity) and with some quality of service (QoS) requirements. Usually the traffic is expressed as a family of requests with parameters attached to them. In order to satisfy these requests, we need to find one (or many) path(s) between their end nodes. The set of paths is chosen according to the technology, the protocol or the QoS constraints. For instance, optical backbones use the WDM technology to take better advantage of the capacity of the optical fibers often already installed. This is achieved through the multiplexing of several wavelength channels onto the same fiber. In that case a resource allocation is an optical channel, also called lightpath, which includes a path and wavelengths assigned to its links, one per link. If wavelength translation is performed in optical switching, then each channel may be assigned different wavelengths on the links of its path; otherwise the wavelength continuity imposes all the links to have the same wavelength. Of course, two lightpaths sharing a link must use different wavelengths on that link. The design can be done at the conception of the network (i.e. when conceiving a virtual network in MPLS where we have to establish virtual paths) or to adapt the network to changes (failures, new link, updates of routers, variation of traffic, ...). Finally there are various optimization criteria which differ according to the point of view: for a network user they are related to his/her satisfaction (minimizing delays, increasing available bandwidth, ...), while for a network operator, economics criteria like minimizing deployment and operating costs are more important.

This very wide topic is addressed by a lot of academic and industrial teams in the world. Our approach is to attack these problems with tools from Discrete Mathematics.

6.1.1.1. Traffic Grooming

In a WDM network, routing a connection request consists in assigning to this request a route in the physical network and a wavelength. When each request uses at most $1/C$ of the bandwidth of the wavelength, we say that the grooming factor is $C$. It means that on a given link of the network we can groom at most $C$ requests on the same wavelength. Under this constraint the objective can be either to minimize the number of wavelengths (related to the transmission cost) or to minimize the number of Add/Drop Multiplexers (ADM) used in the network (related to the cost of the nodes). During the last years, we have addressed this problem in various WDM network topologies with the goal of minimizing the total number of required ADMs.

This year, we considered the minimization of the number of ADMs in optical WDM bidirectional rings, considering symmetric shortest path routing and all-to-all unitary requests [24]. We formulate the problem in terms of graph decompositions, and state a general lower bound for all the values of the grooming factor $C$ and $N$, the size of the ring. We have studied exhaustively the cases $C = 1$, $C = 2$, and $C = 3$, providing improved lower bounds, optimal constructions for several infinite families, as well as asymptotically optimal constructions and approximations. We have also studied the case $C > 3$, focusing specifically on the case $C = k(k + 1)/2$ for some $k \geq 1$. We have also proposed optimal decompositions for several congruence classes of $N$ using the existence of some combinatorial designs.
6.1.1.2. Routing Reconfiguration and its Links with Graph Searching

In production networks, traffic evolution, failures and maintenance operations force to adapt regularly the current configuration of the network (virtual topology, routing of connections). The routing reconfiguration problem in WDM networks is thus to schedule the migration of established lightpaths from current routing to a new pre-computed one while minimizing service disruptions. We have shown in the past the relations between this problem and the graph searching problem (see also Section 6.4.3).

This year, we have continued studying the tradeoffs between the total number and the number of simultaneous interruptions that occurs during the reconfiguration process, proving in particular that the knowledge of one parameter does not help to optimize the other [28], [15]. We have also started investigating the influence of physical layer impairment constraints on the reconfiguration problem [74]. More precisely, using a new wavelength in a fiber of a WDM network forces to tune or recalibrate all already used wavelengths. We thus model the cost of using a new wavelength with a linear function of the number of already used wavelengths. We have then studied the problem of minimizing the cost of the reconfiguration according to this function. We have shown that this optimization problem is already NP-complete in a two-node network. We have also obtained general bounds and characterized instances for which the problem can be solved in polynomial time. We have additionally proposed and evaluated heuristics.

6.1.1.3. Green Networking

The minimization of ICT (Information and Communications Technologies) energy consumption has become a priority with the recent increase of energy cost and the new sensibility of public, governments and corporations towards energy consumption. ICT alone is responsible of 2% to 10% (depending on the estimations) of the world power consumption. For example, it is estimated that switches, hubs, routers account for 6 TWh per year in the US.

Several studies exhibit that the traffic load of the routers only has a small influence on their energy consumption. Hence, the power consumption in networks is strongly related to the number of active network elements, such as interfaces, line cards, base chassis, etc. In [78], [15], we have defined and modeled formally the problem of finding a routing that minimizes the (weighted) number of active network elements. We have proved that this problem is not in APX, that is there is no polynomial-time constant-factor approximation algorithm to solve it. We have obtained general bounds for this problem, and bounds for particular topologies such as trees, grids, and cliques. We have also proposed a heuristic algorithm offering good performance on real topologies. Last, we have analyzed the impact of energy efficient routing on the stretch factor and on fault tolerance.

We have also studied potential energy savings in fixed broadband wireless networks [77], [61]. See Section 6.1.2.1 for more details.

6.1.1.4. Xcast6 Treemap Islands

IP multicast is a protocol that deals with group communications with the aim of reducing traffic redundancy in the network. However, due to difficulty in deployment and poor scalability with a large number of multicast groups, IP multicast is still not widely deployed nor used on the Internet. Recently, Xcast6 and Xcast6 Treemap, the two network layer multicast protocols, have been proposed with complementary scaling properties to IP multicast: they support a very large number of active multicast sessions. However, the key limitation of these protocols is that they only support small multicast groups. To overcome this limitation, we have proposed the Xcast6 Treemap Island [96], a hybrid model of Application Layer Multicast (ALM) and Xcast6 that can work for large multicast groups. Our model has several advantages: ease of deployment, efficiency in bandwidth savings, no control message between end-host and router, zero multicast forwarding state at router and no need for a multicast address allocation protocol. In addition, this model is a potential service from which an ISP (Internet Service Provider) can get new revenue. We have shown the feasibility of our model by simulation and comparison with IP multicast and NICE protocols.

6.1.1.5. Time-Dependent Graphs - Applications to Transport Networks

In [70], we focus on time-dependent graphs which seem to be a good way to model transport networks. In the first part, we remind some notations and techniques related to time-dependent graphs. In the second one, we
introduce new algorithms to take into account the notion of probability related to paths in order to guarantee travelling times with a certain accuracy. We also discuss different probabilistic models and show the links between them.

Other results on multi-interface networks were obtained outside of MASCOTTE [37], [36], [65], [63], [66], [52], [20].

6.1.2. Wireless Networks

MASCOTTE has conducted an intense research effort on wireless access networks. From the technological and architectural point of view, the field is broad, from mesh (or multi-hop cellular) networks to ad-hoc and sensor networks. Nevertheless, many questions and approaches are generic from an algorithmic and structural prospect. In particular, we have considered three of the most prominent performance metrics for radio networks. Using combinatorial optimization and centralized algorithmic with a network design flavor, fast data gathering, call scheduling, transport capacity and energy consumption of the networks have been studied. Our approach is complementary with those developed in other INRIA project-teams such as PLANETE, MAESTRO, SWING, or POPS. The complementarity has been exploited through a joint Ph.D. between MAESTRO and MASCOTTE [15], through an ANR VERSO project in which MAESTRO, MASCOTTE, and SWING are involved, and through regular collaborations with POPS. At the international level, we cooperate with some groups in renowned research centers such as CTI of Patras in Greece, RWTH Aachen in Germany, Universities of Roma or Salerno in Italy, the Technion Institute in Israël, SFU in Vancouver, Canada, UFC Universidade Federal do Ceará, Fortaleza, Brazil, or the University of Sao Paulo in Brazil. We studied a wide range of issues of wireless networks, from the design of efficient cross-layer medium access, call scheduling and routing techniques to energy efficient optimization. We developed theoretical tools for integrating dynamic characteristics of the networks in the optimization models, and analyzing and evaluating dynamic networks. Some graph coloring problems motivated by channel assignment in wireless networks are detailed in Section 6.3.

6.1.2.1. Wireless Backhaul

We have investigated network optimization problems related to the design and configuration of fixed wireless microwave backhaul - the portion of the network infrastructure that provides interconnectivity between the access and the core networks. Unlike wired networks, the capacity of a microwave radio link is prone to variations, either due to external factors (e.g., weather) or by the action of the network operator. This fundamental difference raises a variety of new issues to be addressed appropriately. We concentrated on conceiving reliable fixed broadband wireless networks under outage probability constraints [60], [59]. We have developed a joint optimization of data routing and bandwidth assignment that minimizes the total renewal fees of licenses, while handling all the traffic requirements simultaneously. We have proposed a chance-constrained mathematical program taking into account unreliable channel conditions. This approach remains one of the main challenges of modern stochastic programming and it is still considered as very difficult and widely intractable. We have derived integer linear programming (ILP) counterparts for these chance-constrained programs and propose cutset-based valid inequalities to enhance the performance of ILP solvers. Computational results illustrate the price of reliability and present a comparative study on the performance of the different formulations. Moreover, we have been interested in potential energy savings in fixed broadband wireless networks by selectively turning off idle communication devices in low-demand scenarios [77], [61]. We have proposed a mathematical formulation of the problem relying on a fixed-charge capacitated network design (FCCND) problem, which is very hard to optimize. We have derived from this modeling heuristic algorithms producing feasible solutions in a short time. This work was done in collaboration with the SME 3Roam, and partially developed within the scope of the joint project RAISOM (Réseaux de collecte IP sans fil optimisés).

6.1.2.2. Wireless Mesh Networks

We have addressed the problem of computing the transport capacity of Wireless Mesh Networks (WMNs) dedicated to Internet access [26]. Routing and transmission scheduling have a major impact on the capacity provided to the clients. A cross-layer optimization of these problems allows the routing to take into account
Networks and Telecommunications - New Results - Project-Team MASCOTTE

contentions due to radio interference. We have presented a generic Mixed Integer Linear Programming (MILP) addressing gateway placement, routing, and scheduling optimizations in a WMN. We have then derived new optimization models that can take into account a large variety of radio interference models, and QoS requirements on the routing. We also provide efficient resolution methods that deal with realistic size instances. It allows to work around the combinatoric of simultaneously achievable transmissions and point out a critical region in the network bounding the network achievable capacity. Based upon strong duality arguments, it is then possible to restrict the computation to a bounded area. It allows for computing solutions very efficiently on large networks. We have then extended our models to deal with the dynamic characteristics of the network [75]. We have proposed a new robust optimization model that considers traffic demand uncertainty, in order to compute an optimal robust routing and bandwidth allocation in WMNs. We have presented a linear program efficiently solved by column generation, and we have quantified the price of robustness, i.e. the additional cost to pay in order to obtain a feasible solution for the robust scheme.

We have additionally investigated on the feasibility of providing network connectivity to vehicles over a predefined trajectory (trains, metros, urban buses, etc.) [14]. The communication between the vehicle and the infrastructure network is based only on WiFi technology. The contributions of this work are two-fold: 1) the horizontal handover (between WiFi access points) and 2) the design and analysis of an infrastructure network (backbone network plus WiFi access network) deployed along the trajectory of the vehicle.

6.1.2.3. Data Gathering

We have studied algorithmic and complexity issues originating from the problem of data gathering in wireless networks [56]. We give an algorithm to construct minimum makespan transmission schedules for data gathering when the communication graph is a tree network, the interference range is any integer \( m \geq 2 \), and no buffering is allowed at intermediate nodes. In the interesting case in which all nodes have to deliver an arbitrary non-zero number of packets, we provide a closed formula for the makespan of the optimal gathering schedule. Additionally, we consider the problem of determining the computational complexity of data gathering in general graphs and show that the problem is weakly NP-complete. On the positive side, we design a simple \((1 + 2/m)\) factor approximation algorithm for general networks. We have also considered the data gathering process in multi-hop wireless sensor networks [76], [57]. Wireless sensor networks (WSNs) are deployed to collect huge amounts of data from the environment. This produced data has to be delivered through sensor’s wireless interface using multi-hop communications toward a sink. The position of the sink impacts the performance of the wireless sensor network regarding delay and energy consumption especially for relaying sensors. Optimizing the data gathering process in multi-hop wireless sensor networks is, therefore, a key issue. We have addressed the problem of data collection using mobile sinks in a WSN. We provide a multi-objective optimization framework that studies the trade-off between energy consumption and delay of data collection. This framework provides solutions that allow decision makers to optimally design the data gathering plan in wireless sensor networks with mobile sinks.

6.1.3. P2P Networks

6.1.3.1. Performance Analysis of Distributed Storage Systems

Distributed or peer-to-peer storage solutions rely on the introduction of redundant data to be fault-tolerant and to achieve high reliability. To ensure long-term fault tolerance, the storage system must have a self-repair service that continuously reconstructs lost fragments of redundancy. The speed of this reconstruction process is crucial for the data survival. In [93], we propose a new analytical framework, based on queueing models, to estimate the repair time and the probability of data loss. This model takes into account the correlation of concurrent repairs. The models and schemes proposed are validated by mathematical analysis, extensive set of simulations, and experimentation using the Grid’5000 test-bed platform. Recently, the Regenerating Codes were proposed as an improvement over classical replication and erasure codes to introduce redundancy. These codes make a better use of the available bandwidth when reconstructing the missing information. In [50], we propose a new code based on a hybrid approach, Double Coding, and compare it to existing codes from the point of view of availability, durability and storage space.
6.1.3.2. Well Balanced Designs for Data Placement

In collaboration with MAESTRO. The problem we consider in [88] is motivated by data placement, in particular, data replication in video on-demand systems. We are given a set \( V \) of \( n \) servers and \( b \) files (data, documents). Each file is replicated on exactly \( k \) servers. A placement consists in finding a family of \( b \) subsets of \( V \) (representing the files) called blocks each of size \( k \). Each server has some probability to fail and we want to find a placement which minimizes the variance of the number of available files. It was conjectured that there always exists an optimal placement (with variance better than that of any other placement for any value of the probability of failure). We show that the conjecture is true if there exists a well balanced design, that is, a family of blocks, such that each \( j \)-element subset of \( V \), \( 1 \leq j \leq k \), belongs to the same or almost the same number of blocks (difference at most one). The existence of well balanced designs is a difficult problem as it contains as subproblem the existence of Steiner systems. We completely solve the case \( k = 2 \) and give bounds and constructions for \( k = 3 \) and some values of \( n \) and \( b \).

6.1.3.3. Peer-Assisted Time-shifted Streaming Systems: Design and Promises

Time-shifted streaming (or catch-up TV) allows viewers to watch their TV programs within an expanded time window. In [71], we emphasize the challenging characteristics of time-shifted TV systems that prevent known delivery systems to be used. We model time-shifted TV as multiple-interval graph, then we present a Peer-Assisted Catch-Up Streaming system, namely PACUS, where a set of end users’ computers assists the server for the content delivery. We show in particular how the PACUS tracker server can be efficiently implemented for catch-up TV. We demonstrate the benefits of PACUS by simulations. We especially highlight that PACUS reduces the traffic at the server side with the advantages of lightweight and self-adaptive unstructured peer-to-peer systems.

6.2. Simulation and Optimization Tools

Participants: Olivier Dalle, Luc Hogie, Aurélien Lancin, Emilio Mancini, Juan-Carlos Maureira, Philippe Mussi, Van Dan Nguyen, Judicaël Ribault, Issam Tahiri.

The works related to simulation and optimization tools address two kinds of issues: issues related to the development of the tools and their associated methodology, and issues related to the use of these tools in order to investigate a particular problem or assess the performances or properties of a particular system.

Since 2005, MASCOTTE has been developing a discrete event simulation architecture, named OSA, whose aim is to investigate how new software engineering techniques, such as component-based frameworks or Aspect Oriented Programming can help improving the simulation methodology, especially in terms of software reuse [16], [46], [47]. After six years of research development, OSA entered in the process of being diffused in 2011. This process is supported by a two-year INRIA “Development Action” (ADT) funding. This first year was devoted to cleaning the code base and produce a public release with a significant effort placed on user documentation and tutorial (cf http://osa.inria.fr/).

Aside our efforts on the OSA project, we are strongly involved in the USS-SimGrid ANR funded project, whose aim is at developing an efficient simulation platform geared at Grid Computing and very large scale distributed computing architectures. In this project, we worked on two tasks:

- Monitoring and characterization of the workload of large scale distributed applications [68]:
- Support for modeling Peer-to-peer applications in the SimGrid simulator (originally designed for modeling grid-computing platforms).

We also pursued our involvement in the Discrete Event Systems Specification (DEVS) standardization effort [81], [82]. This formalism has reached a strong agreement amongst the community, but it still lacks implementation standard. Since OSA is aimed at providing better support for methodology, we consider necessary to support DEVS and participate to this effort. Our particular focus was on techniques and Architecture Description Languages (ADLs) for describing very large models of distributed applications [69].
Regarding our works on simulation studies and application-oriented developments, this year was the conclusion of our effort on the Internet on Rails project [14]. In this project, we studied and designed, both by means of simulations and experimentations, a low cost communication architecture based on IEEE 802.11 WiFi to provide high quality Internet access onboard high speed trains.

6.3. Graph Theory

Participants: Julio Araújo, Jean-Claude Bermond, Nathann Cohen, Frédéric Giroire, Frédéric Havet, František Kardoš, Ana Karolinna Maia, Dorian Mazaric, Remigiusz Modrzejewski, Leonardo Sampaio, Michel Syska.

MASCOTTE principally investigates applications in telecommunications via Graph Theory (see other objectives). However it also studies a number of theoretical problems of general interest. Our research mainly focused on graph coloring and some other problems arising from networks problems.

6.3.1. Graph Coloring

Coloring and edge-coloring are two central concepts in Graph Theory. There are many important and long-standing conjectures in these areas. We are trying to make advances towards such conjectures, in particular Steinberg’s conjecture, the List coloring Conjecture and the Acyclic Edge-Coloring Conjecture.

We are also interested in coloring problems arising from some practical problems: improper coloring, $L(p,q)$-labeling, directed star arboricity and good edge-labelling. The first two are both motivated by channel assignment and the last two by problems arising in WDM networks. For many practical problems are posed in a dynamic setting, we study on-line coloring and list coloring.

We also study some other variants of coloring like non-repetitive coloring or frugal coloring.

For all the coloring problems, we also consider the associated algorithmic problem, which consists in designing algorithms for finding the minimum number of colors of a coloring of a given graph. Algorithmic results on graph coloring are presented in Section 6.4.

The most classical notion of coloring (of edges or vertices) is the one of proper coloring, in which we insist on two adjacent elements to have distinct colors. However, it is usual to consider additional constraints, as well as relaxed constraints. For each variant of coloring, one can consider, its list version in which every element $x$ is given a list $L(x)$ of prescribed colors. A graph is said to be $L$-colorable if it has an $L$-coloring (fulfilling the constraints) such that $x \in L(x)$ for all element $x$. The choosability of a graph $G$ is the smallest integer $k$ for which $G$ has an $L$-coloring whenever $|L(x)| \geq k$ for all elements $x$.

6.3.1.1. Coloring Graphs with Few Crossings

The famous Four Color Theorem states that every planar graph can be properly colored with 4 colors and Thomassen Five Color Theorem states that the choosability of every planar graph is at most 5. Hence, a natural question is to ask about the chromatic number and choosability of graphs with few crossings. In [38], we disprove a conjecture of Oporowski and Zhao stating that every graph with crossing number at most 5 and clique number at most 5 is 5-colorable. However, we show that every graph with crossing number at most 4 and clique number at most 5 is 5-colorable. We also show some colorability results on graphs that can be made planar by removing few edges. In particular, we show that if there exists three edges whose removal leaves the graph planar then it is 5-colorable. In [90], we show that every graph with two crossings is 5-choosable. We also prove that every graph which can be made planar by removing one edge is 5-choosable.

Another famous theorem on planar graphs is the one of Grötzsch, which says that every planar graph with no cycle of length 3 can be properly 3-colored. Steinberg’s Conjecture (1976) asserts that a graph with no cycles of length 4 or 5 is 3-colorable. Many approaches have been used towards this conjecture. We considered the following one in which, we relax the constraints on the color classes. Instead of insisting on them be independent sets, we allow them to induce a graph with some bounded degree. A graph $G = (V, E)$ is said to be $(i,j,k)$-colorable if its vertex set can be partitioned into three sets $V_1, V_2, V_3$ such that the graphs $G[V_1], G[V_2], G[V_3]$ induced by the sets $V_1, V_2, V_3$ have maximum degree at most $i, j, k$ respectively. Under
this terminology, Steinberg’s Conjecture says that every graph with no cycle of length 4 or 5 is \((0,0,0)\)-colorable. In [91], we prove that every graph of \(\mathcal{F}\) is \((2,1,0)\)-colorable and \((4,0,0)\)-colorable.

6.3.1.2. Acyclic, Linear and Frugal Colorings

A classical constraint added to a proper coloring is that at least three colors appears on each cycle, in which case we speak about acyclic coloring. In other words, the graph induced by the elements of any two color classes is a forest. The \emph{acyclic chromatic index} of a graph \(G\), denoted \(\chi'_a(G)\), is the minimum \(k\) such that \(G\) admits an \emph{acyclic edge-coloring} with \(k\) colors. The famous Acyclic Edge-Coloring Conjecture asserts that \(\chi'_a(G) = \Delta(G) + 2\), where \(\Delta(G)\) is the maximum degree of the graph. In [21], we conjecture that if \(G\) is planar and \(\Delta(G)\) is large enough then \(\chi'_a(G) = \Delta(G)\). We settle this conjecture for planar graphs with girth at least 5. We also show that \(\chi'_a(G) \leq \Delta(G) + 12\) for all planar \(G\).

Even stronger constraints are the following: a proper coloring of a graph is \emph{2-frugal} (resp. \emph{linear}) if the graph induced by the elements of any two color classes is of maximum degree 2 (resp. a forest of paths). In [29], we improve some bounds on the 2-frugal choosability and linear choosability of graphs with small maximum average degree.

6.3.1.3. Coloring of Plane Graphs with Constraints on the Faces

We studied several variants of vertex and edge colorings of plane graphs insisting some constraints on the faces.

A face of a vertex colored plane graph is called \emph{loose} if the number of colors used on its vertices is at least three. The \emph{looseness} of a plane graph \(G\) is the minimum \(k\) such that any surjective \(k\)-coloring involves a loose face. In [35], we prove that the looseness of a connected plane graph \(G\) equals the maximum number of vertex disjoint cycles in a dual graph \(G^*\) increased by 2. We also show upper and lower bounds on the looseness of graphs based on the number of vertices, the edge connectivity, and the girth of the dual graph. These bounds improve the result of Negami for the looseness of plane triangulations. We also present infinite classes of graphs where the equalities are attained.

A vertex coloring of a 2-connected plane graph \(G\) is a \emph{strong parity vertex coloring} if for every face \(f\) and each color \(c\), the number of vertices incident with \(f\) colored by \(c\) is either zero or odd. Czap et al. [Discrete Math. 311 (2011) 512–520] proved that every 2-connected plane graph has a proper strong parity vertex coloring with at most 118 colors. In [34], we improve this upper bound for some classes of plane graphs.

A \emph{facial parity edge coloring} of a connected bridgeless plane graph is such an edge coloring in which no two face-adjacent edges (consecutive edges of a facial walk of some face) receive the same color, in addition, for each face \(\alpha\) and each color \(c\), either no edge or an odd number of edges incident with \(\alpha\) is colored with \(c\). From Vizing’s theorem it follows that every 3-connected plane graph has a such coloring with at most \(\Delta^*+1\) colors, where \(\Delta^*\) is the size of the largest face. In [33] we prove that any connected bridgeless plane graph has a facial parity edge coloring with at most 92 colors.

A sequence \(r_1, r_2, \cdots, r_{2n}\) such that \(r_i = r_{n+i}\) for all \(1 \leq i \leq n\), is called a \emph{repetition}. A sequence \(S\) is called \emph{non-repetitive} if no \emph{block} (i.e. subsequence of consecutive terms of \(S\)) is a repetition. Let \(G\) be a graph whose edges are colored. A trail is called \emph{non-repetitive} if the sequence of colors of its edges is non-repetitive. If \(G\) is a plane graph, a \emph{facial non-repetitive edge-coloring} of \(G\) is an edge-coloring such that any facial trail (i.e. trail of consecutive edges on the boundary walk of a face) is non-repetitive. We denote \(\pi_f(G)\) the minimum number of colors of a facial non-repetitive edge-coloring of \(G\). In [41], we show that \(\pi_f(G) \leq 8\) for any plane graph \(G\). We also get better upper bounds for \(\pi_f(G)\) in the cases when \(G\) is a tree, a plane triangulation, a simple 3-connected plane graph, a hamiltonian plane graph, an outerplanar graph or a Halin graph. The bound 4 for trees is tight.

6.3.1.4. Improper Coloring

In [85] and [48], we study a coloring problem motivated by a practical frequency assignment problem and up to our best knowledge new. In wireless networks, a node interferes with the other nodes the level of interference depending on numerous parameters: distance between the nodes, geographical topography, obstacles, etc. We model this with a weighted graph \(G\) where the weights on the edges represent the noise (interference) between
the two end-nodes. The total interference in a node is then the sum of all the noises of the nodes emitting on the same frequency. A weighted \( t \)-improper \( k \)-coloring of \( G \) is a \( k \)-coloring of the nodes of \( G \) (assignment of \( k \) frequencies) such that the interference at each node does not exceed some threshold \( t \). The Weighted Improper Coloring problem, that we consider here consists in determining the weighted \( t \)-improper chromatic number defined as the minimum integer \( k \) such that \( G \) admits a weighted \( t \)-improper \( k \)-coloring. We also consider the dual problem, denoted the Threshold Improper Coloring problem, where given a number \( k \) of colors (frequencies) we want to determine the minimum real \( t \) such that \( G \) admits a weighted \( t \)-improper \( k \)-coloring. We show that both problems are NP-hard and first present general upper bounds; in particular we show a generalization of Lovász’s Theorem for the weighted \( t \)-improper chromatic number. We then show how to transform an instance of the Threshold Improper Coloring problem into another equivalent one where the weights are either 1 or \( M \), for a sufficient big value \( M \). Motivated by the original application, we study a special interference model on various grids (square, triangular, hexagonal) where a node produces a noise of intensity 1 for its neighbors and a noise of intensity 1/2 for the nodes that are at distance 2. Consequently, the problem consists of determining the weighted \( t \)-improper chromatic number when \( G \) is the square of a grid and the weights of the edges are 1, if their end nodes are adjacent in the grid, and 1/2 otherwise. Finally, we model the problem using linear integer programming, propose and test heuristic and exact Branch-and-Bound algorithms on random cell-like graphs, namely the Poisson-Voronoi tessellations.

6.3.1.5. On-line Coloring

Several on-line algorithms producing colorings have been designed. The most basic and most widespread one is the greedy algorithm. The largest number of colours that can be given by the greedy algorithm on some graph, is called its Grundy number. Determining the Grundy number of a graph is NP-hard even for \( P_4 \)-free graphs, while it is polynomial-time solvable for \( P_4 \)-free graphs. In [19], we define a new class of graphs, namely the fat-extended \( P_4 \)-laden graphs, which intersects the class of \( P_5 \)-free graphs and strictly contains the one of \( P_4 \)-free. We show a polynomial-time algorithm to determine the Grundy number of such graphs. It implies that the Grundy number can be computed in polynomial time for most graph classes defined in terms of containing few \( P_4 \)'s: \( P_4 \)-reducible, extended \( P_4 \)-reducible, \( P_4 \)-sparse, extended \( P_4 \)-sparse, ...

In [94], we study a game version of greedy coloring. Given a graph \( G = (V, E) \), two players, Alice and Bob, alternate their turns in choosing uncolored vertices to be colored. Whenever an uncolored vertex is chosen, it is colored by the least positive integer not used by any of its colored neighbors. Alice’s goal is to minimize the total number of colors used in the game, and Bob’s goal is to maximize it. The game Grundy number of \( G \) is the number of colors used in the game when both players use optimal strategies. It is proved in this paper that the maximum game Grundy number of forests is 3, and the game Grundy number of any partial 2-tree is at most 7. We also gave some complexity results on \( b \)-colorings, which is a manner of improving colorings on-line [43].

6.3.1.6. Other Results on Graph Coloring

In [18], we aim at characterizing the class of graphs that admit a good edge-labelling. Such graphs are interesting, as they correspond to set of requests in UPP-digraphs (those in which there is at most one dipath from a vertex to another) for which the minimum number of wavelengths is equal to the maximum load. This implies that the problem can be solved efficiently. First, we exhibit infinite families of graphs for which no good edge-labelling can be found. We then show that deciding if a graph admits a good edge-labelling is NP-complete. Finally, we give large classes of graphs admitting a good edge-labelling: \( C_3 \)-free outerplanar graphs, planar graphs of girth at least 6, subcubic \( C_3 \), \( K_2,3 \)-free graphs.

A wheel is a graph formed by a chordless cycle and a vertex that has at least three neighbors in the cycle. We prove in [83] that every 3-connected graph that does not contain a wheel as a subgraph is in fact minimally 3-connected. We prove that every graph that does not contain a wheel as a subgraph is 3-colorable. We were then told that this result was already proved by Thomassen, though with a different proof.

Gallai-Hasse-Roy-Vitaver Theorem states that every \( n \)-chromatic digraph contains a directed path of order \( n \). Let \( f(k) \) be the smallest integer such that every \( f(k) \)-chromatic digraph contains every oriented tree of order \( k \). Burr proved that \( f(k) \leq (k - 1)^2 \) and conjectured \( f(k) = 2n - 2 \). In [84], we give some sufficient conditions...
6.3.3. Hypergraphs

Hypergraphs, also called set systems, are a natural generalization of graphs. In a graph an edge is set of two vertices, while in a hypergraph an edge is a set of any size. It turns out to be an important notion in database theory. A digraph is $\alpha$-acyclic if it can be reduced to the null hypergraph by successively removing either a vertex which in at most one edge or an edge included in another. It is one of the possible generalizations of $\alpha$-theory. A digraph is $\alpha$-acyclic if it contains every oriented tree. In particular, we show that every acyclic $n$-chromatic digraph contains every oriented tree of order $n$. We also show that $f(k) \leq k^2/2 - k/2 + 1$. Finally, we consider the existence of antirected trees in digraphs. We prove that every antidirected tree of order $k$ is contained in every $(5k - 9)$-chromatic digraph. We conjecture that if $|E(D)| > (k - 2)|V(D)|$, then the digraph $D$ contains every antidirected tree of order $k$. This generalizes Burr’s conjecture for antidirected trees and the celebrated Erdős-Sós Conjecture. We give some evidences for our conjecture to be true.

6.3.2. Matchings and Independent Sets

Matchings and independent sets are important substructures which appears in many problems. In particular, color classes of vertex-colorings and edge-colorings are independent sets and matchings, respectively.

In [45], we show that every (sub)cubic $n$-vertex graph with sufficiently large girth has fractional chromatic number at most $2.2978$ which implies that it contains an independent set of size at least $0.4352n$. Our bound on the independence number is valid to random cubic graphs as well as it improves existing lower bounds on the maximum cut in cubic graphs with large girth.

In [39], we show that every cubic bridgeless graph $G$ has at least $2^{|V(G)|/3656}$ perfect matchings. This confirms an old and celebrated conjecture of Lovász and Plummer in the 1970’s. This improves the first superlinear bound given in [40].

6.3.3. Hypergraphs

Hypergraphs, also called set systems, are a natural generalization of graphs. In a graph an edge is set of two vertices, while in a hypergraph an edge is a set of any size. It turns out to be an important notion in database theory. A digraph is $\alpha$-acyclic if it can be reduced to the null hypergraph by successively removing either a vertex which in at most one edge or an edge included in another. It is one of the possible generalizations of forest to hypergraphs. The $\alpha$-arboricity of a hypergraph $H$ is the minimum number of $\alpha$-acyclic hypergraphs that partition the edge set of $H$. In [23], the $\alpha$-arboricity of the complete 3-uniform (every edge is a set of 3 vertices) hypergraph is determined completely.

In [80], we generalize the concept of line digraphs to line dihypergraphs. We give some general properties in particular concerning connectivity parameters of dihypergraphs and their line dihypergraphs, like the fact that the arc connectivity of a line dihypergraph is greater than or equal to that of the original dihypergraph. Then we show that the De Bruijn and Kautz dihypergraphs (which are among the best known bus networks) are iterated line digraphs. Finally we give short proofs that they are highly connected.

6.3.4. Miscellaneous

6.3.4.1. Zagreb Indices

The first and second Zagreb indices of a graph are defined by $M_1 = \sum_{v \in V(G)} d(v)^2$ and $M_2 = \sum_{uv \in E(G)} d(u)d(v)$, respectively. They are used in chemistry where it represents properties of molecules. In [17], we present some classes of graphs with prescribed degrees that satisfy $M_1/n \leq M_2/m$, where $M_1$ and $M_2$ are the first and second Zagreb indices. We also prove that for any $\Delta \geq 5$, there is an infinite family of graphs of maximum degree $\Delta$ such that the inequality is false. Moreover, we give alternative and slightly shorter proof of this inequality for trees and unicyclic graphs.

6.3.4.2. Induced Decomposition

An induced $H$-decomposition of a graph $G$ is a partition $(E_1, \cdots, E_k)$ of its edge set $E(G)$, such that the graph induced by each $E_i$, $1 \leq i \leq k$, is a copy of $H$. Bondy and Szwarcfiter asked for the maximum number $ex(n, H)$ of edges in a graph on $n$ vertices which admits an induced $H$-decomposition. In [13], we prove that for every non-empty graph $H$, $ex(n, H) = n(n - 1)/2 - o(n^2)$.

6.4. Algorithms

Participants: Julio Araújo, Janna Burman, Nathann Cohen, David Coudert, Gianlorenzo d’Angelo, Frédéric Giroire, František Kardoš, Dorian Mazauric, Nicolas Nisse, Stéphane Pérennes, Ronan Pardo Soares, Leonardo Sampaio.
MASCOTTE is also interested in the algorithmic aspects of Graph Theory. In general we try to find the most efficient algorithms to solve various problems of Graph Theory and telecommunication networks.

6.4.1. Coloring Graphs

Almost all graph coloring problems are NP-hard and most of them are even hard to approximate. Hence, to solve them efficiently, we aim at designing general exponential-time algorithms as well as polynomial-time algorithms for special classes. This is exemplified by the following results.

6.4.1.1. L(p,q)-labeling

An L(p,q)-labeling of G is an integer assignment f to the vertex set V(G) such that |f(u) − f(v)| ≥ p, if u and v are adjacent, and |f(u) − f(v)| ≥ q, if u and v have a common neighbor. Such a concept is a modeling of a simple channel assignment, in which the separation between channels depends on the distance. The goal is to find an L(p,q)-labeling f of G with minimum span (i.e. max{|f(u) − f(v), u, v ∈ V(G)}). It is well known that for all k ≥ 4, deciding if a graph has an L(p, 1)-labeling with minimum span k is NP-complete. In [42], we present exact exponential time algorithms that are faster than existing ones.

6.4.1.2. Counting and Enumerating Total and Edge Colorings

In [89], we are interested in computing the number of edge colorings and total colorings of a graph. We prove that the maximum number of k-edge-colorings of a k-regular graph on n vertices is k · (k − 1)^n/2. Our proof is constructive and leads to a branching algorithm enumerating all the k-edge-colorings of a k-regular graph using a time O*(k−1)^n/2 and polynomial space. In particular, we obtain a algorithm on time O*(2^n/2) = O*(1.4143^n) and polynomial space to enumerate all the 3-edge colorings of a cubic graph, improving the running time of O*(1.5423^n) of the algorithm due to Golovach et al. We also show that the number of 4-total-colorings of a connected cubic graph is at most 3.2^3n/2. Again, our proof yields a branching algorithm to enumerate all the 4-total-colorings of a connected cubic graph.

6.4.1.3. Coloring Graphs of Special Classes

For some coloring problems that are known to be NP-hard for general graphs, we give some polynomial-time algorithms for the restriction to some graph classes. These graph classes defined in terms of forbidden induced subgraphs. In [95], [79], we provide linear algorithms for coloring P3-free graphs. In [58], we obtain polynomial time algorithms to determine the acyclic chromatic number, the star chromatic number and the harmonious chromatic number of (q,q−4)-graphs. Such graphs are those such that no set of at most q vertices induces more than q−4 distinct P4's.

6.4.2. Complexity and Computation of Graph Parameters

We used graph theory to model various networks' problems. In general we study their complexity and then we investigate the structural properties of graphs that make these problems hard or easy. In particular, we try to find the most efficient algorithms to solve the problems, sometimes focusing on specific graph classes where the problems are polynomial-time solvable.

6.4.2.1. Path Vertex Cover

A subset S of vertices of a graph G is called a k-path vertex cover if every path of order k in G contains at least one vertex from S. The k-path vertex cover problem consists in finding such a set with minimum cardinality in G. In [25], it is shown that this problem is NP-complete for each k ≥ 2 while it can be solved in linear-time in trees. The particular case of k = 3 is studied in [44], where an exact algorithm is given with running time O*(1.5171^n) in n-node graphs. In [44], we also design a polynomial time randomized approximation algorithm with an expected approximation ratio of \( \frac{14}{11} \) for the minimum 3-path vertex cover.
6.4.2. **Convexity in Graphs**

The geodesic convexity of graphs naturally extends the notion of convexity in Euclidean metric spaces. A set $S$ of vertices of a graph $G = (V, E)$ is convex if any vertex on a shortest path between two vertices of $S$ also belongs to $S$. The convex hull of $S \subseteq V$ is the smallest convex set containing $S$. Finally, a hull set of a graph is a set of vertices the convex hull of it is $V$. The hull number of a graph $G$ is the minimum size of a hull set in $G$. In [86], [49], we prove that computing the hull number is NP-complete in bipartite graphs. We also provide bounds and design various polynomial-time algorithms for this problem in different graph classes as co-bipartite graphs, $P_4$-sparse graphs, etc.

6.4.2.3. **Induced Subdivision in Digraphs**

In [51], we consider the following problem for oriented graphs and digraphs: Given an oriented graph (digraph) $G$, does it contain an induced subdivision of a prescribed digraph $D$? The complexity of this problem depends on $D$ and on whether $H$ must be an oriented graph or is allowed to contain 2-cycles. We give a number of examples of polynomial instances as well as several NP-completeness proofs.

6.4.2.4. **Circuits in Grids**

A circuit in a simple undirected graph $G = (V, E)$ is a sequence of vertices $\{v_1, v_2, \cdots, v_{k+1}\}$ such that $v_1 = v_{k+1}$ and $\{v_i, v_{i+1}\} \in E$ for $i = 1, \cdots, k$. A circuit $C$ is said to be edge-simple if no edge of $G$ is used twice in $C$. In [30], we study the following problem: which is the largest integer $k$ such that, given any subset of $k$ ordered vertices of an infinite square grid, there exists an edge-simple circuit visiting the $k$ vertices in the prescribed order? We prove that $k = 10$. To this end, we first provide a counterexample implying that $k < 11$. To show that $k \geq 10$, we introduce a methodology, based on the notion of core graph, to reduce drastically the number of possible vertex configurations, and then we test each one of the resulting configurations with an ILP solver.

6.4.3. **Graph Searching, Cops and Robber Games**

Pursuit-evasion encompasses a wide variety of combinatorial problems related to the capture of a fugitive residing in a network by a team of searchers. The goal consists in minimizing the number of searchers required to capture the fugitive in a network and in computing the corresponding capture strategy. This can also be viewed as cleaning the edges of a contaminated graph. We investigated several variants of these games.

6.4.3.1. **Process Number and Routing Reconfiguration in WDM Networks**

Graph searching, where the fugitive is arbitrary fast and moves simultaneously to the searchers, has been widely studied for its close relationship with graph decompositions. More recently, a variant of graph searching, namely the graph processing game, has been widely studied as a model for the routing reconfiguration in WDM networks (see Section 6.1.1.2). In [32], we give a linear time (resp., polynomial-time) algorithm to recognize graphs (resp., digraphs) with process number at most 2, along with a characterization in terms of forbidden minors, and a structural description. In [31], we give a polynomial (both in terms of time complexity and in the number of exchanged messages) distributed algorithm to compute the process number of trees. By slightly modifying the initial parameter of the algorithm, it also allows to compute various parameters of trees as pathwidth, search number, etc.

6.4.3.2. **Cops and Robber Games**

The "Cops and Robber" games are turn-by-turn games where a team of cops purchase a robber in a graph. We investigated two generalizations of the game introduced by Quilliot, Nowakoski and Winkler in 1983. We provided structural characterizations of graphs where one cop is sufficient to capture a fast fugitive able to hide [27]. In particular, one of these characterizations relies on hyperbolicity of the considered graph.

A surprising application of "Cops and Robber"-like games is the problem for a web-browser to download documents in advance while an internaut is surfing on the Web. In [92], we provide a modelling of the prefetching problem in terms of Cops and Robber games. The parameter to be optimized is then the download-speed necessary for the Internaut only accesses to already download webpages. This allows us to provide several complexity results and polynomial-time algorithms in some graph classes.
6.4.4. Distributed Algorithms

We investigated algorithmic problems arising in complex networks like the Internet or social networks. In this kind of networks, problems are becoming harder or impracticable because of the size and the dynamicity of these networks. One way to handle the dynamicity is to provide (distributed) fault tolerant algorithms. Studying the mobile agents paradigm seems to be a promising approach (somehow related to Cops and Robber in Section 6.4.3) to address some models of distributed computing. We considered self-stabilizing algorithms for the gathering problem, and algorithms for updating routing tables.

Besides, the more an algorithm uses local information, the easier it is to update/correct the behaviour of the algorithm. In this direction, we investigated communication problems through game theory. We also studied the power of a communication model using only localized information, i.e., we study what can be computed using this communication model.

6.4.4.1. Mobile Agents and Self-stabilization

In [64], we consider a recent model of robot-based computing which makes use of identical, memoryless mobile robots placed on nodes of anonymous graphs. The robots operate in Look-Compute-Move cycles that are performed asynchronously for each robot. In particular, we consider the case of gathering robots on an anonymous ring. We provide a new distributed approach which turns out to be very interesting as it neither completely falls into symmetry-breaking nor into symmetry-preserving techniques.

We address dynamic large scale emerging networks, e.g., mobile sensor (agent) networks. The agents are resource limited and prone to failures. They move almost unpredictably and communicate in pairs. Population Protocol model is a communication model suited for such networks. We use a recently proposed version of this model where every agent is associated with a parameter called Cover Time. Cover Times abstract the interaction characteristics of mobile agents and allow the design of fast converging protocols and the evaluation of their convergence times (this is impossible in the original model). We take advantage of this model and perform first analytical analysis of a data collection protocol used in the ZebraNet project for the wild-life tracking of zebras. We propose alternative data collection protocols for ZebraNet and we analysis their time complexities [72], [53], [54]. To achieve fault-tolerance in population protocols, we develop a generic self-stabilizing transformer [22]. This is an automatic technique to convert a protocol to its self-stabilizing version.

In addition, we address important problems of coordination and synchronization. We present and prove correct two self-stabilizing deterministic protocols solving the classical mutual exclusion problem and the group mutual exclusion one [54].

6.4.4.2. Distributed Update of Routing Tables

In [62], we propose a simple and practical distributed algorithm for computing and updating routing tables for shortest path routing. This algorithm can be combined with every distance vector shortest paths routing algorithm, and allows to reduce the total number of messages sent. We give experimental evidence that it leads to an important gain in terms of the number of messages sent at the price of a little increase in terms of space occupancy per node.

Arc-Flags is a data structure used to speed-up the shortest paths computation in a graph. In [67], we introduce a new data structure, named Road-Signs, which allows us to efficiently update the Arc-Flags of a graph in a dynamic scenario. Road-Signs can be used to compute Arc-Flags, can be efficiently updated and do not require large space consumption for many real-world graphs.

6.4.4.3. Models of Distributed Computation

Since, we need to face both locality and dynamicity issues, we are developing new techniques allowing to obtain global structural information from local (partial) views of the network. In [55], [73], we have investigated the question of determining which graph properties can or cannot be computed using only local information. We consider the following model: each of the \( n \) nodes of a graph which only knows its own ID and the IDs of its neighbours is allowed to send a message of \( O(\log n) \) bits to some central entity, called the referee. We then investigate whether the referee is able to decide some basic structural properties of the
network topology $G$ or not. We show that simple questions like, "does $G$ contain a square?", "does $G$ contain a triangle?" or "Is the diameter of $G$ at most 3?" cannot be solved in general [55], [73]. On the other hand, the referee can decode the messages in order to have full knowledge of $G$ when $G$ belongs to many graph classes such as planar graphs, bounded treewidth graphs and, more generally, bounded degeneracy graphs [55], [73]. Following our framework, we are able to simulate asynchronicity of the network. In particular, we have exhibited a hierarchy of problems and distributed models of computation [87].
MATHFI Project-Team

5. New Results

5.1. Numerical probability

5.1.1. Simulation of stochastic processes

5.1.1.1. Pathwise convergence of the Euler scheme

A. Alfonsi, B. Jourdain and A. Kohatsu-Higa are studying the convergence for the Wasserstein distance of the Euler scheme towards the limit diffusion. This would be a way to analyze the weak pathwise convergence of this discretization scheme. They have obtained some promising results in the one-dimensional case.

5.1.2. Multi-dimensional models and correlation issues

A. Alfonsi and his PhD Student A. Ahdida have submitted a paper on the simulation of Wishart processes. They have introduced a new family of stochastic differential equations that are defined in the space of correlation matrices and provided high order discretization schemes for such processes [ 51 ]. They are currently trying to use this type of matrix valued processes to model the dependence between assets. In particular, they would like to calibrate Index options data. This work is still in progress. The thesis of A. Ahdida has been defended on December 1st [ 12 ].

The PhD student Lokmane Abbas Turki has worked on numerical methods for American option pricing based on Malliavin calculus and parallel implementation. He has submitted a paper (co-authored with B. Lapeyre) [ 50 ]. He is now working on the dependence of option prices with respect to correlations between stocks in multi-dimensional models.

A. Alfonsi and S. De Marco (postdoc CERMICS) have studied how some option prices (such as spread options) are modified when the correlation between stocks is increased.

5.1.3. Stochastic volatility models

Exotic options and stochastic volatility models is the subject of Sidi Mohamed OULD ALY’s thesis, defended on June 16th, 2011. Sidi-Mohamed has results on the effective computation of option prices in a stochastic volatility model, in the context of variance swap modelling. He has worked out a new model, in the spirit of Bergomi’s approach. This model has remarkable features in terms of tractability and calibration. S.M. Ould Aly has developed numerical methods and an original variance reduction method for models with a log normal volatility. He also has results on the monotony of option prices with respect to the correlation between the stock price and the volatility in the Heston model. Sidi Mohamed has submitted three papers.

5.2. American options

Participants: Benjamin Jourdain, Maxence Jeunesse, Damien Lamberton, Ayech Bouselmi.

5.2.1. American put option with discrete dividends.

B. Jourdain and M. Jeunesse are interested in the regularity of the optimal exercise boundary for the American Put option when the underlying asset pays discrete dividends at known times during the lifetime of the option. The dividend amounts are deterministic functions of the asset prices just before the dividend dates. B. Jourdain and M. Jeunesse have proved continuity of the exercise boundary and smooth contact for the value function under general assumptions on the dividend functions.
5.2.2. American options in exponential Lévy models

D. Lamberton and his PhD student A. Bouselmi are working on American options within multi-dimensional exponential Lévy models. They also have preliminary results on the asymptotic behaviour of the exercise boundary of the American put near maturity in the one dimensional case when the limit is strictly smaller than the strike price.

5.3. Financial issues modelling

Participants: Aurélien Alfonsi, Céline Labart, Jérôme Lelong, J. Acevedo.

5.3.1. Credit risk modelling

A. Alfonsi, C. Labart and J. lelong are studying loss models called “stochastic local intensity models” that have been proposed in the literature. First, they are interested in proving mathematically that these models are well posed (it exists and has a unique solution). Second, they aim to provide numerical tools to sample such dynamics.

5.3.2. Limit order markets

A. Alfonsi has an active collaboration with A. Schied (Mannheim University) on limit order book models. A. Schied has visited the CERMICS two weeks in February 2011 and one week on December. They are currently studying some type of non-Markovian resilience for the limit-order book for which they are able to get the optimal execution strategy in a closed form. Moreover A. Alfonsi and his PhD student J. Acevedo study impact models for which the limit order book shape evolves along the time.

5.3.3. Control of systemic risk

Participants: Agnès Sulem, J.Ph. Chancelier, Andreea Minca.

We are interested in contagion modeling and systemic risk in financial networks. We aim to contribute in particular to the domain of control of such systems in order to reduce the systemic risk. We model the propagation of distress in financial systems as an epidemic on a random graph in which the nodes represent financial institutions and edges the exposure between them. Cascade dynamics may be reduced to the evolution of a multi-dimensional markov chain that corresponds to a sequential discovery of exposures and determines the size of contagion. We study the optimal intervention strategy by a lender of last resort who wants to minimize the size of contagion under budget constraints.

5.4. Stochastic control of jump processes and stochastic differential games

Participants: Agnès Sulem [in collaboration with B. Øksendal (Oslo University) and T. Zhang (Manchester University)], John Joseph Absalom Hosking.

5.4.1. Stochastic control under model uncertainty

In [58], we study optimal stochastic control problems with jumps under model uncertainty. We rewrite such problems as (zero-sum) stochastic differential games of forward-backward stochastic differential equations. We prove general stochastic maximum principles for such games, both in the zero-sum case (finding conditions for saddle points) and for the non-zero sum games (finding conditions for Nash equilibria). We then apply these results to study optimal portfolio and consumption problems under model uncertainty. We combine the optimality conditions given by the stochastic maximum principles with Malliavin calculus to obtain a set of equations which determine the optimal strategies.

In [45], we consider some robust optimal portfolio problems for markets modeled by (possibly non-Markovian) Itô–Lévy processes. Mathematically the situation can be described as a stochastic differential game, where one of the players (the agent) is trying to find the portfolio which maximizes the utility of her terminal wealth, while the other player (“the market”) is controlling some of the unknown parameters of the market (e.g. the underlying probability measure, representing a model uncertainty problem) and is trying to minimize this maximal utility of the agent. This leads to a worst case scenario control problem for the agent.
In the Markovian case such problems can be studied using the Hamilton-Jacobi-Bellman-Isaacs (HJBI) equation, but these methods do not work in the non-Markovian case. We approach the problem by transforming it to a stochastic differential game for backward stochastic differential equations (BSDE game). Using comparison theorems for BSDEs with jumps we arrive at criteria for the solution of such games, in the form of a kind of non-Markovian analogue of the HJBI equation. The results are illustrated by examples.

5.4.2. Singular stochastic control

In [59], A. Sulem and B. Øksendal study partial information, possibly non-Markovian, singular stochastic control of Itô–Lévy processes and obtain general maximum principles. The results are used to find connections between singular stochastic control, reflected BSDEs and optimal stopping in the partial information case. As an application we give an explicit solution to a class of optimal stopping problems with finite horizon and partial information. Singular control of SPDEs.

In [57], A. Sulem, B. Øksendal and T. Zhang study general singular control problems for random fields given by a stochastic partial differential equation (SPDE). They show that under some conditions the optimal singular control can be identified with the solution of a coupled system of SPDE and a kind of reflected backward SPDE (RBSPDE). They also establish existence and uniqueness of solutions of RBSPDEs.

5.4.3. Optimal control with delay

In [44], we study optimal control problems for (time-)delayed stochastic differential equations with jumps. We establish sufficient and necessary stochastic stochastic maximum principles for an optimal control of such systems. The associated adjoint processes are shown to satisfy a (time-) advanced backward stochastic differential equation (ABSDE). Several results on existence and uniqueness of such ABSDEs are shown. The results are illustrated by an application to optimal consumption from a cash flow with delay.

In [48], we will prove a sufficient necessary stochastic maximum principles for the optimal control of SPDEs with delay and study associated time-advanced backward stochastic partial differential equations.

5.4.4. Stochastic differential games

In [55], J. Hosking has constructed a stochastic maximum principle (SMP) which provides necessary conditions for the existence of Nash equilibria in a certain form of N-agent stochastic differential game (SDG) of a mean-field type. The information structure considered for the SDG is of a possible asymmetric and partial type. To prove our SMP we use a spike-variation approach with adjoint representation techniques, analogous to that of S. Peng in the optimal stochastic control context. In our proof we apply adjoint representation procedures at three points. The first-order adjoint processes are defined as solutions to certain mean-field backward stochastic differential equations (BSDEs), and second-order adjoint processes of a fist type are defined as solutions to certain BSDEs. Second order adjoint processes of a second type are defined as solutions of backward stochastic equations of a type that we introduce in this paper, and which we term conditional mean-field BSDEs. From the resulting representations, we show that the terms relating to these second-order adjoint processes of the second type are of an order such that they do not appear in our final SMP equations.

5.5. Risk measures, BSDEs with jumps and nonlinear expectations

Participants: Agnès Sulem, Marie-Claire Quenez, Z. Chen [Shandong University].

In the Brownian case, links between dynamic risk measures and Backward Stochastic Differential Equations (BSDEs) have been established. A. Sulem and M.-C. Quenez are exploring these links in the case of stochastic processes with jumps. They have extended some comparison theorems for BSDEs with jumps, and provided a representation theorem of convex dynamic risk measures induced by BSDEs with jumps. They study optimal stopping problems for (non necessarily) convex dynamic risk measures induced by BSDEs with jumps and establish their connections with Reflected BSDEs with jumps. They also study the case of model ambiguity and its relation with mixed control/optimal stopping problems.
There are two classes of nonlinear expectations, one is the Choquet expectation given by Choquet (1955), the other is the Peng’s $g$-expectation given by Peng (1997) via backward differential equations (BSDE). Recently, Peng raised the following question: can a $g$-expectation be represented by a Choquet expectation? In [26], A. Sulem and Z. Chen provide a necessary and sufficient condition on $g$-expectations under which Peng’s $g$-expectation can be represented by a Choquet expectation for some random variables (Markov processes). It is well known that Choquet expectation and $g$-expectation (also BSDE) have been used extensively in the pricing of options in finance and insurance. Our result also addresses the following open question: given a BSDE ($g$-expectation), is there a Choquet expectation operator such that both BSDE pricing and Choquet pricing coincide for all European options? Furthermore, the famous Feynman-Kac formula shows that the solutions of a class of (linear) partial differential equations (PDE) can be represented by (linear) mathematical expectations. As an application of our result, we obtain a necessary and sufficient condition under which the solutions of a class of nonlinear PDE can be represented by nonlinear Choquet expectations [26].

5.6. Malliavin calculus and applications

5.6.1. Lower bounds for the density of functionals on the Wiener space

In collaboration with: B. Fernandez and A. Meda from the University of Mexico, V. Bally gave a lower bound for general Itô processes to remain in a tube around a given curve. This is done under some ellipticity assumption in [21]. Now, with L. Caramellino (University Tor Vergata, Rome) he investigates the case of a diffusion processes which satisfies the Hörmander condition.

5.6.2. Malliavin Calculus for Poisson Point Processes and applications

V. Bally and E. Clément (Université Paris-Est Marne la Vallée) study the density of the law of the solution of a stochastic equation with jumps, which has discontinuous coefficients [18], [19]. Moreover, with N. Fournier (university of Creteil), V. Bally obtained results on the smoothness of the law of a bidimensional Boltzman equation [22].

5.6.3. Riesz transform and regularity of the law of a random variable

The idea of using the Riesz transform in order to study the regularity of the law of a random variable appears in former works of P. Malliavin and A. Thalmaier. In collaboration with L. Caramellino (University Tor Vergata, Rome) we gave regularity results using this tool [17].
6. New Results

6.1. Théorie spectrale max-plus et géométrie métrique/Max-plus spectral theory and metric geometry

6.1.1. Introduction

Participants: Marianne Akian, Stéphane Gaubert, Cormac Walsh.

Étant donné un noyau \( a : S \times S \to \mathbb{R} \cup \{-\infty\} \), on peut lui associer le problème spectral max-plus

\[
\sup_{y \in S} a(x, y) + u(y) = \lambda + u(x), \quad \forall x \in S,
\]

dans lequel on cherche le vecteur propre \( u : S \to \mathbb{R} \cup \{-\infty\} \) et la valeur propre correspondante \( \lambda \in \mathbb{R} \cup \{-\infty\} \). Comme nous l’avons rappelé dans les § 3.2 et 3.3, le problème spectral (9) intervient en contrôle ergodique: l’ensemble \( S \) est l’espace des états, et l’application \( a(x, y) \) fournit le gain associé à la transition \( x \to y \). Le cas où \( S \) est fini est classique, l’on a alors un résultat précis de représentation de l’espace propre, à l’aide d’un certain graphe, dit graphe critique. Des résultats existent également lorsque \( S \) est compact et que le noyau vérifie certaines propriétés de régularité.

Dans [79], nous avons considéré le cas où \( S \) est non compact. Lorsque \( \lambda = 0 \), l’espace propre est analogue à l’espace des fonctions harmoniques défini en théorie (classique ou probabiliste) du potentiel. En introduisant l’analogue max-plus de la frontière de Martin, nous avons obtenu un analogue de la formule de représentation de Poisson des fonctions harmoniques : toute solution \( u \) de (9) peut être représentée sous la forme :

\[
u = \sup_{w \in \mathcal{M}_m} w + \mu_u(w),
\]

où \( \mathcal{M}_m \subset (\mathbb{R} \cup \{-\infty\})^S \) est l’analogue max-plus de la frontière de Martin minimale (l’ensemble des fonctions harmoniques extrémales normalisées), et où \( \mu_u \) joue le rôle de la mesure spectrale. Nous avons montré aussi que les éléments de l’espace de Martin minimal peuvent être caractérisés comme les limites de “quasi-géodésiques”. La frontière de Martin max-plus généralise dans une certaine mesure la frontière d’un espace métrique construite à partir des horo-fonctions (fonctions de Busemann généralisées), ou horo-frontière. Ces résultats inspirent les travaux des sections suivantes, qui portent sur des cas remarquables d’espaces métriques (§ 6.1.4) ou sur des applications en théorie des jeux (§ 6.1.2).

English version

Let the kernel \( a : S \times S \to \mathbb{R} \cup \{-\infty\} \) be given. One may associate the max-plus spectral equation (9), where the eigenvector \( u : S \to \mathbb{R} \cup \{-\infty\} \) and the eigenvalue \( \lambda \in \mathbb{R} \cup \{-\infty\} \) are unknown. As we recalled in § 3.2 and refinomonote, this spectral problem arises in ergodic optimal control: the set \( S \) is the state space, and the map \( a(x, y) \) is the transition reward. The case when \( S \) is finite is classical, a precise spectral theorem is known, with a characterisation of the eigenspace in terms of a critical graph. Some results have been shown when \( S \) is compact, assuming that the kernel \( a \) satisfies some regularity properties.
In [79], we considered the case where \( S \) is non-compact. When \( \lambda = 0 \), the eigenspace is analogous to the set of harmonic functions defined in classical or probabilistic potential theory. By introducing a max-plus analogue of the classical Martin boundary, we obtained an analogue of the Poisson representation of harmonic functions, showing that any solution \( u \) of (9) may be represented as in (10) where \( \mathcal{M}_0 \subset (\mathbb{R} \cup \{-\infty\})^S \) is a max-plus analogue of the minimal Martin boundary (the set of normalised extremal harmonic functions), and \( \mu_u \) plays the role of the spectral measure. We also showed that the elements of the minimal Martin boundary can be characterised as limits of certain “almost-geodesics”. The max-plus Martin boundary generalises to some extent the boundary of metric spaces defined in terms of horofunctions (generalised Busemann functions), or horoboundary. These results have inspired the work of the next sections, which deal either with remarkable examples of metric spaces (§ 6.1.4) or applications to zero-sum games (§ 6.1.2).

### 6.1.2. Une caractérisation maximin du taux de fuite d’applications nonexpansives/A maximin characterization of the escape rate of nonexpansive mappings

**Participants:** Stéphane Gaubert, Guillaume Vigeral.

The problem of the existence of the mean payoff per time unit for repeated games leads to studying the existence of the limit of \( f^k(v)/k \) where \( f \) is a nonexpansive map (the dynamic programming operator) acting on a Banach space, see § 3.3 for more background. The limit may not exist, but a result of Kohlberg et Neyman shows that there is always a norm one linear form \( \phi \) such that the limit of \( \phi(f^k(x)/k) \) exists as \( k \) tends to infinity (the escape rate). In [29], we extend this result to the case of a nonexpansive map defined on a metric space satisfying a mild form of Busemann nonpositive curvature condition. Then, the linear form \( \phi \) is replaced by an horofunction, and we obtain a maximin type characterization of the escape rate, which extends the Collatz-Wielandt formula in Perron-Frobenius theory. This is motivated by the study of quadratic optimal control and game problems, in which the metric space is the cone of positive semi-definite matrices equipped with the Riemannian invariant metric or with Thompson metric.

### 6.1.3. Isométries de la géométrie de Hilbert/Isometries of the Hilbert geometry

**Participants:** Cormac Walsh, Bas Lemmens [Kent University, UK].

L’un des intérêts de l’horo-frontière est de renseigner sur le groupe des isométries d’un espace métrique. En effet, ce groupe agit naturellement sur l’horo-frontière, et cette action peut parfois être mieux comprise que l’action du groupe sur l’espace d’origine.

Nous étudions le groupe des isométries pour la métrique de Hilbert. De La Harpe [188] a donné plusieurs conjectures relatives à ce groupe. Nous conjecturons que le groupe des isométries est exactement le groupe des transformations linéaires projectives à moins que le domaine ne soit une coupe d’un cône symétrique non-Lorentzien. Nous avons démontré cette conjecture lorsque le domaine est un polytope [32].
Dans le cas général, on prouve, en utilisant les horo-fonctions, que si il existe une bijection entre deux cônes homogène de degré $-1$, antitone, et d’inverse antitone, ces deux cônes sont symétriques. Nous essayons maintenant de montrer que toute isométrie de Hilbert sur un domaine convexe est la version projective d’un automorphisme linéaire du cône sur le domaine, ou d’une bijection du cône, homogène de degré $-1$, qui est antitone et d’inverse antitone. Ce résultat permettrait de compléter la preuve de la conjecture proposée plus haut.

**English version**

One use for the horofunction boundary is to study the group of isometries of a metric space. This is because this group has a well defined action on the horoboundary and it is likely that in many cases this action will be easier to understand than the action on the space itself.

We have been investigating the isometries of the Hilbert geometry. De La Harpe [188] has previously made several conjectures about the isometry group of this space. We conjecture that the isometry group is exactly the group of projective linear transformations unless the domain on which the geometry is defined is a cross section of a non-Lorentzian symmetric cone. We have previously proved that this conjecture is true in the case of a polytope domain [32].

In the general case, we can now prove, using horofunctions, that if a bijection between cones is homogeneous of degree $-1$, order inverting, and has an order inverting inverse, then both cones are symmetric. We are working on showing that every Hilbert isometry on a convex domain arises by considering projectively either a linear automorphism on the cone over the domain, or a homogeneous $-1$, order inverting bijection on this cone with order inverting inverse. Establishing this result would complete our proof of the above conjecture.

**6.1.4. Espace de Teichmüller/Teichmüller space**

**Participant:** Cormac Walsh.

L’espace de Teichmüller d’une surface est un espace métrique composé des structures conformes de cette surface. On peut le voir comme l’ensemble des classes d’équivalence des métriques riemanniennes de cette surface, où deux métriques sont équivalentes si il existe une application conforme homotope à l’identité qui envoie l’une des métriques sur l’autre.

Il existe plusieurs métriques naturelles sur l’espace de Teichmüller. Nous avons travaillé précédemment sur la métrique Lipschitz de Thurston et avons prouvé [70] que l’horofrontière de cet espace métrique était la frontière de Thurston.

Néanmoins, la métrique la plus utilisées ur l’espace de Teichmüller est la métrique de Teichmüller. L’horofrontière de cet espace métrique n’est autre que la frontière déjà introduite dans la littérature sous le nom de frontière de Gardiner–Masur. Nous étudions cette frontière, en particulier nous donnons explicitement ses points de Busemann.

Par la suite, nous avons l’intention d’utiliser cette propriété afin d’étudier les sous-groupes du groupe modulaire, qui est le groupe des isométries de la métrique de Teichmüller.

**English version**

An interesting metric space is the Teichmüller space of a surface. This is the space of conformal structures on the surface. One may think of it as the space of equivalence classes of Riemannian metrics on the surface, where two such metrics are regarded as being equivalent if there is a conformal map on the surface taking one to the other that is homotopic to the identity.

There are several natural metrics on Teichmüller space. Previously, we have worked with Thurston’s stretch metric and have shown [70] that the horofunction boundary with this metric is just the usual Thurston boundary.
However, the most commonly used metric on Teichmüller space is Teichmüller’s metric. The horofunction boundary of this metric space turns out to be the same as a previously defined boundary, called the Gardiner–Masur boundary. We have been investigating this boundary, in particular we have managed to work out explicitly its Busemann points.

In future work, we intend to apply this knowledge to study subgroups of the mapping class group, which is the isometry group of the Teichmüller metric.

6.2. Algèbre linéaire max-plus et convexité abstraite/Max-plus linear algebra and abstract convex analysis

6.2.1. Convexité max-plus ou tropicale/Max-plus or tropical convexity

Participants: Xavier Allamigeon, Stéphane Gaubert, Eric Goubault [CEA], Ricardo Katz [Conicet, Argentine].

On étudie les analogues max-plus ou tropicaux des ensembles convexes. Ceux-ci sont utiles en particulier pour représenter de manière effective les ensembles d’états accessibles de systèmes à événements discrets [9], ils sont aussi apparus récemment en géométrie tropicale, dans toute une série de travaux à la suite de Sturmfels et Develin [114]. Les polyèdres max-plus peuvent aussi être vus comme des limites de déformations de polyèdres classiques, sur lesquels ils donnent un éclairage de nature combinatoire. Toutes ces motivations ont inspiré la recherche d’analogues des résultats fondamentaux d’analyse convex classique: séparation, projection, points extrêmaux, à la suite en particulier de [8].

On en déduit un analogue tropical de la méthode de la double description [57] (méthode très utilisée sur les polyèdres classiques, et dûe à Motzkin et al. [158]). Cet algorithme permet de calculer les sommets d’un polyèdre défini de façon externe (intersection de demi-espaces ou d’hyperplans tropicaux). Grâce au critère combinatoire précédent, l’algorithme améliore de plusieurs ordres de grandeur les techniques connues jusqu’alors. Ceci est confirmé par de nombreuses expérimentations. Ce travail est motivé par des applications à l’analyse statique [82] et aux systèmes à événements discrets [116], dans lesquelles la manipulation de tels polyèdres est le goulot d’étranglement.

Dans un travail de X. Allamigeon, S. Gaubert, et R. Katz [57], on étend le théorème de McMullen au cas tropical: ce dernier caractérise le nombre maximal de points extrêmes d’un polyèdre, en fonction du nombre d’inégalités qui le définissent et de sa dimension. Nous montrons que la même borne est valide dans le cas tropical (à une modification triviale près). Cependant, le calcul de la borne optimale est encore ouvert dans ce cas.

Dans un travail de S. Gaubert et R. Katz [26], on étudie la représentation d’un polyèdre tropical comme intersection de demi-espaces, ou si l’on préfère, comme conjonction d’inégalités affines. Nous donnons notamment un contre-exemple, montrant les inconvénients de la représentation en termes de demi-espaces minimaux proposée précédemment dans la littérature tropicale.

We study the max-plus or tropical analogues of convex sets. These have been used in particular to represent effectively the accessible sets of certain discrete event systems [9]. They also appeared in tropical geometry, following the work of Sturmfels and Develin [114]. Max-plus polyhedra can be thought of as limits of deformations of classical polyhedra, on which they give a combinatorial insight. These motivations have inspired the investigation of analogues of basic results of classical convex analysis: separation, projection, representation by extreme points, following [8].

In a work of X. Allamigeon, S. Gaubert, and E. Goubault [57], we introduce a combinatorial criterion for the characterization of the vertices of tropically convex polyhedra. It is expressed in terms of directed hypergraphs and their strongly connected components. This criterion can be verified in almost linear time in the size of the hypergraph.

This allows to develop a tropical analogue of the double description method [57] (this method is widely used for classical convex polyhedra, and is due to Motzkin et al. [158]). This algorithm is able to determine all the vertices of a polyhedron defined externally (intersection of tropical half-spaces of hyperplanes). Thanks to the combinatorial criterion mentioned above, the algorithm improves the existing methods by several orders of magnitude. This is confirmed by several experiments. This is motivated by applications to static analysis [82] and discrete event systems [116], in which computing such polyhedra turns out to be the bottleneck.

In a work of S. Gaubert and R. Katz [26], we study the representation of a tropical polyhedron as an intersection of half-spaces. We give in particular a counter example, showing some inconvenients of the representation in terms of minimal half-spaces proposed previously in the tropical litterature.

It is well-known that a tropical polyhedron can be represented as the convex hull of a minimal set of points and rays, provided by its vertices and extreme rays [125]. In an ongoing work of X. Allamigeon and R. Katz, partly done during the visit of R. Katz at INRIA (July 2011), the dual problem of characterizing the minimal representations by half-spaces is studied. We show that a tropical polyhedron admits essentially a unique minimal external representation by half-spaces, provided that their apices belong to the polyhedron. We prove that the apices of these half-spaces correspond to certain vertices of the tropical complex introduced by Develin and Sturmfels [114]. We also establish a combinatorial criterion allowing to eliminate redundant half-spaces using directed hypergraphs.

6.2.2. Convexes max-plus et jeux avec paiements ergodiques/Max-plus convex sets and mean payoff games

Participants: Marianne Akian, Xavier Allamigeon, Stéphane Gaubert, Alexander Guterman [Moscow State University], Ricardo Katz [Conicet, Argentine], Sergei Sergeev.

Dans un travail d’Akian, Gaubert et Guterman [16], on montre un résultat d’équivalence entre les jeux ergodiques à somme nulle et les systèmes d’inégalités max-plus linéaires: décider la non-vacuité d’un polyèdre tropical est équivalent à vérifier si un jeu déterministe à somme nulle a un paiement moyen par unité de temps positif ou nul. Plus généralement, la même question pour un jeu stochastique à somme nulle est équivalente à vérifier si un convexe tropical (non-polyédral, i.e., défini par un système infini d’inégalités) est vide. Ces résultats sont démontrés à l’aide de techniques de théorie de Perron-Frobenius non-linéaire. Ils sont ensuite appliqués à l’étude de l’indépendance linéaire dans le semi-anneau tropical.

Le résultat de [16] a eu plusieurs retombées.
In [16], we show the equivalence mean payoff games and max-plus linear inequalities: testing whether a tropical polyhedron is non-empty is equivalent to checking whether a mean payoff deterministic game is winning. More generally, checking whether a mean payoff stochastic game is winning is equivalent to checking the non-emptiness of a tropical convex set defined by an infinite family of inequalities. These results are established using techniques of non-linear Perron-Frobenius theory. Then, they are applied to the study of linear independence over the tropical semiring.

The equivalence established in [16] had several consequences.

First, a work of Allamigeon, Gaubert, and Katz [20] yields a tropical analogue of Farkas’ theorem: we show that deciding whether a max-plus linear inequality follows from a family of such inequalities is also equivalent to solving a mean payoff game. Moreover, the work [20] comprises a characterization of the “faces” (more precisely, the extreme points of the polar) of a tropical polyhedron in terms of minimal transversals of a hypergraph.

Next, in a work of Gaubert and Sergeev [127], the tropical spectral problem for matrix pencils, $Ax = \lambda Bx$, is reduced to a parametric game (which allows one to compute the spectrum in pseudo-polynomial time).

Finally, in a work of Gaubert, Katz, and Sergeev [27], a (pseudo-polynomial) tropical linear programming algorithm is developed, based on the same correspondence with mean payoff games. Allamigeon and Sergeev developed recently an ocaml prototype in order to experiment this method. This prototype includes in particular mean payoff game solvers, namely the version of [115] of the policy iteration algorithm of Gaubert-Gunawardena [124], the modification of this algorithm due to Chaloupka [98], as well as the policy iteration algorithm of Björklund-Vorobyov [91].
We are studying projectors on max-plus linear spaces, as well as separating half-spaces over the max-plus semiring. In \cite{18}, we establish new results, and derive an explicit formula for the distance in Hilbert’s projective metric between a point and a half-space, as well as explicit descriptions of the set of minimizers of this distance. We also obtain, as a consequence of the previous results, a cyclic projection type algorithm to solve systems of max-plus linear inequalities. This work is carried out as part of a LEA Math-mode project.

\subsection*{6.2.4. Miscellanées en algèbre linéaire max-plus/Topics in max-plus linear algebra}

\textbf{Participant:} Sergei Sergeev.

Pendant son année de séjour post-doctoral dans l’équipe, S. Sergeev a collaboré avec celle-ci sur les questions de convexité tropicale et de jeux répétés (voir § 6.2.2 supra). Il a en outre mené des recherches touchant à diverses questions d’algèbre linéaire max-plus, en collaboration avec plusieurs coauteurs étrangers \cite{37}, \cite{66}, \cite{63}, \cite{67}.

\begin{itemize}
  \item \textit{Z-matrix equations and weakly stable matrices.} Sergeev continued his joint research with P. Butkovič and H. Schneider on traditional topics of max-plus linear algebra. They described solution set to Z-matrix equations $\lambda x = Ax \oplus b$, comparing the results with nonnegative matrix setting (old works of H. Schneider with coauthors) and extending them to linear algebra over more general semirings. \textit{Weakly stable matrices} are such that the set of vectors $x$ whose orbit $A^kx$ converges to an eigenvector, is exactly the eigenvector cone. The weak stability was characterized in terms of relations between spectral classes of $A$ and the critical graph in each strongly connected component.

  \item \textit{CSR expansions.} Sergeev continued his research on CSR expansions of matrix powers in max-plus algebra, see the accepted paper with H. Schneider \cite{37}, and paper with T. Nowak in preparation, which is going to be a survey on transience bounds in max-plus algebra based on CSR expansion schemes. New results may be applied in analysing the performance of reversal routing and reversal scheduling algorithms in collaboration with the team of B. Charron-Bost (École Polytechnique).

  \item \textit{Ultradiscrete KdV.} Sergeev learned about the ultradiscrete KdV model at the conferences in Manchester (April 2011) and Glasgow (July 2011), and worked on the application of max-plus spectral theory to the ultradiscrete analogue of the Lax pair studied recently by R. Willox, J. Satsuma, J. Nimmo and others, based on the idea of S. Gaubert (who also took part in both conferences). In submission \cite{66}, he suggested the notion of pairs of fundamental eigenvectors associated with each soliton and showed that the problem can be reduced to finite-dimensional spectral theory with two additional constraints. In some special cases the problem can be solved by means of fundamental eigenvectors, which can be also used in the operation of undressing. However, in the case of several massive solitons the fundamental eigenvectors can never provide a solution, and more elaborate theory is needed.

  \item \textit{max-Łukasiewicz algebra} Sergeev learned about some new fuzzy linear algebras during his research visit to Czech Republic. He observed that the linear algebraic problems over max-Łukasiewicz algebra, defined in the interval $[0,1]$ with operations $a \otimes b := \max(a + b - 1, 0)$ and $a \oplus b := \max(a, b)$ can be reduced to some problems over max-plus algebra. This observation, being used in submission \cite{63} has led to a new collaboration with Martin Gavalec and his group at the University of Hradec Kralove.

  \item \textit{Visualization scaling and multi-objective optimization.} Sergeev continued his research on diagonal similarity scalings in max-plus algebra, see submission \cite{67} and new collaboration with B. Benek Gursoy and O. Mason (in preparation). In this new collaboration, the authors analyze the possibilities of simultaneous matrix scaling (visualization), the special case of symmetrically reciprocal matrices, and extension to Pareto optimality.
\end{itemize}
6.3. Algèbre max-plus, déformations et asymptotiques /Max-plus algebra, deformations and asymptotic analysis

6.3.1. Introduction

Comme indiqué dans le § 3.7, l’algèbre max-plus est la limite d’une déformation de l’algèbre classique, ou plutôt du semi-corps des réels positifs. Elle peut aussi fournir des estimations de ces déformations, puisque

\[
\max(a, b) \leq \epsilon \log (e^{a/\epsilon} + e^{b/\epsilon}) \leq \epsilon \log (2) + \max(a, b). \quad (10)
\]

L’utilisation de ces propriétés a déjà conduit dans le passé aux travaux sur les perturbations de valeurs propres [75], [74], [73], ou sur les grandes déviations [1], [77]. Dans les travaux qui suivent, nous exploitons ces propriétés dans des contextes reliés ou similaires à ceux de nos travaux précédents.

6.3.2. Aspects tropicaux des algorithmes de scaling matriciel/Tropical aspects of matrix scaling problems

Participants: Marianne Akian, Stéphane Gaubert, Laura Grigori, Meisam Sharify Najafabadi.

Le travail de thèse de M. Sharify [13] a porté sur les méthodes de mise à l’échelle utilisées en algorithmique numérique matricielle pour améliorer la précision des calculs.

Une première partie du travail, appliquant les techniques de [73], [74], porte sur les problèmes de valeurs propres. On montre notamment que l’ordre de grandeur des valeurs propres d’un faisceau matriciel est donné (sous des conditions de non-dégénerescence) par les valeurs tropicales, qui peuvent être calculées de manière robuste, et fournissent ainsi une mise à l’échelle pour calculer les valeurs propres classiques.

Une seconde partie du travail (collaboration avec L. Grigori) porte sur le calcul de mises-à-l’échelle issues de la résolution d’un problème d’affectation optimale. On a développé un algorithme dont l’idée est de voir le problème d’affectation comme une limite d’un problème de maximisation d’entropie. Ceci conduit à un préprocessing parallèle, qui permet d’éliminer a priori des coefficients qui ne participent pas aux affectations optimales, de sorte que le problème réduit devient résoluble sur une machine séquentielle. L’algorithme ainsi obtenu est étudié dans le preprint [69], qui comprend également des résultats expérimentaux.

6.3. Algèbre max-plus, déformations et asymptotiques /Max-plus algebra, deformations and asymptotic analysis

6.3.1. Introduction

As detailed in § 3.7, max-plus algebra is the limit of a deformation of classical algebra, or more precisely of the semi-field of usual real positive numbers. It can also give estimations for these deformations using for instance (11). By using these properties, we already obtained some works on singular perturbations of matrix eigenvalues [75], [74], [73], or on large deviations [1], [77]. In the works described below, we are exploiting again these properties in contexts that are related or similar to those of our earlier works.

6.3.2. Aspects tropicaux des algorithmes de scaling matriciel/Tropical aspects of matrix scaling problems

Participants: Marianne Akian, Stéphane Gaubert, Laura Grigori, Meisam Sharify Najafabadi.

The PhD work of M. Sharify [13] deals with the development of scaling methods in matrix analysis to improve the accuracy of numerical computations.

A first part of the work, applying the techniques of [73], [74], deals with eigenvalue problems. We show in particular that the order of magnitude of the eigenvalues of a matrix pencil can be determined (under nondegeracy conditions) by computing tropical eigenvalues. The latter can always be computed accurately and provide a scaling which can be combined with standard numerical methods for matrix pencils.

A second part of the work (collaboration with L. Grigori) deals with the parallel computation of scalings based on the optimal assignment problem. The latter is thought of as a limit of an entropy maximization problem. This leads to a parallel preprocessing, allowing one to eliminate a priori entries which do not belong to optimal assignment, so that the reduced problem becomes solvable on a sequential machine. This algorithm is studied in the preprint [69], which also comprises experimental results.
6.3.3. Mesures et applications maxitives

Participants: Marianne Akian, Paul Poncet.

Les mesures et intégrales maxitives qui ont été introduites et ré-introduites sous divers noms dans la littérature (intégrale de Shilkret, sup-mesures, mesures de possibilité, mesures idempotentes de Maslov, etc.), sont définies de manière analogue aux mesures et intégrales usuelles, en remplaçant les lois additive et multiplicative par celles d’un semi-anneau idempotent, comme par exemple le semi-anneau max-plus. Elles peuvent aussi être obtenues comme limites de mesures positives après déformation logarithmique, par le principe des grandes déviations. Entre autres motivations à l’étude de ces mesures, citons les processus max-stables et leur représentation intégrale, les processus extrêmes, ou les grandes déviations à la loi des grands nombres.

Le travail de thèse de Paul Poncet [12] est parti de ces motivations. Il traite essentiellement de ce que l’on appelle l’analyse idempotente, c’est-à-dire l’étude des espaces fonctionnels ou linéaires de dimension infinie sur l’algèbre tropicale, ou tout autre semi-anneau idempotent. Paul Poncet a développé pour cela un point de vue treillis continu comme dans [1], ou plus généralement domaines, et ses travaux pourraient donc aussi avoir des applications en informatique.

La première partie de la thèse traite des mesures maxitives. Paul Poncet a donné une revue des résultats existants concernant l’existence d’une densité cardinale ou d’une densité d’une mesure par rapport à une autre (théorème de Radon-Nikodym), et la régularité d’une mesure maxitive, tout en les comparant et les complétant. En particulier il prouve une réciproque au théorème de Radon-Nikodym pour les mesures maxitives, c’est-à-dire qu’il donne une caractérisation des mesures maxitives ayant la propriété de Radon-Nikodym, il caractérise les mesures maxitives régulières à valeurs dans un domaine, donne un théorème de décomposition des mesures maxitives aussi publié dans [34], et donne un théorème de représentation de Riesz pour les formes linéaires max-plus continues.

Une deuxième partie concerne les convexes dans les semi-treillis ou l’algèbre max-plus. Paul Poncet s’est intéressé à l’existence d’un théorème de type Krein-Milman, à sa réciproque de Milman, et à celle d’un théorème de type représentation de Choquet dans ces structures. Dans le cas des semi-treillis, certains de ces résultats se déduisent rapidement des travaux sur les semi-treillis compacts, mais d’autres sont entièrement nouveaux. Le théorème de Krein-Milman pour les convexes tropicaux, qui n’avait été établi dans la littérature qu’en dimension finie [137], [96], [125], est prouvé en dimension infinie au moyen de celui sur les semi-treillis. Le théorème de représentation de Choquet utilise les notions de mesures maxitives introduites dans la première partie. De tels résultats permettent de retrouver partiellement les résultats sur la frontière de Martin max-plus décrits dans la section 6.1.1.

Enfin dans une troisième et dernière partie, Paul Poncet étudie les semi-groupes inverses dans une tentative d’unification de l’algèbre usuelle et de l’algèbre tropicale.

English version

Maxitive measures and integrals, which have been introduced and re-introduced under different names in the literature (Shilkret integral, sup-measures, possibility measures, Maslov idempotent measures, etc.), are defined analogously to usual measures and integrals, by replacing the additive and multiplicative laws by the laws of an idempotent semiring, such as the max-plus semiring. They can also be obtained as limits of positive measures after logarithmic deformation, by the large deviation principle. Among motivations for the study of this notion, let us mention max-stable processes and their integral representations, extremal processes, or large deviations to the law of large numbers.

The PhD thesis work of Paul Poncet [12] started from these motivations. It concerns essentially what is called idempotent analysis, that is the study of infinite dimensional functional or linear spaces over tropical algebra, or any other idempotent semiring. For this aim, Paul Poncet developed the point of view of continuous lattices, as in [1], or more generally of domains, and his works may have applications in computer science.
The first part of his thesis concerns maxitive measures. Paul Poncet gave a survey of existing results concerning the existence of a cardinal density of a measure, that of a density of a measure with respect to another (Radon-Nikodym theorem), and the regularity of a maxitive measure, while comparing and extending them. In particular he proves a converse to the Radon-Nikodym theorem for maxitive measures, which lead to a characterisation of maxitive measures that have the Radon-Nikodym property, he characterizes domain valued maxitive measures that are regular, gives a decomposition theorem of maxitive measures also published in [34], and gives a Riesz representation theorem for continuous max-plus linear forms.

A second part concerns convex sets in lattices or max-plus algebra. Paul Poncet is showing a Krein-Milman type theorem, its Milman converse, or a Choquet representation type theorem in these structures. In the case of semilattices, some of these results can be deduced easily from works on compact semilattices, but some others are new. The Krein-Milman on tropical convex sets, which in the litterature was established in finite dimension only [137], [96], [125], is deduced in infinite dimension from the analogous result concerning semilattices. The Choquet representation theorem uses the notions of maxitive measures introduced in the first part. Such results lead in particular to new proofs of some of the results on Martin boundaries described in Section 6.1.1.

In the third and last part, Paul Poncet is studying inverse semigroups in an attempt to unify usual and tropical algebras.

6.4. Algorithmes/Algorithms

6.4.1. Méthodes multigrilles pour le contrôle stochastique et les jeux répétés à somme nulle/Multigrid methods for stochastic control and repeated zero sum games

Participants: Marianne Akian, Sylvie Detournay.

L’algorithme d’itération sur les politiques est bien connu pour résoudre efficacement les équations de la programmation dynamique associées à des problèmes de contrôle stochastique avec critère à horizon infini (Howard) ou ergodique (Denardo et Fox). Récemment, il a été généralisé au cas de problèmes de jeux à deux joueurs et somme nulle dégénérés (avec paiements ergodiques et de type “multi-chaîne”), au moyen de techniques d’algèbre max-plus et de théorie du potentiel non linéaire [103]. Chaque itération de base de cet algorithme utilise la résolution d’un système d’équations linéaires dont l’opérateur est monotone, mais dont la taille peut être grande, soit parce qu’il provient d’une discrétisation fine d’une équation aux dérivées partielles, soit parce qu’il est associé à un problème discret de grande taille comme le graphe du Web.

Or, la méthode multigrille est l’une des rares méthodes permettant de résoudre, au moins dans les bons cas, des systèmes linéaires en un temps de l’ordre de la taille du système. De plus, alors que la méthode multigrille classique ne s’applique qu’à des discrétisations d’équations aux dérivées partielles elliptiques, la méthode multigrille algébrique (voir par exemple [172]) peut s’appliquer à tout système linéaire présentant des propriétés de monotonie (principe du maximum ou système avec M-matrice).

L’association entre méthodes multigrilles et itérations sur les politiques a déjà été utilisée et étudiée dans le cas de problèmes de contrôle stochastique actualisé (voir par exemple [72], [80]), ainsi que dans le cas d’un algorithme d’itération sur les politiques simplifié pour le contrôle ergodique (voir par exemple [5]), mais pour lequel il n’existe pas de preuve de convergence. La méthode multigrille algébrique a été récemment associée à des méthodes d’apprentissage (voir par exemple [187]). Nous l’avons aussi testée dans le cas de l’itération sur les politiques pour des problèmes de jeux à somme nulle actualisés au cours du stage de Shantanu Gangal en 2007.

La thèse de Sylvie Detournay a pour but de développer et d’étudier un algorithme associant une méthode d’itération sur les politiques du type de celle introduite par Cochet-Terrasson et Gaubert dans [103] et une méthode multigrille algébrique, afin de résoudre des problèmes de jeux à somme nulle dégénérés, éventuellement posés directement sous forme discrète. Sylvie Detournay a d’abord travaillé sur le cas non dégénéré (actualisé) en codant d’abord seulement l’itération sur les politiques (en C) et appelant des codes libres de méthodes multigrilles algébriques. Ces codes n’étant pas assez souples pour être modifiés, elle a
ensuite codé elle-même certains types de méthodes multigrilles algébriques. Des tests sur des discrétisations d’équations aux dérivées partielles d’Hamilton-Jacobi-Bellman ou d’Isaacs, ou d’inéquations variationnelles ont donné de bons résultats et sont présentés dans [15].

Sylvie Detournay a travaillé cette année sur le cas de problèmes avec critère moyen en temps. Elle a implémenté et raffiné l’algorithme proposé par Cochet-Terrasson et Gaubert [103], en l’associant soit à des méthodes de résolution exacte de systèmes linéaires, soit à des méthodes multigrilles algébriques, en utilisant aussi des méthodes multigrilles multiplicatives pour le calcul de la mesure invariante de chaînes de Markov irréductibles. Ceci a permis en particulier l’obtention de résultats numériques dans le cas de discrétisations d’équations d’Isaacs associées à des jeux de poursuite déterministes ou aléatoires. Plusieurs de ces résultats ont été présentés cette année lors de 2 conférences internationales [44], [45], et devraient faire l’objet d’un article en préparation. Par ailleurs dans un article avec Jean Cochet-Terrasson et Stéphane Gaubert [54], nous présentons l’algorithme, sa convergence et des résultats numériques obtenus avec des méthodes de résolution exacte de systèmes linéaires.

**English version**

Policy iteration is a powerful and well known algorithm to solve the dynamic programming equation associated to one player problems. It has recently been extended to degenerate two players problems (with ergodic payoff and in “multichain” cases) using ideas from max-plus algebra and nonlinear potential theory [103]. One basic iteration of the algorithm consists in solving a linear system which operator is monotone, but which size may be large since it comes from the discretization of a partial differential equation or since it is associated to a large size discrete problem such as the Web graph.

For the solution of large size linear systems, the state of art consists of multigrid methods which are often able to solve systems in linear time. Whereas multigrid methods can only be applied to systems that come from discretizations of elliptic partial differential equations, algebraic multigrid methods (see for instance [172]) can be applied to any linear system with monotonicity properties (discrete maximum principle or system with a M-matrix).

The association of multigrid methods with policy iteration has been used and studied in the case of discounted stochastic control problems (see for instance [72], [80]), or in the case of a simplified policy iteration algorithm for ergodic control (see for instance [5]), but for which no proof of convergence is known. Some recent work combines the algebraic multigrid method with learning methods [187]. We have also tested it in the case of policy iterations for discounted zero-sum two-player games, during the internship of Shantanu Gangal in 2007.

The aim of the PhD thesis of Sylvie Detournay is to develop and study an algorithm for degenerate two player games (that may come from a discrete time and finite state space model) combining a policy iteration such as that introduced in [103] and an algebraic multigrid method (AMG). Sylvie Detournay has first worked on the nondegenerate (discounted) case, by coding first the policy iterations (in C) and using free AMG softwares. Since these softwares cannot be modified easily, she has then implemented some types of AMG algorithms (in C). Some tests on discretisations of Hamilton-Jacobi-Bellman or Isaacs partial differential equations or variational inequalities gave good results and are presented in [15].

She has worked this year on the case of problems with mean-payoff criteria. She has implemented and refined the algorithm proposed by Cochet-Terrasson and Gaubert [103], associated either to direct linear solvers, or to the AMG methods already used in the nondegenerate case, and also used multiplicative AMG methods developed in the literature for computing invariant measures of Markov chains. This allows her to obtain numerical results in the case of discretisations of Isaacs equations associated to deterministic or stochastic pursuit games. Several of these results were presented this year in 2 international conferences [44], [45] and are part of an article in preparation. Moreover, in an article with Jean Cochet-Terrasson and Stéphane Gaubert [54], we are presenting the algorithm, its convergence and numerical results obtained with direct linear solvers.

6.4.2. Algorithmique des polyèdres tropicaux/Algorithmics of tropical polyhedra
Participants: Xavier Allamigeon, Stéphane Gaubert, Eric Goubault [CEA].

X. Allamigeon, S. Gaubert, et E. Goubault, ont développé dans [82], [57] plusieurs algorithmes permettant de manipuler des polyédres tropicaux. Ceux-ci correspondent aux travaux décrits dans § 6.2.1. Ils permettent notamment de déterminer les sommets et rayons extrêmes d’un polyèdre tropical défini comme intersection de demi-espaces, ou inversement, de calculer une représentation externe à partir d’un ensemble de générateurs. Ces algorithmes sont implémentés la bibliothèque TPLib (voir § 5.3).

English version

X. Allamigeon, S. Gaubert, and E. Goubault, have developed in [82],[57] algorithms allowing one to manipulate tropical polyhedra. They correspond to the contributions described in § 6.2.1. In particular, they can be used to determine the vertices and extreme rays of a tropical polyhedron defined as the intersection of half-spaces, or inversely, to compute an external description from a set of generators. These algorithms are implemented in the library TPLib (see § 5.3).

6.4.3. Problèmes d’accessibilité dans les hypergraphes orientés et leur complexité/Reachability problems in directed hypergraphs and their complexity

Participant: Xavier Allamigeon.

Les hypergraphes orientés sont une généralisation des graphes orientés, dans lesquelles chaque arc relie un ensemble de sommets à un autre. Ils jouent un rôle important dans les travaux récents sur la convexité tropicale (voir § 6.2.1), puisqu’ils offrent une représentation naturelle des cônes définis sur le sous-semi-anneau booléen $B = \{-\infty, 0\}$.

Dans un travail de X. Allamigeon [56], on étudie la complexité de problèmes d’accessibilité sur les hypergraphes orientés. Nous introduisons un algorithme de complexité presque linéaire permettant de déterminer les composantes fortement connexes terminales (qui n’accèdent à aucune autre composante si ce n’est elles-mêmes) d’un hypergraphe.

Nous établissons également une borne inférieure sur-linéaire sur la taille de la réduction transitive de la relation d’accessibilité dans les hypergraphes. Cela indique que la relation d’accessibilité dans les hypergraphes orientés est combinatoirement plus complexe que celle des graphes orientés. Cela suggère aussi que des problèmes comme le calcul des composantes fortement connexes est plus difficile sur les hypergraphes que sur les graphes. Nous mettons d’ailleurs en évidence une réduction en temps linéaire de la problématique du calcul des ensembles minimaux dans une famille d’ensembles donnée, vers le problème du calcul de toutes les composantes fortement connexes d’un hypergraphe. Le problème du calcul des ensembles minimaux a été largement étudié dans la littérature [163], [183], [182], [164], [165], [166], [118], [88], et aucune algorithme en temps linéaire n’est connu à ce jour.

English version

Directed hypergraphs are a generalization of directed graphs, in which the tail and the head of the arcs are sets of vertices. It appears that they play an important role in the recent works on tropical convexity (see § 6.2.1), since they offer a natural representation of cones defined over the boolean sub-semiring $B = \{-\infty, 0\}$.

In a work of X. Allamigeon [56], we study the complexity of reachability problems on directed hypergraphs. We introduce an almost linear-time algorithm allowing to determine the terminal strongly connected components (a component is said to be terminal when no other component is reachable from it).

We also establish a super-linear lower bound over the size of the transitive reduction of the reachability relation in directed hypergraphs. This indicates that the reachability relation is combinatorially more complex in directed hypergraphs than in directed graphs. This also suggests that reachability problems such as computing all strongly connected components are likely to be harder in hypergraphs than in graphs. Besides, we show that the minimal set problem can be reduced in linear time to the problem of computing all strongly connected components in hypergraphs. The former problem consists in finding all minimal sets among a given family of sets. It has been well studied in the literature [163], [183], [182], [164], [165], [166], [118], [88], and no linear time algorithm is known.
6.4.4. Approximation max-plus de fonctions valeurs/Max-plus approximation of value functions

Participants: Stéphane Gaubert, Zheng Qu, Shanjian Tang [Fudan University, Shanghai], William McEneaney [San Diego University].

La thèse de Zheng Qu, démarrée en septembre 2010, supervisée par S. Gaubert et S. Tang, porte sur le développement de méthodes tropicales en programmation dynamique approchée.

Un problème de base consiste à approcher au mieux la fonction valeur d’un problème de contrôle ou de jeux par le supremum d’un petit nombre de fonctions choisies dans un dictionnaire fixé a priori. Ce problème est abordé dans [43]. À l’aide de résultats de Grüber portant sur l’approximation de corps convexes par des polytopes, on donne tout d’abord une borne montrant le caractère inévitable de la malédiction de la dimension, pour certaines méthodes de type base max-plus, lorsque la fonction valeur est $C^2$ et strictement convexe. Ce résultat montre que ces familles de méthodes sont asymptotiquement coûteuses lorsque la précision requise tend vers 0. Elles permettent cependant d’obtenir rapidement des approximations certifiées d’une précision donnée pas trop petite (dans ce cas, la malédiction de la dimension est absente). On s’intéresse ensuite à un problème algorithmique clé sous-jacent à ces méthodes, qui consiste à éliminer dynamiquement des fonctions redondantes intervenant dans la représentation. On démontre dans [43] que ce problème est équivalent à un problème géométrique de localisation, dans lequel la métrique est non symétrique (de type Bregman). Ceci a permis d’appliquer divers algorithmes de localisation, conduisant à une amélioration de la méthode antérieure [155].

Un autre travail de Zheng Qu porte sur les équations de Riccati généralisées associées à des problèmes de contrôles stochastique avec critère quadratique, dans lesquels la dynamique comporte un terme bilinéaire en le contrôle et le bruit. Alors que le flot de l’équation de Riccati classique est contractant pour la métrique Riemanienne invariante, pour la métrique de Thompson, ainsi que pour toutes les métriques de Finsler invariantes sur le cône des matrices symétriques positives, on montre ici que le flot de l’équation de Riccati généralisée en question est seulement contractant pour la métrique de Thompson (sous des hypothèses naturelles).

English version

The PhD work of Zheng Qu, which started in September 2010, and is supervised by S. Gaubert and S. Tang, aims in particular at developing tropical methods in approximate dynamic programming.

A basic problem consists in approximating the value function of an optimal control or game problem by a supremum of a small number of functions taken from a prescribed dictionary. This problem is addressed in [43]. By applying results of Grüber concerning the approximation of convex bodies by polytopes, we give first a negative result, showing that the curse of dimensionality cannot be avoided by a family of max-plus basis methods, when the value function is $C^2$ and strictly convex. This result shows that this family of methods is asymptotically computationally expensive when the requested precision tends to 0. However, they can be used to obtain quickly (in a curse of dimensionality free way) certified approximations with a fixed (not too small) precision. Then, we addressed a key algorithmic subproblem, consisting in trimming dynamically the redundant functions in a max-plus representation. We showed in [43] that this problem is equivalent to a geometric facility location problem, with a non symmetric Bregman type metric. This allowed us to apply several facility location algorithms, leading to an improvement of the earlier method [155].

Another work of Zheng Qu deals with the generalized Riccati equations associated to stochastic optimal control problems with quadratic cost, in which the dynamics comprises a term which is bilinear in the control and in the noise. Whereas the flow of the standard Riccati equation is known to be a contraction for the invariant Riemannian metric, the Thompson metric, and more generally, for all invariant Finsler metrics on the cone of positive definite matrices, it is shown here that the flow of this generalized Riccati equation is only contracting with respect to Thompson metric (under natural assumptions).

6.5. Applications
6.5.1. Introduction

Nous présentons maintenant plusieurs travaux de nature appliquée, touchant à des domaines variés, dans lesquels nous exploitons certaines des techniques mathématiques présentées précédemment, et particulièrement celles qui relèvent de la théorie de Perron-Frobenius non-linéaire et de la convexité tropicale. Ces applications utilisent aussi des techniques d’algèbre linéaire ou d’optimisation convexe.

**English version**

In this section, we describe several applied works in which we use some of the theoretical tools developed by the team, including non-linear Perron-Frobenius theory and tropical convexity. Some of these applications also make an intensive use of linear algebraic and convex programming methods.

6.5.2. Propriétés des valeurs propres de Perron et de Floquet, et application en chronothérapeutique/Properties of Perron and Floquet eigenvalue, with an application to chronotherapeutics

**Participants:** Frédérique Billy [Projet BANG, INRIA], Jean Clairambault [Projet BANG, INRIA], Olivier Fercoq, Stéphane Gaubert, Thomas Lepoutre [Projet BANG puis DRACULA, INRIA].

On s’intéresse à des modèles de systèmes dynamiques monotones structurés en âge représentant la croissance de populations de cellules (saines ou tumorales), à la suite de travaux de Clairambault et Perthame. Il s’agit de comprendre l’influence du contrôle circadien sur la croissance des cellules. Dans le cas stationnaire, le taux de croissance est représenté par une valeur propre de Perron. Dans le cas périodique, il s’agit d’une valeur propre de Floquet. Les travaux [42], [52], [58] portent sur l’identification de ces modèles ainsi que sur un problème de contrôle thérapeutique, consistant à minimiser le taux de croissance des cellules tumorales sous une contrainte de non-toxicité du traitement (maintien d’une population de cellules saines). Ce travail s’appuie en particulier sur un algorithme d’optimisation de la valeur propre de Perron d’une matrice développé par Fercoq dans un autre contexte [62].

**English version**

We study monotone dynamical systems representing the growth of cells (healthy or tumoral), following a work of Clairambault and Perthame. The goal is to understand how the circadian control influences the growth of cells. In the case of stationary monotone systems, this growth is measured by the Perron root. In the time periodic case, this Perron root is replaced by a Floquet multiplier.

The works [42], [52], [58] deal with the identification of these models, together with a therapeutic control problem, consisting in minimizing the growth rate of tumor cells, under a non-toxicity constraint (preserving the population of healthy cells). This works relies in particular on a fast algorithm to optimize the Perron eigenvalue of a matrix, developed by Fercoq in a different context [62].

6.5.3. Équations aux dérivées partielles en dynamique des populations/Partial differential equations from population dynamics

**Participant:** Sepideh Mirrahimi.

Un des problèmes sur lequel on a travaillé est un modèle de propagation de populations sexuées dans l’espace [64] où on dérive un modèle étudié par des biologistes, à partir d’un modèle de populations structurées et on étudie la dynamique de ce dernier. Nous avons aussi travaillé sur un problème de protéines moteurs, où nous étudions le comportement asymptotique d’un système de deux équations couplées de Fokker-Planck dans un environnement périodique. Avec une approche d’homogénéisation et en utilisant des techniques de solutions de viscosité, on montre que les protéines se déplacent dans une direction constante [65]. De plus, en utilisant des idées venant des problèmes similaires mais discrets, avec Stéphane Gaubert nous étudions les EDPs qui décrivent la dynamique d’une population asexuée sous l’effet des mutations et de la sélection naturelle, et on cherche à déterminer la limite en temps long de la densité de population.

**English version**
One of the problems studied is a model of propagation of a sexual population in space [64], where we derive a model studied by biologists, from a structured population model. We then study the behavior of the solution to the latter model. We also have worked on a problem of motor proteins, where we study the asymptotic behavior of a time dependent, weakly coupled, Fokker-Planck system of two equations set in a periodic environment. By a homogenization approach and using viscosity solutions technics we prove that the molecules either move along a fixed filament with a constant speed and direction or remain immobile [65]. Moreover, using ideas coming from discrete models, with Stéphane Gaubert we study some PDEs that describe the dynamics of an asexual population under mutations and natural selection. We try to determine the long-time limit of the population density.

6.5.4. Identification du trafic dans les réseaux IP/Traffic identification in IP networks

Participants: Mustapha Bouhtou [Orange Labs], Stéphane Gaubert, Guillaume Sagnol.

Le travail de thèse de Guillaume Sagnol, réalisé en collaboration avec Orange Labs dans le cadre d’un contrat “CRE”, a porté sur l’identification du trafic dans des réseaux IP, problème auquel il a appliqué des d’optimisation SDP et d’optimisation sous-modulaire afin de développer des algorithmes passant à l’échelle. Cette thèse s’est achevée fin 2010 [173]. Les articles suivants relatifs au travail de thèse ont été publiés cette année: [36], [35].

English version

The PhD work of Guillaume Sagnol, done in collaboration with Orange Labs in the framework of a “CRE” research contract, dealt with the identification of the traffic in IP networks. Sagnol applied SDP and submodular optimization techniques to develop scalable algorithms (adapted to large networks). The PhD defense took place in 2010 [173]. Some contributions of the PhD have been published this year in [36], [35].

6.5.5. Analyse statique de programmes et itération sur les politiques/Static analysis of computer programs and policy iteration

Participants: Assale Adjé, Stéphane Gaubert, Eric Goubault [CEA].

Un problème important consiste à déterminer le plus petit point fixe (l’algorithme de [14] fournit un point fixe, qui peut ne pas être minimal). Ce problème est abordé dans [30], où l’approche de [14] est comparée avec une approche duale développée par Gawlitza et Seidl.

English version

The PhD work of A. Adjé [11], co-supervised by S. Gaubert and E. Goubault, applies methods from game theory and optimization (generalized duality, convex and non convex programming) to the fixed point problems arising in static analysis of programs by abstract interpretation. We introduced in [14] a new domain in static analysis, which extends to nonlinear cases the “templates” introduced by Manna, Sankaranarayanan, and Sipma [175]. This domain allows one to represent accessible sets that are non convex. These are defined by finitely many inequalities taken from a dictionary. This allows one to use in particular the information provided by Lyapunov functions, which are often known in applications arising from engineering. We showed in [14] that experimentally accurate invariants can be obtained by coupling policy iteration with Shor
relaxation (SDP relaxation of convex programming problems). This yields accurate abstractions of some numerical programs, like linear filters with thresholds.

An important problem consists in determining the smallest fixed point (the algorithm of [14] yields a possibly non minimal fixed point). This problem is addressed in [30], in which the approach of [14] is compared with a dual approach developed by Gawlitza and Seidl.

6.5.6. Optimization du référencement sur la toile/Optimization of web referencing

Participants: Marianne Akian, Mustapha Bouhtou [Orange Labs], Olivier Fercoq, Stéphane Gaubert.

La thèse d’O. Fercoq, co-encadrée par M. Akian, M. Bouhtou, et S. Gaubert, financée par un CRE d’Orange Labs, a pour but d’appliquer des méthodes d’optimisation et de théorie des jeux à l’optimisation de services en lignes. On a tout d’abord étudié le problème de l’optimisation du référencement, que l’on formalise en se donnant par exemple un ensemble d’hyperliens et de ressources obligatoires, dont la nature et la position sur le site web sont déterminées à l’avance par le concepteur. Cet ensemble forme en quelque sorte le squelette du site web. On se donne aussi un ensemble d’hyperliens ou de ressources facultatives, pour lesquels le concepteur du site a certains degrés de liberté (le lien ou le contenu peut être mis sur une page plutôt qu’une autre, voire être omis).

Dans [61], on aborde le problème de l’optimisation du “Pagerank” dans ce cadre, en appliquant des techniques de décision Markovienne classiques et sous-contraintées. Le problème peut en effet se ramener à un problème de contrôle ergodique ou de contrôle ergodique sous contraintes (ergodiques), selon que les contraintes sur les hyperliens sont locales à chaque page ou font intervenir plusieurs pages. On traite à la fois le cas relaxé où les probabilités de passage d’une page à une autre peuvent être des réels positifs quelconques (on peut par exemple supposer que cette probabilité dépend de la position et des caractères utilisés pour l’hyperlien correspondant) et le cas discret où ces probabilités sont uniformes parmis celles qui sont strictement positives (comme dans la modélisation classique conduisant au calcul du Pagerank). On montre que cette famille de problèmes correspondent à des problèmes de programmation dynamique avec un nombre exponentiel de contrôles, mais où les polytopes des mesures de probabilités de transition admettent des oracles de séparation polynômiaux. On obtient de la sorte des résultats de complexité, ainsi que, sous certaines hypothèses, des algorithmes adaptés à des instances de grande taille, couplant programmation dynamique et relaxation Lagrangienne. Ces algorithmes ont été testés sur un fragment du graphe du web.

Un critère de référencement classique, alternatif au pagerank, est donné par le vecteur propre de Perron. O. Fercoq a abordé le problème associé d’optimisation du référencement, qui se révèle plus difficile que celui du pagerank, en raison de l’absence de propriété de convexité. Cependant, il a développé un algorithme rapide et creux (basé sur des propriétés de rang 1 d’opérateurs intervenant dans le calcul de dérivées du critère) permettant de calculer un optimum local du référencement [62]. Il a enfin donné un algorithme analogue pour optimiser le score “HOTS” de Tomlin.

English version

The goal of the PhD work of O. Fercoq, cosupervised by M. Akian, M. Bouhtou, and S. Gaubert, and supported by a research contract (CRE) of Orange Labs, is to apply optimization and game theory methods to the optimization of online services. We started by investigating the problem of the optimization of referencing, which we modelled by considering a family of compulsory hyperlinks and resources (fixed in advance by the website designer, these constitute the “skeleton” of the website) and also a family of facultative hyperlink or resources (some links may be omitted or some other links may be added).

In [61], we are approaching the problem of the pagerank optimization in this framework, by applying usual and constrained Markov decision processes techniques. This problem can indeed be reduced to an ergodic control problem without or with (ergodic) constraints, depending on the fact that hyperlinks constraints are local to each web page or depend on several web pages. We study the relaxed problem where the transition probabilities from one page to another may be any positive real (one may assume for instance that this probability depends on the position and type used for the corresponding hyperlink), as well as the discrete problem where these probabilities are uniform among the positive ones (as in the usual modelisation leading
to the Pagerank). We show that these problems can be reduced to dynamic programming problems with exponentially many discrete actions, in which however the polytopes of transition probability measures admit polynomial time separation oracles. We derive from this approach polynomial time complexity results, as well as under some additional assumption, scalable algorithms (adapted to large web graphs), coupling dynamic programming and Lagrange relaxation. The latter have been tested on a real subgraph of the web.

A classical alternative ranking relies on the Perron eigenvector. O. Fercoq treated the associated optimisation problem, which turns out to be harder than in the pagerank case, due to the lack of convexity properties. However, he developed a fast (sparse) algorithm, exploiting the rank 1 properties of operators appearing when computing the derivative of the objective function, allowing one to compute a local optimum [62]. He also developed a similar method to optimize Tomlin’s “HOTS” score.

6.5.7. Gestion du revenu appliquée à la tarification de services données/Yield management applied to pricing of data services

Participants: Mustapha Bouhtou [Orange Labs], Jean-Baptiste Dumont, Stéphane Gaubert.

Le travail de thèse CIFRE de J-B. Dumont, qui a démarré en Septembre 2010, sous la supervision de M. Bouhtou et S. Gaubert, porte sur la tarification de services data et la gestion des ressources dans les réseaux mobiles, qui est abordée à l’aide de techniques de contrôle et d’optimisation stochastique. Dumont a développé un premier modèle de tarification, permettant d’inciter les clients à reporter leur demande en dehors des périodes les plus chargées.

English version

The CIFRE PhD work of J-B. Dumont started in September 2012, under the joint supervision of M. Bouhtou and S. Gaubert. It deals with the pricing of data services and resource allocation in mobile networks. This is addressed through stochastic control and stochastic optimization techniques. Dumont developed a first model of pricing, giving some incentive to the customers to move their demand from loaded to less loaded time periods.
6. New Results

6.1. Multi-fluid flows

- Microfluidics : (2011) Participants CHB, Johana Pinilla (doc), Sandra Tancogne (MC Reims) To handle oil recovery by chemical processes it is useful to better understand the behaviour of multi-fluids flows in a saturated soil. The porous medium is mimiced by a network of micro channels. The simulation of immiscible multi-fluids flows is then performed by means of the level-sets and the penalization methods to track the interfaces between the fluids and to get rid of the geometry difficulties. In addition the Cox law is added in the model to better move the interfaces during the simulations.

- Microfluidics : concerning visco-elastic fluids in micro-channel, one has often to compute solutions of system for which the viscosity in the Stokes part is much smaller than that involved in the extra-stress. In his thesis, V. Huber has introduced a new scheme to overcome this difficulties without changing the complexity of the scheme (PhD in progress).

6.2. Cancer modelling

In 2010, we have improved our generic mathematical models describing tumor growth. These models were then specialized for several types of cancer (thyroidal lung nodules, brain tumors). The algorithm used to recover the parameters of these models from medical images has also been greatly improved and is now adapted to run on HPC architectures.

- Secondary tumors in the lung:
  The mathematical models describing the growth of secondary in the lungs have now settled and are well understood. The main focus of the year was to keep on using these models on patient data. New clinical case were selected by clinicians from the Institut Bergonié, there are currently under study. The model is currently able to reproduce the growth observed on 5 clinical cases. In 2011, various improvements to the calibration algorithms were made. The initial seeding of the algorithms was a weak point of the procedure. This has been much improved using a genetic algorithm. A complete rewrite of the routines was done to improve their versatility and efficiency. Previously, the numerical simulations and calibration were performed in 2D (clinicians selected the most relevant slice showing the evolution of the tumor). Work is now ongoing to switch to full 3D computations and calibration.

- Breast cancer modeling:
  In collaboration with the University of Houston and the Methodist Hospital, a new mathematical model describing the growth of breast cancer has been developed. This multi-scale model takes many aspects of the disease into account and allows to study the interplays between the various mechanisms responsible for the evolution of the tumor.

- Modeling glioblastomas:
  In 2011, a hierarchy of models describing the growth of brain tumors was developed (and described in a submitted paper) in collaboration with University of Alabama at Birmingham. As we wished to obtain models that could be calibrated from patient data and yet be reasonably accurate, we believe that these models are suitable trade-offs between the simplicity of the SwansonOs model (the only one used on patient data of brain tumors so far) and the accuracy of more complex models (that cannot really produce quantitative results). In particular, two models were built. The first one allows to study the efficacy of anti-angiogenic therapies. It seems to predict that the efficacy of these treatments is limited, this could be confirmed by a world-wide ongoing clinical study. The second model has been validated and we are trying to recover its parameters for a patient in 3D (which is a rather unique initiative to our knowledge).
Modelling of electrochemotherapy: Two articles related to the electrical cell modelling have been done ([58], [54]). The first one deals with the influence of the ionic fluxes on the transmembrane voltage potential and on the cell volume. The main insight of the results consists in linking the transmembrane potential with the cell volume: it has been observed experimentally that cells with a low voltage potential do divide, whereas cells with high voltage potential do not, and the obtained relationship between voltage potential and cell volume can provide an explanation. The second article deals with a new model of cell electroporation essentially based on the experimental results of the I.G.R. In this paper we describe precisely the model, which takes into account the main experimental results in the electroporation process, and we present a variationnal formulation inherent to the model that leads to new efficient schemes in order to numerically solve the involved P.D.E.

6.3. Newtonian fluid flows simulations and their analysis

- Simulations of water distribution systems: Water losses may constitute a large amount of the distributed total water volume throughout water distribution systems. Here, a new model method is proposed that intends to minimize the total water volume distributed through leakage reduction. Our group has worked on the derivation of advection-reaction-diffusion type equations with an explicit relationship between the local pressure and the leakage rate. An original splitting technique to solve this type of hydraulic problem was then achieved. This technique allows pressure-dependent leakage to be taken into account, whereas in most models leakage is assumed to be uniform along a pipe. Finally, a constrained optimization problem was formulated for leakage reduction in WDS. The control variable had the mean of a local head loss and is considered in the Boundary Conditions to avoid dealing with discontinuities in the governing equations. The objective function to minimize was a regularization of the total water volume distributed. Specific operational constraints were added to ensure enough pressure at consumption points. The direct solution for this minimization problem was sought with a Gradient type method. The leakage reduction was proven to be significant in a case study. The percentage of leakage reduced from 24% to 10% in the linear relationship between pressure and leakage flow rate. With other leakage exponents, the same rate of reduction was achieved. The method was applied on a real network in the South-West of France. Controlling the pressure at two different strategic points permits a significant amount of the total distributed water to be saved (5%). This work was performed in collaboration with Cemagref Bordeaux. Future work will consist of applying a sensibility analysis of control location points to optimize the method.

- Incompressible flows: modeling and simulation of moving and deformable bodies. The incompressible Navier-Stokes equations are discretized in space onto a fixed cartesian mesh. The deformable bodies are taken into using a first order penalization method and/or second order immersed boundary method. The interface between the solid and the fluid is tracked using a level-set description so that it is possible to simulate several bodies freely evolving in the fluid. A turbulence model based on Samgorinsky model has been added to the numerical code. The numerical code written in the C language is massively parallel. The large linear systems (over than 100 millions of dofs) are solved using the Petsc Library. As an illustration of the methods, fish-like locomotion is analyzed in terms of propulsion efficiency. Underwater maneuvering and school swimming are also explored. We were able to simulate the three-dimensional flow about a swimmer for realistic physical configurations. See [17]. Another application is the turbulent 3D flow around complex wind turbine (see http://www.math.u-bordeaux1.fr/bergmann/ and http://www.math.u-bordeaux1.fr/MAB/mc2/analysis.html for simulation movies). Wake flows generated by boat propellers are also modeled and simulated.

- Turbulence flow on an hemisphere: (2011) Participants CHB, Patrick Fischer, Yong Liang Xiong (PD) ANR Cyclobulle lead by Hamid Kellay Soap hemi-bubble film experiments have shown some links between the formation of vortices when the hemi-bubble is heated at the equator and the formation of tornados in the earth atmosphere. Two-dimensional simulations using a stereographic map are used to compare to these experimental results and confirm the results when Coriolis force and heat source terms are added.

- Compressible flows: Immersed boundary methods. We are concerned with immersed boundary methods, i.e., integration schemes where the grid does not fit the geometry, and among this class
of methods, more specifically with cartesian grid methods, where the forcing accounting for the presence of boundaries is performed at the discrete level. We have developed a simple globally second order scheme inspired by ghost cell approaches to solve compressible flows, inviscid as well as viscous. In the fluid domain, away from the boundary, we use a classical finite-volume method based on an approximate Riemann solver for the convective fluxes and a centered scheme for the diffusive term. At the cells located on the boundary, we solve an ad hoc Riemann problem taking into account the relevant boundary condition for the convective fluxes by an appropriate definition of the contact discontinuity speed. This method can easily be implemented in existing codes and is suitable for massive parallelization. It has been validated in 1D and 2D for Euler and Navier-Stokes compressible equations. The order of convergence of the method is similar to those observed in the literature: second order globally and first order locally, near the interface for Euler equations, and second order locally and globally for Navier-Stokes equations.

We have developed a new cartesian method to solve elliptic problems with immersed interfaces. These problems appear in numerous applications, among them: heat transfer, electrostatics, fluid dynamics, but also tumour growth modelling, or modelling of electric potential in biological cells. This method is second order accurate in the whole domain, notably near the interface. The originality of the method lies on the use of additional unknowns located on interface points, on which are expressed flux equalities. Special care is dedicated to the discretization near the interface, in order to recover a stable second order accuracy. Actually, a naive discretization could lead to a first order scheme, notably if enough accuracy in the discretization of flux transmission conditions is not provided. Interfaces are represented with a distance level-set function discretized on the grid points. The method has been validated on several test-cases with complex interfaces in 2D. A parallel version has been developed using the PETSC library.

- Simulations of fluid-solid interactions: The interaction of an elastic structure and an fluid occurs in many phenomena in physics. To avoid the difficulty of coupling lagrangian elasticity with an eulerian fluid we consider a whole eulerian formulation. The elasticity of the structure is computed with retrograde characteristics which satisfy a vectorial transport equation. We derive the associated fluid-structure models for incompressible and compressible media. The equations are discretized on a cartesian mesh with finite differences and finite volumes schemes. The applications concern the bio-locomotions and the study of air-elastic interaction.

- Vortex methods: The aim of this work is to couple vortex methods with the penalization methods in order to take advantage from both of them. This immersed boundary approach maintains the efficiency of vortex methods for high Reynolds numbers focusing the computational task on the rotational zones and avoids their lack on the no-slip boundary conditions replacing the vortex sheet method by the penalization of obstacles. This method that is very appropriate for bluff-body flows is validated for the flow around a circular cylinder on a wide range of Reynolds numbers. Its validation is now extended to moving obstacles (axial turbine blades) and three-dimensional bluff-bodies (flow around a sphere). See [71]. Moreover, using the global properties of the penalization method, this technique permits to include porous media simultaneously in the flow computation. We aim to adapt the porous media flows to our new method and to apply it in order to implement passive control techniques using porous layers around bluff-bodies.

- Domain decomposition: Domain decomposition methods are a way to parallelize the computation of numerical solutions to PDE. To be efficient, domain decompositions methods should converge independently on the number of subdomains. The classical convergence result for the additive Schwarz preconditioner with coarse grid is based on a stable decomposition. The result holds for discrete versions of the Schwarz preconditioner, and states that the preconditioned operator has a uniformly bounded condition number that depends only on the number of colors of the domain decomposition, and the ratio between the average diameter of the subdomains and the overlap width. Constants are usually non explicit and are only asserted to depend on the "shape regularity" of the domain decomposition.
Last year, we showed the result holds the additive Schwarz preconditioner can also be defined at the continuous level and provided completely explicit estimates. This year, we established that a similar result also holds for non-shape regular domain decompositions where the diameter of the smallest subdomain is significantly smaller than the diameter of the largest subdomain. The constants are also given explicitly and are independent of the ratio between the diameter of the largest subdomain and the diameter of the smallest subdomain.

### 6.4. Flow control and shape optimization

- Flow control: (2011) Participants CHB, Iraj Mortazavi, Emmanuel Creus (Lille), Patrick Gilliron (Renault chercheur indépendant !) An efficient active control of the two- and three-dimensions flow around the 25¡ rear window Ahmed body has been performed. A careful theoretical and numerical study of the trajectories of the vortices allows to adapt the control in order to improve its efficiency and get a better drag reduction.
6. New Results

6.1. Perfect simulation

We have proposed a new approach for sampling the stationary distribution of general Markov chains that only needs to consider two trajectories. We show that this new approach is particularly effective when the state space can be partitioned into pieces where envelopes can be easily computed [26]. We further show that most Markovian queuing networks have this property and we propose efficient algorithms for some of them, in particular when the rates of events range over several orders of magnitude [45]. We also provided a novel approach for efficient sampling of queues with phase type servers [37] (this paper has received the best paper award at ASMTA 2011) and Markov chains with infinite state spaces (but with a known bounding process). Perfect sampling has been used for model checking of probabilistic models in [14].

6.2. Economic models for clouds

Recently introduced spot instances in the Amazon Elastic Compute Cloud (EC2) offer low resource costs in exchange for reduced reliability; these instances can be revoked abruptly due to price and demand fluctuations. Mechanisms and tools that deal with the cost-reliability trade-offs under this scheme are of great value for users seeking to lessen their costs while maintaining high reliability. We study how mechanisms, namely, checkpointing and migration, can be used to minimize the cost and volatility of resource provisioning. Based on the real price history of EC2 spot instances, we compare several adaptive checkpointing schemes in terms of monetary costs and improvement of job completion times. We evaluate schemes that apply predictive methods for spot prices. Furthermore, we also study how work migration can improve task completion in the midst of failures while maintaining low monetary costs. Trace-based simulations show that our schemes can reduce significantly both monetary costs and task completion times of computation on spot instance [25].

6.3. Game theory and networks

We studied the traffic routing problem in networks whose users try to minimize their latencies by employing a distributed learning rule inspired by the replicator dynamics of evolutionary game theory. The stable states of these dynamics coincide with the network’s (Wardrop) equilibrium points. Despite this abundance of stable states, we find that (almost) every solution trajectory converges to an equilibrium point at an exponential rate. When network latencies fluctuate unpredictably we show that the time-average of the traffic flows of sufficiently patient users is still concentrated in a neighborhood of evolutionarily stable equilibria and we estimate the corresponding stationary distribution and convergence times [42].

We also analyzed the distributed power allocation problem in parallel multiple access channels (MAC) by studying an associated non-cooperative game which admits an exact potential function. We show that the parallel MAC game admits a unique equilibrium almost surely. Furthermore, if the network’s users employ a distributed learning scheme based on the replicator dynamics, we show that they converge to equilibrium from almost any initial condition, even though users only have local information at their disposal [41].

Using a large deviations approach we calculate the probability distribution of the mutual information of MIMO channels in the limit of large antenna numbers. We calculate the full distribution, including its tails which strongly deviate from the Gaussian behavior near the mean. This calculation provides us with a tool to obtain outage probabilities analytically at any point in the parameter space, as long as the number of antennas is not too small [20].
6.4. Mean field analysis for networks

We have studied the deterministic limits of Markov processes made of several interacting objects. While most classical results assume that the limiting dynamics has Lipschitz properties, we show that these conditions are not necessary to prove convergence to a deterministic system.

We show that under mild assumptions, the stochastic system converges to the set of solutions of a differential inclusion and we provide simple way to compute the limiting inclusion. When this differential inclusion satisfies a one-sided Lipschitz condition, there exists a unique solution of this differential inclusion and we show convergence in probability with explicit bounds.

This extends the applicability of mean field techniques to systems exhibiting threshold dynamics such as queuing systems with boundary conditions or controlled dynamics. This is illustrated by applying our results to several types of systems: fluid limits of priority queues, best response dynamics in games, push-pull queues with a large number of sources and a large number of servers and self-adapting computing systems [65].

6.5. Idleness and failure prediction in large infrastructures

We have proposed a method to discover statistical models of availability in large distributed systems and applied it to run an enlightening study of SETI@home [19]. This was also used to make long-term availability predictions for groups of desktop grid resources [21]. We have used statistically based models of heterogeneous failures in parallel systems and assessed their tolerance [39]. A similar approach was used to design correlated resource models of Internet end hosts [38], [17].

6.6. Scheduling and Game Theory

A stochastic model of failures has been used to optimize the scheduling of checkpoints on desktop grids [28].

We have also shown that non-cooperative scheduling can be considered harmful in collaborative volunteer computing environments [33].

Optimal scheduling and route selection have been investigated using a novel approach based on Lagrangian optimization. This result is inspired from flow control in multi-path networks and was used for multiple mag- of-tasks application scheduling on grids [61].

In the similar context of broker-based networks of non-observable parallel queues, we provide lower bounds on the minimum response time. We introduce the “Price of Forgetting” (PoF), the ratio between the minimum response times achieved by a probabilistic broker and a broker with memory, that is shown to be unbounded or arbitrarily close to one depending on the coefficient of variation of the service time distributions. We also put our results in the context of game theory revisiting the “Price of Anarchy” (PoA) of parallel queues: It can be decomposed into the product of the PoA achieved by a probabilistic broker (already well understood) and the PoF [10].

6.7. Validity study of flow-based network models.

Researchers in the area of distributed computing conduct many of their experiments in simulation. While packet-level simulation is often used to study network protocols, it can be too costly to simulate network communications for large-scale systems and applications. The alternative chosen in SimGrid and a few other simulation frameworks is to simulate the network based on less costly flow-level models. Surprisingly, in the literature, validation of these flow-level models is at best a mere verification for a few simple cases. Consequently, although distributed computing simulators are widely used, their ability to produce scientifically meaningful results is in doubt. In [9], [70] we focus on the validation of state-of-the-art flow-level network models of TCP communication, via comparison to packet-level simulation. While it is straightforward to show cases in which previously proposed models lead to good results, instead we systematically seek cases that lead to invalid results. Careful analysis of these cases reveal fundamental flaws and also suggest improvements. One
contribution of this work is that these improvements lead to a new model that, while far from being perfect, improves upon all previously proposed models. A more important contribution, perhaps, is provided by the pitfalls and unexpected behaviors encountered in this work, leading to a number of enlightening lessons. In particular, this work shows that model validation cannot be achieved solely by exhibiting (possibly many) "good cases." Confidence in the quality of a model can only be strengthened through an invalidation approach that attempts to prove the model wrong.

6.8. Visualization

We have proposed a methodology for detecting resource usage anomalies in large scale distributed systems. The methodology relies on four functionalities: characterized trace collection, multi-scale data aggregation, specifically tailored user interaction techniques, and visualization techniques. We have shown the efficiency of this approach through the analysis of simulations of the volunteer computing Berkeley Open Infrastructure for Network Computing architecture (BOINC). Three scenarios have been analyzed in [48], [23]: analysis of the resource sharing mechanism, resource usage considering response time instead of throughput, and the evaluation of input file size on Berkeley Open Infrastructure for Network Computing architecture. The results show that our methodology enables to easily identify resource usage anomalies, such as unfair resource sharing, contention, moving network bottlenecks, and harmful short-term resource sharing. Triva, the resulting software, has been demonstrated at the SuperComputing conference.

We also have investigated how to use trace-based visualization to understand applications I/O performance [49] and how to visually compare two traces [70] and highlight differences.

6.9. Experimental methodology

In the scientific experimentation process, an experiment result needs to be analyzed and compared with several others, potentially obtained in different conditions. Several tools are dedicated to the control of the experiment input parameters and the experiment replay. In parallel, concurrent and distributed systems, experiment conditions are not only restricted to the input parameters, but also to the software environment in which the experiment was carried out. It is therefore essential to be able to reconstruct this type of environment. This can quickly become complex for experimenters, particularly on research platforms dedicated to scientific experimentation, where both hardware and software are in constant rapid evolution. We study the concept of the reconstructability of software environments and propose a tool for dealing with this problem in [64].

We have also started investigating the systematic use of Design of Experiments to computer studies (see [61]). Nonetheless such approach provides results that are much more trustworthy than what is generally done in the parallel and distributed computing community but it also enables to shorten the experiments cycle and to use less computing resources.

6.10. Multi-core platforms

We have used memory access traces to map threads on hierarchical multi-core platforms [13]. We have also used software transactional memory to analyze and trace applications running on multi-core architectures [30].

An approach based on machine learning was used to map threads on transactional memory applications in [31].

The impact of CPU and memory affinity on multi-core platforms was investigated in [46] using numerical scientific multi-threaded applications as a typical case study. This resulted in improvement of the performance of parallel systems using a NUMA-aware load balancer [68].

We have also carried a performance evaluation of WiNoCs for parallel workloads based on collective communications [43] as well as for Infiniband networks [40].
6.11. High performance computing

We have developed a runtime system, named SGPU 2, that enable large applications to run on clusters of hybrid nodes [44].

BigDFT is a parallel simulator of the matter at the nano scale. It uses Daubechies Wavelets for High Performance Electronic Structure Calculations [16]. This tool is shown to make efficient use of massive parallel hybrid architectures [57].

6.12. Input-Output

Atmospheric models usually demand high processing power and generate large amounts of data. As the degree of parallelism grows, the I/O operations may become the major impacting factor of their performance. In [27], we evaluate the Ocean-Land-Atmosphere Model (OLAM) on the PVFS file system in order to point the I/O characteristics of the application. We show that storing the files on PVFS has lower performance than using the local disks of the cluster nodes due to file creation and network concurrency. Additionally, we study the performance of a new version of OLAM that used MPI associated with OpenMP and show that the combined strategy presents I/O times 20 times shorter than the original MPI-only version and 9 times shorter on total execution time. Finally, a survey on I/O Characterization of several applications is given in [51].
METISS Project-Team

6. New Results

6.1. Audio and speech content processing

6.1.1. Audio motif discovery

Participants: Frédéric Bimbot, Laurence Catanese, Armando Muscariello.

This work was performed in close collaboration with Guillaume Gravier from the Texmex project-team.

As an alternative to supervised approaches for multimedia content analysis, where predefined concepts are searched for in the data, we investigate content discovery approaches where knowledge emerge from the data. Following this general philosophy, we pursued work on motif discovery in audio contents.

Audio motif discovery is the task of finding out, without any prior knowledge, all pieces of signals that repeat, eventually allowing variability. In 2011, we extended our recent work on seeded discovery to near duplicate detection and spoken document retrieval from examples. First, we proposed algorithmic speed ups for the discovery of near duplicate motifs (low variability) in large (several days long) audio streams, exploiting subsampling strategies [muscariello-cbmi-11]. Second, we investigated the use of previously proposed efficient pattern matching techniques to deal with motif variability in speech data [muscariello-icassp-11] in a different setting, that of spoken document retrieval from an audio example. We demonstrated the potential of model-free approaches for efficient spoken document retrieval on a variety of data sets, in particular in the framework of the Spoken Web Search task of the MediaEval 2011 international evaluation [muscariello-is-11, muscariello-mediaeval-11].

This work is carried out in the context of the Quaero Project.

6.1.2. Landmark-driven speech recognition

Participant: Stefan Ziegler.

This work is supervised by Guillaume Gravier and Bogdan Ludusan from the Texmex project-team.

Speech recognition is a key issue to access multimedia spoken contents. In this context, speech recognition faces several challenges among which robustness to acoustic and linguistic variability.

In 2011, we initiated research on landmark-driven speech recognition to increase robustness. The idea of this approach consists in accurately detecting in the signal landmarks corresponding to broad phonetic classes (vowels, nasals, etc.). These landmarks, which represent almost certain knowledge about the phonetic content of the signal, are then used to bias the search space in Viterbi decoding towards solutions consistent with the landmarks. We proposed a landmark detection system, which employs numerous attributes extracted from a segment based representation of speech. We use a decision tree for BPC classification, since this allows the evaluation of each BPC on its most informative attributes, selected from a large variety of attributes. Then, each segment is converted into a landmark and a probability estimate for each BPC is provided. Second, we extend a previously proposed landmark-driven decoding strategy by a more flexible implementation, which reinforces paths at the detected landmarks according to the obtained BPC probabilities. Results obtained on French broadcast news data show a relative improvement in word error rate of about 2 % with respect to the baseline.

6.2. Recent results on sparse representations

The team has had a substantial activity ranging from theoretical results to algorithmic design and software contributions in the field of sparse representations, which is at the core of the FET-Open European project (FP7) SMALL (Sparse Models, Algorithms and Learning for Large-Scale Data, see Section 7.2.1 ) and the ANR project ECHANGE (ECHantillonnage Acoustique Nouvelle GEnération, see, Section 6.3.1 ).
6.2.1. A new framework for sparse representations: analysis sparse models

Participants: Rémi Gribonval, Sangnam Nam.

Main collaboration: Mike Davies (Univ. Edinburgh), Michael Elad (The Technion), Hadi Zayyani (Sharif University)

In the past decade there has been a great interest in a synthesis-based model for signals, based on sparse and redundant representations. Such a model assumes that the signal of interest can be composed as a linear combination of few columns from a given matrix (the dictionary). An alternative analysis-based model can be envisioned, where an analysis operator multiplies the signal, leading to a cosparse outcome. Within the SMALL project, we initiated a research programme dedicated to this analysis model, in the context of a generic missing data problem (e.g., compressed sensing, inpainting, source separation, etc.). We obtained a uniqueness result for the solution of this problem, based on properties of the analysis operator and the measurement matrix. We also considered a number of pursuit algorithms for solving the missing data problem, including an L1-based and a new greedy method called GAP (Greedy Analysis Pursuit). Our simulations demonstrated the appeal of the analysis model, and the success of the pursuit techniques presented. These results have been published in international conferences [64], [63], and a journal paper is in preparation.

Our simulations demonstrated the appeal of the analysis model, and the success of the pursuit techniques presented. These results have been published in conferences [64], [91], [92] and a journal paper submitted to Applied and Computational Harmonic Analysis is under revision [103]. Other algorithms based on iterative cosparse projections [57] as well as extensions of GAP to deal with noise and structure in the cosparse representation have been developed, with applications to toy MRI reconstruction problems and acoustic source localization and reconstruction from few measurements (submitted to ICASSP 2012).

6.2.2. Theoretical results on sparse representations and dictionary learning

Participants: Rémi Gribonval, Sangnam Nam, Nancy Bertin.

Main collaboration: Karin Schnass (EPFL), Mike Davies (University of Edinburgh), Volkan Cevher (EPFL), Simon Foucart (Université Paris 5, Laboratoire Jacques-Louis Lions), Charles Soussen (Centre de recherche en automatique de Nancy (CRAN)) Jérôme Idier (Institut de Recherche en Communications et en Cybernétique de Nantes (IRCCyN)), Cédric Herzet (Equipe-projet FLUMINANCE (INRIA - CEMAGREF, Rennes)) Morten Nielsen (Department of Mathematical Sciences [Aalborg]), Gilles Puy, Pierre Vandergheynst, Yves Wiaux (EPFL) Mehrdad Yaghoobi, Rodolphe Jenatton, Francis Bach (Equipe-projet SIERRA (INRIA, Paris)) Boaz Ophir, Michael Elad (Technion) Mark D. Plumbley (Queen Mary, University of London)

Sparse recovery conditions for Orthogonal Least Squares: We pursued our investigation of conditions on an overcomplete dictionary which guarantee that certain ideal sparse decompositions can be recovered by some specific optimization principles / algorithms. This year, we extended Tropp’s analysis of Orthogonal Matching Pursuit (OMP) using the Exact Recovery Condition (ERC) to a first exact recovery analysis of Orthogonal Least Squares (OLS). We showed that when ERC is met, OLS is guaranteed to exactly recover the unknown support. Moreover, we provided a closer look at the analysis of both OMP and OLS when ERC is not fulfilled. We showed that there exist dictionaries for which some subsets are never recovered with OMP. This phenomenon, which also appears with $\ell_1$ minimization, does not occur for OLS. Finally, numerical experiments based on our theoretical analysis showed that none of the considered algorithms is uniformly better than the other. This work has been submitted for publication in a journal [108].

New links between the Restricted Isometry Property and nonlinear approximations: It is now well known that sparse or compressible vectors can be stably recovered from their low-dimensional projection, provided the projection matrix satisfies a Restricted Isometry Property (RIP). We establish new implications of the RIP with respect to nonlinear approximation in a Hilbert space with a redundant frame. The main ingredients of our approach are: a) Jackson and Bernstein inequalities, associated to the characterization of certain approximation spaces with interpolation spaces; b) a new proof that for overcomplete frames which satisfy a Bernstein inequality, these interpolation spaces are nothing but the collection of vectors admitting a representation in the dictionary with compressible coefficients; c) the proof that the RIP implies Bernstein...
inequalities. As a result, we obtain that in most overcomplete random Gaussian dictionaries with fixed aspect ratio, just as in any orthonormal basis, the error of best $m$-term approximation of a vector decays at a certain rate if, and only if, the vector admits a compressible expansion in the dictionary. Yet, for mildly overcomplete dictionaries with a one-dimensional kernel, we give examples where the Bernstein inequality holds, but the same inequality fails for even the smallest perturbation of the dictionary. This work has been submitted for publication in a journal [102].

**Performance guarantees for compressed sensing with spread spectrum techniques** : We advocate a compressed sensing strategy that consists of multiplying the signal of interest by a wide bandwidth modulation before projection onto randomly selected vectors of an orthonormal basis. Firstly, in a digital setting with random modulation, considering a whole class of sensing bases including the Fourier basis, we prove that the technique is universal in the sense that the required number of measurements for accurate recovery is optimal and independent of the sparsity basis. This universality stems from a drastic decrease of coherence between the sparsity and the sensing bases, which for a Fourier sensing basis relates to a spread of the original signal spectrum by the modulation (hence the name "spread spectrum"). The approach is also efficient as sensing matrices with fast matrix multiplication algorithms can be used, in particular in the case of Fourier measurements. Secondly, these results are confirmed by a numerical analysis of the phase transition of the $l_1$-minimization problem. Finally, we show that the spread spectrum technique remains effective in an analog setting with chirp modulation for application to realistic Fourier imaging. We illustrate these findings in the context of radio interferometry and magnetic resonance imaging. This work has been presented at a conference [93] and accepted for publication in a journal [105].

**Dictionary learning** : An important practical problem in sparse modeling is to choose the adequate dictionary to model a class of signals or images of interest. While diverse heuristic techniques have been proposed in the literature to learn a dictionary from a collection of training samples, there are little existing results which provide an adequate mathematical understanding of the behaviour of these techniques and their ability to recover an ideal dictionary from which the training samples may have been generated.

In 2008, we initiated a pioneering work on this topic, concentrating in particular on the fundamental theoretical question of the identifiability of the learned dictionary. Within the framework of the Ph.D. of Karin Schnass, we developed an analytic approach which was published at the conference ISCCSP 2008 [13] and allowed us to describe "geometric" conditions which guarantee that a (non overcomplete) dictionary is "locally identifiable" by $l_1$ minimization.

In a second step, we focused on estimating the number of sparse training samples which is typically sufficient to guarantee the identifiability (by $l_1$ minimization), and obtained the following result, which is somewhat surprising considering that previous studies seemed to require a combinatorial number of training samples to guarantee the identifiability: the local identifiability condition is typically satisfied as soon as the number of training samples is roughly proportional to the ambient signal dimension. The outline of the second result was published in conferences [12], [25]. These results have been published in the journal paper [15].

This year we have worked on extending the results to noisy training samples with outliers. A journal paper is in preparation, and the results will be presented at a workshop at NIPS 2011.

**Analysis Operator Learning for Overcomplete Cosparse Representations** : Besides standard dictionary learning, we also considered learning in the context of the cosparse model. We consider the problem of learning a low-dimensional signal model from a collection of training samples. The mainstream approach would be to learn an overcomplete dictionary to provide good approximations of the training samples using sparse synthesis coefficients. This famous sparse model has a less well known counterpart, in analysis form, called the cosparse analysis model. In this new model, signals are characterized by their parsimony in a transformed domain using an overcomplete analysis operator. We proposed two approaches to learn an analysis operator from a training corpus, both published in the conference EUSIPCO 2011 [79], [67].

The first one uses a constrained optimization program based on $L_1$ optimization. We derive a practical learning algorithm, based on projected subgradients, and demonstrate its ability to robustly recover a ground truth analysis operator, provided the training set is of sufficient size. A local optimality condition is derived,
providing preliminary theoretical support for the well-posedness of the learning problem under appropriate conditions. Extensions to deal with noisy training samples are currently investigated, and a journal paper is in preparation.

In the second approach, analysis "atoms" are learned sequentially by identifying directions that are orthogonal to a subset of the training data. We demonstrate the effectiveness of the algorithm in three experiments, treating synthetic data and real images, showing a successful and meaningful recovery of the analysis operator.

**Connections between sparse approximation and Bayesian estimation:** Penalized least squares regression is often used for signal denoising and inverse problems, and is commonly interpreted in a Bayesian framework as a Maximum A Posteriori (MAP) estimator, the penalty function being the negative logarithm of the prior. For example, the widely used quadratic program (with an \(\ell^1\) penalty) associated to the LASSO / Basis Pursuit Denoising is very often considered as MAP estimation under a Laplacian prior in the context of additive white Gaussian noise (AWGN) reduction.

A first result, which has been published in IEEE Transactions on Signal Processing [35], highlights the fact that, while this is one possible Bayesian interpretation, there can be other equally acceptable Bayesian interpretations. Therefore, solving a penalized least squares regression problem with penalty \(\phi(x)\) need not be interpreted as assuming a prior \(C \cdot \exp(-\phi(x))\) and using the MAP estimator. In particular, we showed that for any prior \(P_X\), the minimum mean square error (MMSE) estimator is the solution of a penalized least square problem with some penalty \(\phi(x)\), which can be interpreted as the MAP estimator with the prior \(C \cdot \exp(-\phi(x))\). Vice-versa, for certain penalties \(\phi(x)\), the solution of the penalized least squares problem is indeed the MMSE estimator, with a certain prior \(P_X\). In general \(dP_X(x) \neq C \cdot \exp(-\phi(x))dx\).

A second result, obtained in collaboration with Prof. Mike Davies and Prof. Volkan Cevher (a paper is under revision) characterizes the "compressibility" of various probability distributions with applications to underdetermined linear regression (ULR) problems and sparse modeling. We identified simple characteristics of probability distributions whose independent and identically distributed (iid) realizations are (resp. are not) compressible, i.e., that can be approximated as sparse. We prove that many priors which MAP Bayesian interpretation is sparsity inducing (such as the Laplacian distribution or Generalized Gaussian distributions with exponent \(p\leq1\)), are in a way inconsistent and do not generate compressible realizations. To show this, we identify non-trivial undersampling regions in ULR settings where the simple least squares solution outperform oracle sparse estimation in data error with high probability when the data is generated from a sparsity inducing prior, such as the Laplacian distribution.

### 6.2.3. Wavelets on graphs

**Participant:** Rémi Gribonval.

**Main collaboration:** Pierre Vandergheynst, David Hammond (EPFL)

Within the framework of the SMALL project 7.2.1, we investigated the possibility of developing sparse representations of functions defined on graphs, by defining an extension to the traditional wavelet transform which is valid for data defined on a graph.

There are many problems where data is collected through a graph structure: scattered or non-uniform sampling, sensor networks, data on sampled manifolds or even social networks or databases. Motivated by the wealth of new potential applications of sparse representations to these problems, the partners set out a program to generalize wavelets on graphs. More precisely, we have introduced a new notion of wavelet transform for data defined on the vertices of an undirected graph. Our construction uses the spectral theory of the graph laplacian as a generalization of the classical Fourier transform. The basic ingredient of wavelets, multi-resolution, is defined in the spectral domain via operator-valued functions that can be naturally dilated. These in turn define wavelets by acting on impulses localized at any vertex. We have analyzed the localization of these wavelets in the vertex domain and showed that our multi-resolution produces functions that are indeed concentrated at will around a specified vertex. Our theory allowed us to construct an equivalent of the continuous wavelet transform but also discrete wavelet frames.
Computing the spectral decomposition can however be numerically expensive for large graphs. We have shown that, by approximating the spectrum of the wavelet generating operator with polynomial expansions, applying the forward wavelet transform and its transpose can be approximated through iterated applications of the graph Laplacian. Since in many cases the graph Laplacian is sparse, this results in a very fast algorithm. Our implementation also uses recurrence relations for computing polynomial expansions, which results in even faster algorithms. Finally, we have proved how numerical errors are precisely controlled by the properties of the desired spectral graph wavelets. Our algorithms have been implemented in a Matlab toolbox that has been released in parallel to the main theoretical article [16]. We also plan to include this toolbox in the SMALL project numerical platform.

We now foresee many applications. On one hand we will use non-local graph wavelets constructed from the set of patches in an image (or even an audio signal) to perform de-noising or in general restoration. An interesting aspect in this case, would be to understand how wavelets estimated from corrupted signals deviate from clean wavelets. In a totally different direction, we will also explore the applications of spectral graph wavelets constructed from brain connectivity graphs obtained from whole brain tractography. Our preliminary results show that graph wavelets yield a representation that is very well adapted to how the information flows in the brain along neuronal structures.

### 6.2.4. Algorithmic breakthrough in sparse approximation: LoCOMP

**Participants:** Rémi Gribonval, Frédéric Bimbot, Ronan Le Boulch.

**Main collaborations:** Pierre Vandergheynst (EPFL), Boris Mailhé (former team member, now with Queen Mary University, London)

Our team had already made a substantial breakthrough in 2005 when first releasing the Matching Pursuit ToolKit (MPTK, see Section 5.3) which allowed for the first time the application of the Matching Pursuit algorithm to large scale data such as hours of CD-quality audio signals. In 2008, we designed a variant of Matching Pursuit called LoCOMP (ubiquitously for LOw Complexity Orthogonal Matching Pursuit or Local Orthogonal Matching Pursuit) specifically designed for shift-invariant dictionaries. LoCOMP has been shown to achieve an approximation quality very close to that of a full Orthonormal Matching Pursuit while retaining a much lower computational complexity of the order of that of Matching Pursuit. The complexity reduction is substantial, from one day of computation to 15 minutes for a typical audio signal [20], [19]. The main effort this year has been to integrate this algorithm into MPTK to ensure its dissemination and exploitation, and a journal paper has been published [22].

### 6.3. Emerging activities on compressive sensing and inverse problems

#### 6.3.1. Nearfield acoustic holography (ECHANGE ANR project)

**Participants:** Rémi Gribonval, Nancy Bertin.

**Main collaborations:** Albert Cohen (Laboratoire Jacques-Louis Lions, Université Paris 6), Laurent Daudet, Gilles Chardon, François Ollivier, Antoine Peillot (Institut Jean Le Rond d’Alembert, Université Paris 6)

Compressed sensing is a rapidly emerging field which proposes a new approach to sample data far below the Nyquist rate when the sampled data admits a sparse approximation in some appropriate dictionary. The approach is supported by many theoretical results on the identification of sparse representations in overcomplete dictionaries, but many challenges remain open to determine its range of effective applicability. METISS has chosen to focus more specifically on the exploration of Compressed Sensing of Acoustic Wavefields, and we have set up the ANR collaborative project ECHANGE (ECHantillonnage Acoustique Nouvelle Génération) which began in January 2009. Rémi Gribonval is the coordinator of the project.

In 2010, the activity on ECHANGE has concentrated on Nearfield acoustic holography (NAH), a technique aiming at reconstructing the operational deflection shapes of a vibrating structure, from the near sound field it generates. In this application scenario, the objective is either to improve the quality of the reconstruction (for a given number of sensors), or reduce the number of sensors, or both, by exploiting a sparsity hypothesis which helps regularizing the inverse problem involved.
Contributions of the team in this task spans: notations and model definitions, experimental setting design and implementation, choice of an adapted dictionary in which the sparsity hypothesis holds, improved acquisition strategies through pseudo-random sensor arrays and/or spatial multiplexing of the inputs, experimental study of robustness issues, and theoretical study of potential success guarantees based on the restricted isometry property (which revealed being not verified in our case, despite improved experimental performance).

A paper about robustness issues and spatial multiplexing (an alternative to building antennas with random sensor position) was published in GRETSI [88]. A journal paper is under revision.

6.3.2. Sparse reconstruction for underwater acoustics (ECHANGE ANR project)

Participants: Rémi Gribonval, Valentin Emiya, Nikos Stefanakis, Nancy Bertin.

Main collaborations: Jacques Marchal, Pierre Cervenka (UPMC Univ Paris 06)

Underwater acoustic imaging is traditionally performed with beamforming: beams are formed at emission to insonify limited angular regions; beams are (synthetically) formed at reception to form the image. We proposed to exploit a natural sparsity prior to perform 3D underwater imaging using a newly built flexible-configuration sonar device. The computational challenges raised by the high-dimensionality of the problem were highlighted, and we described a strategy to overcome them. As a proof of concept, the proposed approach was used on real data acquired with the new sonar to obtain an image of an underwater target. We discussed the merits of the obtained image in comparison with standard beamforming, as well as the main challenges lying ahead, and the bottlenecks that will need to be solved before sparse methods can be fully exploited in the context of underwater compressed 3D sonar imaging. This work has been submitted to ICASSP 2012 and a journal paper is in preparation.

6.3.3. Audio inpainting (SMALL FET-Open project)

Participants: Rémi Gribonval, Valentin Emiya.

Main collaborations: Amir Adler, Michael Elad (Computer Science Department, The Technion, Israel); Maria G. Jafari, Mark D. Plumbley (Centre for Digital Music, Department of Electronic Engineering, Queen Mary University of London, U.K.).

Inpainting is a particular kind of inverse problems that has been extensively addressed in the recent years in the field of image processing. It consists in reconstructing a set of missing pixels in an image based on the observation of the remaining pixels. Sparse representations have proved to be particularly appropriate to address this problem. However, inpainting audio data has never been defined as such so far.

METISS has initiated a series of works about audio inpainting, from its definition to methods to address it. This research has begun in the framework of the EU Framework 7 FET-Open project FP7-ICT-225913-SMALL (Sparse Models, Algorithms and Learning for Large-Scale data) which began in January 2009. Rémi Gribonval is the coordinator of the project. The research on audio inpainting has been conducted by Valentin Emiya in 2010 and 2011.

The contributions consist of:

- defining audio inpainting as a general scheme where missing audio data must be estimated: it covers a number of existing audio processing tasks that have been addressed separately so far – click removal, declipping, packet loss concealment, unmasking in time-frequency;
- proposing algorithms based on sparse representations for audio inpainting (based on Matching Pursuit and on $l_1$ minimization);
- addressing the case of audio declipping (i.e. desaturation): thanks to the flexibility of our inpainting algorithms, they can be constrained so as to include the structure of signals due to clipping in the objective to optimize. The resulting performance are significantly improved. This work has been reported in [47] and it will appear as a journal paper [96].
Current and future works deal with developing advanced sparse decomposition for audio inpainting, including several forms of structured sparsity (e.g. temporal and multichannel joint-sparsity) and several applicative scenarios (declipping, time-frequency inpainting).

6.4. Music Content Processing and Music Information Retrieval

6.4.1. Acoustic music modeling

Participants: Nancy Bertin, Emmanuel Vincent.

Main collaborations: R. Badeau (Télécom ParisTech), J. Wu (University of Tokyo)

Music involves several levels of information, from the acoustic signal up to cognitive quantities such as composer style or key, through mid-level quantities such as a musical score or a sequence of chords. The dependencies between mid-level and lower- or higher-level information can be represented through acoustic models and language models, respectively.

Our acoustic models are based on nonnegative matrix factorization (NMF) and variants thereof. NMF models an input short-term magnitude spectrum as a linear combination of magnitude spectra, which are adapted to the input under suitable constraints such as harmonicity and temporal smoothness. While our previous work considered harmonic spectra only, we proposed the use of wideband spectra to represent attack transients and showed that this resulted in improved pitch transcription accuracy [77]. Our past work on the convergence properties of NMF was also disseminated [50].

We used the resulting model parameters to identify the musical instrument associated with each note, by means of a Support Vector Machine (SVM) classifier trained on solo data, and obtained improved instrument classification accuracy compared to state-of-the-art Mel-Frequency Cepstral Coefficient (MFCC) features [42], [78].

6.4.2. Music language modeling

Participants: Frédéric Bimbot, Emmanuel Vincent.

Main collaboration: S.A. Raczynski (University of Tokyo, JP)

We pursued our pioneering work on music language modeling, with a particular focus on the joint modeling of "horizontal" (sequential) and "vertical" (simultaneous) dependencies between notes by log-linear interpolation of the corresponding conditional distributions. We identified the normalization of the resulting distribution as a crucial problem for the performance of the model and proposed an exact solution to this problem.

We also applied the log-linear interpolation paradigm to the joint modeling of melody, key, chords and meter, which evolve according to different timelines. In order to synchronize these feature sequences, we explored the use of beat-long templates consisting of several notes as opposed to short time frames containing a fragment of a single note.

Both of these studies are ongoing.

6.4.3. Music structuring

Participants: Frédéric Bimbot, Gabriel Sargent, Emmanuel Vincent.

External collaboration: Emmanuel Deruty (as an independent consultant)

The structure of a music piece is a concept which is often referred to in various areas of music sciences and technologies, but for which there is no commonly agreed definition. This raises a methodological issue in MIR, when designing and evaluating automatic structure inference algorithms. It also strongly limits the possibility to produce consistent large-scale annotation datasets in a cooperative manner.

We have pursued our investigations on autonomous and comparable blocks, based on principles inspired from structuralism and generativism for producing music structure annotation. This work has allowed consolidating the methodology and producing additional annotations (over 400 pieces) [53].
We have also developed an algorithm aiming at the automatic inference of autonomous and comparable blocks using the timbral and harmonic content of music pieces, in combination with a regularity constraint [72]. Tested within the QUAERO project and during the MIREX 2011 campaign [94], the algorithm ranked among state-of-the-art methods.

6.5. Source separation

6.5.1. A general framework for audio source separation

**Participants:** Alexis Benichoux, Frédéric Bimbot, Charles Blandin, Ngoc Duong, Rémi Gribonval, Nobutaka Ito, Alexey Ozerov, Emmanuel Vincent.

**Main collaborations:** H. Tachibana (University of Tokyo, JP), N. Ono (National Institute of Informatics, JP)

Source separation is the task of retrieving the source signals underlying a multichannel mixture signal. The state-of-the-art approach, which we presented in a survey chapter [95], consists of representing the signals in the time-frequency domain and estimating the source coefficients by sparse decomposition in that basis. This approach relies on spatial cues, which are often not sufficient to discriminate the sources unambiguously. Last year, we proposed a general probabilistic framework for the joint exploitation of spatial and spectral cues [39] that was disseminated in several invited talks [43], [44]. This framework relies in particular on the thesis of Ngoc Duong, which was defended this year [30]. It makes it possible to quickly design a new model adapted to the data at hand and estimate its parameters via the EM algorithm. As such, it is expected to become the basis for a number of works in the field, including our own.

Since the EM algorithm is sensitive to initialization, we devoted a major part of our work to reducing this sensitivity. One approach is to set probabilistic priors over the model parameters, including spatial position priors [56] or temporal continuity priors [55]. A complementary approach is to initialize the parameters in a suitable way using source localization techniques specifically designed for environments involving multiple sources and possibly background noise [33], [54], [83]. In a longer-term perspective, we also investigated the design and exploitation of sparsity priors over time-domain acoustic transfer functions [52], [82].

6.5.2. Exploiting filter sparsity for source localization and/or separation

**Participants:** Alexis Benichoux, Prasad Sudhakar, Emmanuel Vincent, Rémi Gribonval, Frédéric Bimbot.

**Main collaboration:** Simon Arberet (EPFL)

Estimating the filters associated to room impulse responses between a source and a microphone is a recurrent problem with applications such as source separation, localization and remixing.

We considered the estimation of multiple room impulse responses from the simultaneous recording of several known sources. Existing techniques were restricted to the case where the number of sources is at most equal to the number of sensors. We relaxed this assumption in the case where the sources are known. To this aim, we proposed statistical models of the filters associated with convex log-likelihoods, and we proposed a convex optimization algorithm to solve the inverse problem with the resulting penalties. We provided a comparison between penalties via a set of experiments which shows that our method allows to speed up the recording process with a controlled quality tradeoff. This work was presented at two conferences [52], [82] and a journal paper including extensive experiments with real data is in preparation.

We also investigated the filter estimation problem in a blind setting, where the source signals are unknown. We proposed an approach for the estimation of sparse filters from a convolutive mixture of sources, exploiting the time-domain sparsity of the mixing filters and the sparsity of the sources in the time-frequency (TF) domain. The proposed approach is based on a wideband formulation of the cross-relation (CR) in the TF domain and on a framework including two steps: (a) a clustering step, to determine the TF points where the CR is valid; (b) a filter estimation step, to recover the set of filters associated with each source. We proposed for the first time a method to blindly perform the clustering step (a) and we showed that the proposed approach based on the wideband CR outperforms the narrowband approach and the GCC-PHAT approach by between 5 dB and 20 dB. This work has been published at ICASSP 2011 [49] and submitted for publication as a journal paper.
On a more theoretical side, we studied the frequency permutation ambiguity traditionally incurred by blind convolutive source separation methods. We focussed on the filter permutation problem in the absence of scaling, investigating the possible use of the temporal sparsity of the filters as a property enabling permutation correction. The obtained theoretical and experimental results highlight the potential as well as the limits of sparsity as an hypothesis to obtain a well-posed permutation problem. This work has been submitted for publication as a journal paper [99].

6.5.3. Towards real-world separation and remixing applications

Participants: Valentin Emiya, Alexey Ozerov, Laurent Simon, Emmanuel Vincent.

Shoko Araki (NTT Communication Science Laboratories, JP), Cédric Févetotte (Télécom ParisTech, FR), Antoine Liutkus (Télécom ParisTech, FR), Volker Hohmann (University of Oldenburg, DE)

Following our founding role in the organization of a regular source separation evaluation campaign (SiSEC), we wrote an invited paper summarizing the outcomes of the three latest campaigns [41]. While some challenges remain, this paper highlighted that progress has been made and that audio source separation is closer than ever to successful industrial applications. This is also exemplified by the i3DMusic project and the contract recently signed with MAIA Studio.

In order to exploit our know-how for these real-world applications, we investigated issues such as how to implement our algorithms in real time and how best to exploit human input or metadata [68], [70]. In addition, while the state-of-the-art quality metrics previously developed by METISS remain widely used in the community, we proposed a new set of perceptually motivated metrics which greatly increase correlation with subjective assessments [34].

6.5.4. Source separation for multisource content indexing

Participants: Kamil Adiloglu, Alexey Ozerov, Emmanuel Vincent.

Main collaborations: J. Barker (University of Sheffield, UK), M. Lagrange (IRCAM, FR)

Another promising real-world application of source separation concerns information retrieval from multi-source data. Source separation may then be used as a pre-processing stage, such that the characteristics of each source can be separately estimated. The main difficulty is not to amplify errors from the source separation stage through subsequent feature extraction and classification stages. To this aim, we proposed a principled Bayesian approach to the estimation of the uncertainty about the separated source signals [45] and propagated this uncertainty to the features. We then exploited it in the training of the classifier itself, thereby greatly increasing classification accuracy [69].

While our work in this direction was initially motivated by music applications (e.g. artist recognition by separating the vocals from the accompaniment), we eventually applied it to noise-robust speech recognition, which is a better defined task [71]. In order to motivate further work by the community, we created a new international evaluation campaign on that topic (CHiME) [86].
6. New Results

6.1. Verification of Concurrent Recursive Programs

We have introduced a mathematical model to capture the behavior of concurrent and recursive systems. We have also identified typical properties of these systems that programmers may want to verify. We have come up with a specification language which is powerful enough to express such properties. In fact, we give a framework by which programmers can define their own specification language depending on the specific application as long as the semantics of the operators can be defined in monadic second-order logic. We have shown that checking whether a specified property is satisfiable or whether a given system satisfies a property specified in such a language is decidable with a manageable complexity (double exponential time). The proof technique is so general that it captures the results for various other well studied models. Our results were presented at MFCS’11 [50].

6.2. Product form for Petri nets

While product-form Petri nets have been intensively studied some important questions were left open. In [52], we have solved most of the open problems. We have provided a sound and complete set of rules to synthetise product form Petri nets. We have characterized the complexity class of standard problems (liveness, reachability and cover ability). At last we have proposed a large subclass of product form Petri nets for which the normalising constant (a key quantity) can be efficiently computed. This paper has obtained the outstanding paper award of the ATPN’2011 conference.

6.3. Statistical model checking

We have designed a logic HASL for stochastic systems that can express elaborated performance indices related to path behaviours [46]. We have shown how it can be integrated in the design process of flexible manufacturing systems [47]. We have developed a tool COSMOS for statistical model checking of HASL formula over a stochastic Petri net with general distributions [45]. In parallel, we have developed the first importance sampling method for rare event that still produces a confidence interval (rather than an estimated value) and we have integrated this method in COSMOS [48].

6.4. Symmetry and stochastic systems

We have developed a framework to efficiently solve large Markov decision problems specified by high-level Petri nets [42]. Such a specification allows to decrease the size of the MDP by the analysis of the symmetries of the model. In a purely probabilistic context, we have designed two complementary methods for handling partial symmetries in stochastic high level Petri nets and studied their efficiency on several relevant case studies [41].

6.5. Automata for Data Words

We studied data words, i.e, strings where each position carries both a label from a finite alphabet and some values from an infinite domain. Data words are suitable to model the behavior of concurrent systems with dynamic process creation, as the infinite alphabet can be used to represent an unbounded number of process identifiers. A variety of formalisms, including logic and automata, have been studied to specify sets of data words in the context of verification. However, logic and automata that capture dynamic communicating systems were missing. We closed this gap and developed a quite general logical and automata-theoretic framework for the specification and implementation of sets of data words. On the specification side, we considered a fragment of monadic second-order (MSO) logic, which comes with a predicate to test two word
positions for data equality. As a model of an implementation, we introduced class register automata. Our model combines the well known models of register automata and class memory automata, and it indeed captures dynamic communicating automata, whose semantics can be described as a set of message sequence charts. We studied the realizability problem and show that every formula from the existential fragment of MSO logic can be effectively translated into a class register automaton. These results were presented at CONCUR’11 [49].

6.6. Weighted Logics with Navigation for Trees

We continued our study of the verification of quantitative properties and applications to queries over XML documents. Verification of quantitative systems follow a classical scheme in three steps: specification, modeling, and algorithmics. Hence, we started by exhibiting a specification language. To describe natural qualitative properties, we chose to use, as a fragment, boolean logic like first-order logic or monadic second-order logic. We then encapsulate this properties into the quantitative formalism, allowing sums and products computations in a specified general semiring. In the word case, we obtained very strong results relating this kind of specification/computation languages with the well-known weighted finite automata, and the new weighted pebble automata, which permit to model several interesting quantitative computations over words. We extended these results to trees, and in particular, finite unranked trees or nested words, which are a natural model for XML documents. We published preliminary results in a research report [57], and we have worked on a submission of these results to several conferences. Our next goal is to tackle some of the algorithmic questions that naturally arise in this context, like satisfiability or model checking.

6.7. Contextual Petri nets

Contextual nets are an extension of Petri nets that – unlike ordinary Petri nets – faithfully models concurrent read accesses to shared resources. This is not only interesting from a semantic but also from an algorithmic point of view, as the analysis of such nets can better exploit the fact that concurrent reads are independent and concurrent.

In particular, the unfolding of a contextual net may be up to exponentially smaller in certain situations. While the theoretical foundations of contextual unfoldings were established in [66] and [6], it remained unclear whether the approach could be useful in practice. Recent work on the theoretical foundations, as well as appropriate data structures and algorithms, has closed this gap. This underlying work has been presented at Concur’11 [53] and has resulted in an efficient tool [59]. More details can be found in a technical report [58].

We are currently exploring applications of these techniques in the areas of verification, diagnosis, and planning. Some preliminary steps have been presented in [54].

6.8. Occurrence net Synthesis

Occurrence nets are a well known partial order model for the concurrent behavior of Petri nets. The causality and conflict relations between events, which are explicitly represented in occurrence nets, induce logical dependencies between event occurrences: the occurrence of an event e in a run implies that all its causal predecessors also occur, and that no event in conflict with e occurs. But these structural relations do not express all the logical dependencies between event occurrences in maximal runs: in particular, the occurrence of e in any maximal run may imply the occurrence of another event that is not a causal predecessor of e, in that run. The reveals relation had been introduced in [33] to express this dependency between two events. In this work, presented at ACSID 2011 [44], we extend the theory in two ways: first, we generalize the reveals relation to express more general dependencies, involving more than two events, and we introduce ERL logic to express these dependencies as boolean formulas. Secondly, we solve the synthesis problem that arises: given an ERL formula φ, is there a finite occurrence net N such that φ describes exactly the dependencies between the events of N? The resulting method requires only two synthesis rules.
6.9. Computing Reveals

The *reveals* relation has been introduced in [33] between events in occurrence nets. Essentially, event $a$ is said to *reveal* event $b$ if in any maximal run that contains $a$, $b$ must also occur, be it before, after, or concurrently with $a$, and even if $a$ and $b$ are not causally related. Information of this kind is useful for diagnosis; a sensor for event $a$ may render a sensor for $b$ unnecessary.

In [33], the reveals relation was shown to be decidable for occurrence nets that represent unfoldings of safe Petri nets. However, the upper bound was prohibitive for computing the relation in practice. In [51] we address this problem and drastically reduce the upper bound. We also propose efficient algorithms to actually compute the relation on a given occurrence net.
MICMAC Project-Team

5. New Results

5.1. Computational quantum chemistry

Participants: Eric Cancès, Ismaïla Dabo, Virginie Ehrlacher, Salma Lahbabi, Francis Nier, Gabriel Stoltz.

In computational quantum chemistry as in most of our scientific endeavours, we pursue a twofold goal: placing the models on a sound mathematical grounding, and improving the numerical approaches.

E. Cancès, V. Ehrlacher, S. Lahbabi and G. Stoltz have addressed issues related to the modeling and simulation of local defects in periodic crystals (see [61] for a pedagogical introduction).

Computing the energies of local defects in crystals is a major issue in quantum chemistry, materials science and nano-electronics. In collaboration with M. Lewin (CNRS, Cergy), E. Cancès and A. Deleurence have proposed in 2008 a new model for describing the electronic structure of a crystal in the presence of a local defect. This model is based on formal analogies between the Fermi sea of a perturbed crystal and the Dirac sea in Quantum Electrodynamics (QED) in the presence of an external electrostatic field. The justification of this model is obtained using a thermodynamic limit of Kohn-Sham type models. In [29], E. Cancès and G. Stoltz studied the time evolution of defects within this model, in the context of linear response, which allowed them to give a rigorous meaning to the Adler-Wiser formula for the frequency-dependent dielectric permittivity of crystals. In [27], E. Cancès et V. Ehrlacher have proved that local defects are always neutral in the Thomas-Fermi-von Weisäcker (TFW) theory. In this respect, all TFW crystals behave like metals. In collaboration with M. Lewin, E. Cancès and S. Lahbabi are working on the extension of Kohn-Sham like models to disordered systems.

On the numerical side, E. Cancès has worked with Y. Maday and R. Chakir (University Paris 6) on the numerical analysis of the electronic structure models. In [26], they have obtained optimal \textit{a priori} error bounds for the the planewave approximation of the Thomas-Fermi-von Weizsäcker and the Kohn-Sham LDA models. Together with Y. Maday, E. Cancès and V. Ehrlacher have analyzed the computation of eigenvalues in spectral gaps of locally perturbed periodic Schrödinger operators [28].

Photovoltaic cells based upon organic photovoltaic (OPV) semiconductors are cost-effective, light-weight alternatives to conventional silicon and thin-film technologies. This year, in collaboration with A. Ferretti, N. Poilvert, N. Marzari (MIT and University of Oxford), M. Cococcioni (University of Minnesota), and Y. L. Li (Xiamen University), I. Dabo has worked on the prediction of the electronic spectra and electrical response of molecular and polymer compounds for OPV applications. Specifically, Y. L. Li and I. Dabo have implemented an efficient computational method for studying the electrical response of semiconducting polymers, in close agreement with more expensive local basis-set algorithms [52]. In parallel, A. Ferretti, I. Dabo, M. Cococcioni, and N. Marzari have applied recently developed electronic-structure theories, namely, orbital-dependent density-functional theories (OD-DFTs), to describe donor and acceptor levels in semiconducting organic materials, demonstrating that OD-DFT is apt at describing donor and acceptor levels within 0.1-0.4 and 0.2-0.6 eV of experiment [41]. Future work includes the prediction of the band structure of semiconductor alloys and the simulation of molecular heterojunctions.

The current works by F. Nier related to electronic structure calculations concern the mean field limit of the quantum dynamics in the bosonic setting; and the non linear modelling of Bose-Einstein condensates. A few years ago, Z. Ammari and F. Nier initiated a program about the Hamilton mean field dynamics of a large numbers of bosons. Their approach reconsidered the old idea that the mean field limit in the bosonic setting is actually a semiclassical limit in infinite dimension. In previous works, they proved results which are general with respect to the initial data but hold for bounded interactions. They also proved that the dynamics of the BBGKY hierarchy, often used within the mean field theory, is actually a projected picture of the dynamics of Wigner measures in the infinite dimensional phase-space. Recently in [10], they obtained such results for
singular pair interaction potentials, which include the Coulombic (attractive or repulsive) case in dimension $d = 3$. Regarding the modelling of Bose-Einstein condensates, F. Nier and collaborators have developed in [9] complete analysis of the nonlinear adiabatic ansatz proposed by physicists for the simulation of rotating Bose-Einstein condensates.

5.2. Computational Statistical Physics

Participants: Matthew Dobson, Claude Le Bris, Frédéric Legoll, Tony Lelièvre, Francis Nier, Stefano Olla, Grigorios Pavliotis, Giovanni Samaey, Gabriel Stoltz.

The extremely broad field of Molecular dynamics (MD) is a domain where the MICMAC project-team, originally more involved in the quantum chemistry side, has invested a lot of efforts in the recent years. Molecular dynamics may also be termed computational statistical physics since the main aim is to numerically estimate average properties of materials as given by the laws of statistical physics. The project-team studies both deterministic and probabilistic techniques used in the field.

5.2.1. Free Energy calculations

For large molecular systems, the information of the whole configuration space may be summarized in a few coordinates of interest, called reaction coordinates. An important problem in chemistry or biology is to compute the effective energy felt by those reaction coordinates, called free energy.

In the article [51], Tony Lelièvre, Mathias Rousset and Gabriel Stoltz study the application of constrained Langevin dynamics to the computation of free energy differences, by thermodynamic integration techniques and fluctuation relation (à la Jarzynski).

The work by T. Lelièvre and K. Minoukadeh on the longtime convergence of the ABF method in a particular bi-channel scenario (which was already mentioned in last year’s activity report) has been accepted for publication [50]. Likewise, the work by Nicolas Chopin (CREST, ENSAE), T. Lelièvre and G. Stoltz on application of the ABF method to Bayesian inference is about to appear, see [30].

5.2.2. Sampling trajectories

There exist a lot of methods to sample efficiently Boltzmann-Gibbs distributions. The situation is much more intricate as far as the sampling of trajectories (and especially metastable trajectories) is concerned.

In [32], T. Lelièvre and D. Pommier, in collaboration with F. Cérou and A. Guyader (INRIA Rennes, ASPI) investigated the interest of an Adaptive Multilevel Splitting algorithm to compute reactive paths, and estimate transition rates. The obtained results are very interesting. Current research aims at testing the technique on practical cases.

In [49], C. Le Bris and T. Lelièvre together with M. Luskin and D. Perez have proposed a mathematical analysis of the parallel replica algorithm, introduced by A. Voter in 1997 to efficiently simulate metastable trajectories. This work opens a lot of perspectives using a generic tool (the quasi stationary distribution) to relate continuous state space dynamics (Langevin type dynamics) to discrete state space dynamics (kinetic Monte Carlo type models). A follow-up work consists in theoretically investigating another related approach, the hyperdynamics method.

5.2.3. Nonequilibrium systems

The efficient simulation of molecular systems is known to be a much more complicated problem when the system is subjected to a non-conservative external forcing than when the system experiences conservative forces. Together with the sampling of metastable dynamics mentioned above, these are the two major research focus in MD of the project-team.
On this topic, G. Stoltz continued his long lasting collaboration with physicists at CEA/DAM on reduced models for shock and detonation waves. More precisely, he published two works applying some simulation techniques he devised to actual energetic materials of interest to physicists, namely (i) a technique to sample constraints in average and allowing to compute the Hugoniot curve efficiently, which was applied to reacting TATB [24]; and (ii) a reduced stochastic dynamics to model detonation waves, applied to a material with properties close to nitromethane and allowing an atomistic simulation of the shock-to-detonation transition [55].

F. Legoll and G. Stoltz pursued their studies of the anomalous thermal conductivity of one dimensional chains. They have investigated the case of a chain of rotors subjected to a mechanical forcing. In collaboration with A. Iacobucci and S. Olla (CEREMADE, Paris Dauphine) they have shown in [44] that the mechanical forcing can have a counter-intuitive effect and reduce the thermal current. Besides this numerical study, G. Stoltz, in collaboration with C. Bernardin (ENS Lyon) considered in [18] the issue of thermal transport in one of the simplest possible one dimensional model, a chain of oscillators whose kinetic and potential energy functions are the same, and which are subjected to a stochastic noise exchanging all the variables. The system therefore has only two conservation laws, the energy and the total length. A hydrodynamic limit consisting of a system of conservation laws can be obtained before the onset of shocks. However, the thermal transport is anomalous: this can be proved by analytical computations for harmonic interactions, or demonstrated numerically in the general case.

G. Stoltz also studied techniques to compute the viscosity of fluids using steady state nonequilibrium dynamics with an external nongradient bulk forcing, in the framework of the context of the PhD of Rémi Joubaud, see [45]. The two authors have proved a linear response result, and obtained asymptotic scalings of the viscosity in terms of the friction coefficients of the underlying Langevin dynamics. G. Stoltz and G. Pavliotis are now extending the results to the case of time dependent nongradient external forcings.

Nonequilibrium molecular dynamics simulations can also be used to compute the constitutive relation between the strain rate and stress tensor in complex fluids. This is fulfilled simulating molecular systems subject to a steady, non-zero macroscopic flow at a given temperature. Starting from a bath model, M. Dobson, F. Legoll, T. Lelièvre, and G. Stoltz have derived a Langevin-type dynamics for a heavy particle in a non-zero background flow. The resulting dynamics, which is theoretically obtained when a unique large particle is considered, is numerically observed to also perform well when a system of many interacting particles within shear flow is considered.

5.2.4. Effective dynamics

For a given molecular system, and a given reaction coordinate \( \xi: \mathbb{R}^n \to \mathbb{R} \), the free energy completely describes the statistics of \( \xi(X) \) when \( X \in \mathbb{R}^n \) is distributed according to the Gibbs measure. On the other hand, obtaining a correct description of the dynamics along \( \xi \) is complicated.

F. Legoll and T. Lelièvre have continued their work on the definition and the analysis of a coarse-grained dynamics that approximates \( \xi(X_t) \), when the state of the system \( X_t \) evolves according to the overdamped Langevin equation (which is ergodic for the Gibbs measure). The aim is to get a coarse-grained description giving access to some dynamical quantities, such as residence times in metastable basins. These basins are usually assumed to be completely described by \( \xi \). They have proposed an effective dynamics, which is derived using conditional expectations. The first accuracy result, obtained in 2010, is phrased in terms of an estimate on the relative entropy between the law of \( \xi(X_t) \) and the law of its approximation, at any time \( t \) (see [63] for a description of the results in a simple case). If an appropriate time-scale separation is present in the system, then the effective dynamics is accurate in the sense of time-marginals. The obtained numerical results showed that this dynamics can also be used to accurately compute residence times in potential energy wells, and thus seem to be accurate in a much stronger sense. Together with S. Olla, they have started to analyze the pathwise accuracy of the proposed coarse-grained dynamics.

The extension of the numerical strategy to the case when the reference dynamics on the whole system is the Langevin dynamics has also been studied. Promising numerical results have already been obtained in collaboration with a master’s student (F. Galante).
5.2.5. Convergence to equilibrium

An important question for the analysis of sampling techniques is the rate of convergence to equilibrium for stochastic trajectories.

F. Nier continues to investigate the spectral properties of Witten Laplacians and Kramers-Fokker-Planck operators. In a recent collaboration with D. Le Peutrec and C. Viterbo, the Arrhenius law for metastable states, in its refined version also known as Eyring-Kramers law, was extended to \( p \)-forms. Very accurate analytical results have been provided for the exponentially small eigenvalues of Witten Laplacians acting on \( p \)-forms.

F. Nier has started a collaboration with T. Lelièvre about accurate exit laws for Smoluchowski processes, via a Witten complex approach. Investigations with G. Pavliotis and T. Lelièvre have started about non gradient diffusion systems.

5.2.6. Hamiltonian dynamics

Constant energy averages are often computed as long time limits of time averages along a typical trajectory of the Hamiltonian dynamics. One difficulty of such a computation is the presence of several time scales in the dynamics: the frequencies of some motions are very high (e.g. for the atomic bond vibrations), while those of other motions are much smaller. This problem has been addressed in a two-fold manner.

Fast phenomena are often only relevant through their mean effect on the slow phenomena, and their precise description is not needed. Consequently, there is a need for time integration algorithms that take into account these fast phenomena only in an averaged way, and for which the time step is not restricted by the highest frequencies. In [38], M. Dobson, C. Le Bris, and F. Legoll developed integrators for Hamiltonian systems with high frequencies. The integrators were derived using homogenization techniques applied to the Hamilton-Jacobi PDE associated to the Hamiltonian ODE. This work extends previous works of the team. The proposed algorithms can now handle the case when the (unique) fast frequency depends on the slow degrees of freedom, or when there are several fast constant frequencies.

Another track to simulate the system for longer times is to resort to parallel computations. An algorithm in that vein is the parareal in time algorithm. It is based on a decomposition of the time interval into subintervals, and on a predictor-corrector strategy, where the propagations over each subinterval for the corrector stage are concurrently performed on the processors. Using a symmetrization procedure and/or a (possibly also symmetric) projection step, C. Le Bris and F. Legoll, in collaboration with X. Dai and Y. Maday, have introduced several variants of the original plain parareal in time algorithm [35]. These variants, compatible with the geometric structure of the exact dynamics, are better adapted to the Hamiltonian context.

5.3. Complex fluids

Participants: David Benoit, Sébastien Boyaval, Claude Le Bris, Tony Lelièvre.

In [48], Claude Le Bris and Tony Lelièvre have reviewed the state-of-the-art of numerical and mathematical results on micro-macro models for viscoelastic fluids.

Following previous works, Claude Le Bris and Tony Lelièvre together with Lingbing He have analyzed in [43] the longtime behaviour of nematic polymeric fluids (liquid crystals). The longtime asymptotics for such models is much richer than for flexible polymers, which were considered in previous analysis. Indeed, for these models, periodic in time behaviours are expected.

In his PhD under the supervision of Claude Le Bris and Tony Lelièvre, David Benoit studies models of aging fluids developed at the ESPCI (Ecole supérieure de physique et de chimie industrielles) and designed to take into account phenomena such as shear thinning, aging and shear banding in falling sphere experiments. The work consists on the one hand in studying the mathematical well-posedness of some macroscopic models and on the other hand in trying to understand the link between such macroscopic models and microscopic models which have been proposed to describe such fluids.
In the line of his former work [15], Sébastien Boyaval has pursued his work about the mathematical modelling of viscoelastic fluid flows. A new reduced model for thin layers of elastic gravity flows with a free surface was derived in collaboration with François Bouchut, following similar hydrostatic assumptions to those which lead to the Saint-Venant equations as a usual reduced model for shallow water flows. The model is naturally endowed with an energy but the conservative part is non-standard: the energy is not convex with respect to the conservative variables. It is convex with respect to other (more physical) variables. For the numerical simulation of possibly discontinuous solutions, a relaxation scheme is proposed in order to ensure that the numerical approximation mimics the natural energy dissipation.

In [58], Tony Lelièvre together with Giovanni Samaey and Vincent Legat explored some numerical techniques to get closed macroscopic equations from microscopic models. The proposed method can be seen as a way to justify and extend techniques based on the so-called quasi-equilibrium approximation.

In [40], the effect of a topography on a free surface flow is studied using the free-surface Navier Stokes equations and ALE method for discretization.

5.4. Application of greedy algorithms

Participants: Sébastien Boyaval, Eric Cancès, Virginie Ehrlacher, Tony Lelièvre.

The manuscript [25] where E. Cancès, V. Ehrlacher and T. Lelièvre study the convergence of greedy algorithms to nonlinear convex problems has been accepted for publication. Current research now aims at extending such techniques to non-symmetric problems.

S. Boyaval has continued his study of a new variance reduction method introduced with T. Lelièvre. It makes an innovative use of a greedy algorithm in order to construct control variates for a parameterized family of Monte-Carlo estimator. New successful applications are typical problems in uncertainty quantification.

5.5. Homogenization

Participants: Ronan Costaouec, Claude Le Bris, Frédéric Legoll, Francis Nier, Florian Thomines.

The project-team has pursued its efforts in the field of stochastic homogenization of elliptic equations. The various contributions of the team, which aim at designing numerical approaches that both are practically relevant and keep the computational workload limited, have been presented from a unified perspective in [59].

An interesting case in that context is when the randomness comes as a small perturbation of the deterministic case. As previously shown by former works of the project-team, this situation can indeed be handled with a dedicated approach, which turns out to be far more efficient than the standard approach of stochastic homogenization. This previous analysis was performed manipulating the exact correctors, solutions to PDEs posed on $\mathbb{R}^d$. In practice, one can only consider a truncated version of these corrector problems, which is next discretized using e.g. a Finite Element method. The previous analysis has been extended to this practical situation by R. Costaouec [31].

In the work mentioned above, the perturbation to the deterministic case is supposed to be small in the $L^\infty$ norm (that is, almost surely small). The team has also considered the case when the perturbation is small in a weaker norm, typically a $L^p$ norm with $p < \infty$ (the case when only the expectation of the perturbation is assumed to be small, rather than the perturbation itself, is covered by that framework). The approach proves to be very efficient from a computational viewpoint, in comparison to the standard approach of stochastic homogenization, as shown in [13], [12]. In that setting, the computation of the homogenized matrix requires repeatedly solving a corrector-like equation for various configurations of the material. For this purpose, C. Le Bris and F. Thomines have shown how to adapt the Reduced Basis approach to the specific context, to even further reduce the computational cost [62].
The team has also proceeded to address, from a numerical viewpoint, the case when the randomness is not small. In that case, using the standard homogenization theory, one knows that the homogenized tensor, which is a deterministic matrix, depends on the solution of a stochastic equation, the so-called corrector problem, which is posed on the whole space $\mathbb{R}^d$. This equation is therefore delicate and expensive to solve. In practice, the space $\mathbb{R}^d$ is truncated to some bounded domain, on which the corrector problem is numerically solved. In turn, this yields a converging approximation of the homogenized tensor, which happens to be a random matrix. For a given truncation of $\mathbb{R}^d$, R. Costaouec, C. Le Bris and F. Legoll, in collaboration with X. Blanc (CEA), have studied how to reduce the variance of this matrix, using the technique of antithetic variables, which is a method widely used in other fields of application. Its efficiency in the context of stochastic homogenization has been extensively studied, both numerically and theoretically [60], [19]. R. Costaouec, C. Le Bris and F. Legoll are currently investigating the possibility to use other variance reduction approaches, such as control variate techniques.

From a numerical perspective, the Multiscale Finite Element Method is a classical strategy to address the situation when the homogenized problem is not known, or when the scale of the heterogeneities, although small, is not considered to be zero (and hence the homogenized problem cannot be considered as a sufficiently accurate model). The extension of this strategy to the stochastic case, when the tensor describing the properties of the material is the sum of a periodic term and a small random term, has been studied by C. Le Bris, F. Legoll and F. Thomines [46]. A method with a much smaller computational cost than the original MsFEM in the stochastic setting has been proposed. Provided the stochastic perturbation is indeed small, the proposed method is as accurate as the original one. The work [46] also provides a complete analysis of the approach, extending that available for the deterministic setting. Such an analysis often relies on the rate of convergence of the two scale expansion (in the sense of homogenization theory) of the solution to the highly oscillatory elliptic partial differential equation. The result is classic for periodic homogenization. In generic stochastic homogenization, the rate can be arbitrary small, depending on the rate with which the correlations of the random coefficient vanish. In [47], such a result has been established for weakly stochastic homogenization. This result is a key ingredient for the numerical analysis of the MsFEM approach proposed in [46].

Still in the framework of the Multiscale Finite Element approach, F. Thomines has further investigated, in collaboration with Y. Efendiev and J. Galvis (Texas A&M University), the use of Reduced Basis methods. They have considered an extension of the MsFEM approach, well suited to the high contrast case, i.e. the case when the ratio between the maximum and the minimum values of the heterogeneous coefficient is large. The main idea of this extension is to complement the standard MsFEM basis functions with the eigenfunctions (associated to the first small eigenvalues) of a local eigenproblem. In [39], Y. Efendiev, J. Galvis and F. Thomines have considered the case when the problem depends on an additional parameter, and shown how to use the Reduced Basis approach to more efficiently compute the eigenfunctions mentioned above.

The theoretical results obtained by the team on variance reduction [19] and on the rate of convergence of the two scale expansion of the solution to a highly oscillatory, weakly random PDE [47], both rely on asymptotic properties of the Green function of the elliptic operator $Lu = -\text{div} (A \nabla u)$, where $A$ is a periodic, coercive and bounded matrix. In collaboration with X. Blanc (CEA) and A. Anantharaman, F. Legoll has established some results of this question [11]. This contribution presents in a unified manner and complements several results already given in the literature.

All the works previously mentioned are concerned with elliptic PDEs. F. Nier has studied various problems in the context of wave propagation in random heterogeneous media. In collaboration with S. Breteaux (PhD student in Rennes), he has derived a Boltzmann type equation from first principles of quantum mechanics, using the bosonic QFT presentation of Gaussian random fields. Various extensions of this result are currently under investigation.

5.6. Atomistic to continuum methods

Participants: Matthew Dobson, Claude Le Bris, Frédéric Legoll.
The project-team has continued their theoretical and numerical efforts on the general topic of "passage from the atomistic to the continuum". This concerns theoretical issues arising in this passage but also the development and the improvement of numerical simulations coupling the two scales.

The quasicontinuum method couples an atomistic model to a continuum approximation in order to compute deformed states of a crystalline lattice at a reduced computational cost compared to a full atomistic simulation. In collaboration with M. Luskin (University of Minnesota) and C. Ortner (Warwick), M. Dobson analyzed the use of numerical solvers for approximating solutions to the equilibrium equations of the force-based quasicontinuum method [37]. In particular, it was shown that a previously-proposed modified conjugate gradient algorithm has unstable modes since the linearized operator is generally not positive-definite. Based on observed properties of the spectrum, convergence rates are given for the GMRES method applied to the operator.

Still in the framework of quasicontinuum methods, several consistent couplings have been proposed in the literature in the past years. M. Dobson showed the impossibility of constructing higher-order consistent couplings for quasicontinuum energies [36]. The analysis is performed in the one-dimensional situation, and is based on the fact that the truncation error gives lower bounds on the global error on the deformation gradient. A consequence of this result is that the so-called quasi-nonlocal energy (which is one of the coupling schemes proposed earlier) has asymptotically optimal error bounds.

The team has also addressed questions related to the finite temperature modeling of atomistic systems and derivation of coarse-grained descriptions, such as canonical averages of observables depending only on a few variables. In the one-dimensional setting, an efficient strategy that bypasses the simulation of the whole system had been proposed in 2010. In collaboration with X. Blanc (CEA), F. Legoll has extended this strategy to the so-called membrane setting [20]: the system is composed of atoms that lie on a two-dimensional lattice, and have a unique degree of freedom, representing their height. The strategy can also be used to derive the stress-strain relation for one-dimensional chains of atoms, e.g. the relation between the elongation of the chain and the stress, at any given temperature [63].

5.7. Surface chemistry and electrochemistry

Participants: Ismaila Dabo.

Rising energy imperatives have revived strong interest in electrochemical cells (e.g., fuel cells) and photoelectrochemical cells (e.g., dye-sensitized solar cells). Understanding and improving the electrical performance of such systems entails the accurate description of electrode-electrolyte interfaces at the microscopic level. Despite recent advances in the application of computational methods to study realistic electrode-electrolyte interfaces, capturing the effect of the applied electrical voltage and solvent electrical response remains a central challenge in computational electrochemistry. In order to address this difficulty, a comprehensive model for chemical systems embedded in ionic media has been developed. The model couples a quantum description of the electrode with a continuum representation of the electrolyte.

This year, in collaboration with O. Andreussi (MIT) and N. Marzari (University of Oxford), I. Dabo has worked on improving the predictive accuracy and numerical implementation of the continuum solvation model to describe molecular systems and metallic surfaces in interaction with a solvent [14]. The revised model overcomes some of the numerical limitations encountered in existing solvation models and extends their range of applicability. The approach proceeds by recasting the problem in terms of induced polarization charges that act as a direct mapping of the continuum dielectric solvent. The model is defined in a self-consistent manner in terms of the first-principles electronic density of the solute, thereby limiting the number of numerical parameters involved in existing solvation methods. The model accounts for additional pressure and cavitation contributions. The resulting self-consistent continuum solvation (SCCS) model provides an effective, compact fit of computational and experimental data, with solvation energies in error of 0.3-0.4 kcal/mol. The model is implemented in the widely used open-source program QUANTUM-ESPRESSO, exploiting a numerical approach that is intrinsically parallel, robust, and straightforward to adapt to most electronic-structure codes.
In terms of practical applications in surface science and electrochemistry, the adsorption of arsenate (a severe contaminant in drinking water) at the surface of biogeochemical minerals has been studied in collaboration with M. Blanchard and G. Morin (Université Paris 6) [22]. The simulation of infrared spectroscopic experiments for carbon monoxide (a severe catalytic poison) at catalytic surfaces has also been addressed in [33]. Future work includes the generalization of the SCCS model to surfaces in contact with a reservoir of electrons, and molecular dynamics simulations of electrode surfaces.
6. New Results

6.1. Motion Sensing and analysis

6.1.1. Sensing human activity for detecting falling motions

Participants: Franck Multon [contact], Richard Kulpa, Anthony Sorel, Edouard Auvinet.

Sensing human activity is a very active field of research, with a wide range of applications ranging from entertainment and serious games to personal ambient living assistance. MimeTIC aims at proposing original methods to process raw motion capture data in order to compute relevant information according to the application.

In personal ambient living monitoring, we have collaborated with University of Montreal, Department of Computer Science and Operations Research (DIRO) which main activity is biomedical engineering. A co-supervised student is addressing two complementary problems: detecting people falling in everyday environment and providing easy-to-use clinical gait analysis systems for early detection of potential risks of falling. These two problems have been addressed by reconstructing the visual hull of a subject according to synchronized classical of depth cameras. As visual hull is based on videos it’s subject to occlusions which generally occur in natural environment, such as a room with furniture. We have adapted the classical visual hull algorithm in order to be less sensible to occlusions. We also have proposed an index based on 3D silhouette vertical distribution which enhance this property to tackle occlusion problems [1]. This index is based on a ratio: the volume above a given threshold divided by the total body volume. It has been successfully applied to dozens of falling scenarios involving natural occlusions with furniture. The second problem consists in extracting relevant indexes in gait that could enable clinicians to identify elderly people who have a risk of falling. Classical indexes are based on gait regularity and asymmetry in dual tasks protocols (such as walking while counting downward). 3D silhouettes intrinsically contain all the required information in a unique representation contrary to multi-point motion capture systems. However extracting the relevant information from 3D volumes is complex. We have proposed an original approach based on statistical analysis of the volumes in order to compute indexes for gait asymmetry while simply using 3 depth-cameras (Microsoft Kinects) [1] (see figure 4).

Figure 4. 3D silhouettes reconstructed with three depth-cameras in order to analyze gait asymmetry.
In entertainment and serious games, the problem is different as we need to accurately know the action performed by the user in order to react in a convenient manner. Collaboration with Artefacto Company enabled us to develop such motion recognition methods in serious games scenarios. Given motion capture data provided by an optical motion capture system lead to large state vectors in which the relevant information is hidden. Mixture of Gaussians is generally used as an input of Hidden Markov Models to recognize a motion according to this raw data. To simplify, features are generally introduced in order to capture the relevant geometrical property of the motion with either general information (such as joint angles or Cartesian positions) or application-specific information. The former type of information has the advantage to be generic but leads to recognizers that are very sensitive to style and morphology variations. We have proposed a new generic feature based on morphology-independent representation that enables to tackle this problem (submitted to Eurographics2012). The recognition rate is above 75% for very similar upper-limb motions (see figure 5) while classical methods fail to recognize the same motions (recognition rate below 50%).

6.1.2. The Joyman: a novel immersive locomotion device for virtual environments

Participant: Julien Pettré [contact].

We proposed a novel interface called Joyman, designed for immersive locomotion in virtual environments [18]. Whereas many previous interfaces preserve or stimulate the users proprioception, the Joyman aims at preserving equilibriocception in order to improve the feeling of immersion during virtual locomotion tasks. The proposed interface is based on the metaphor of a human-scale joystick. The device has a simple mechanical design that allows a user to indicate his virtual navigation intentions by leaning accordingly. We also propose a control law inspired by the biomechanics of the human locomotion to transform the measured leaning angle into a walking direction and speed - i.e., a virtual velocity vector. We aim at using this interface to enable natural interaction with virtual humans with low-cost devices. The Joyman is patented and was presented at the Emerging Technologies, Siggraph Asia, Hong-Kong [20].

These are joint results with the VR4i team (Anatole Lécuyer and Maud Marchal).

6.2. VR and Sports

Participants: Richard Kulpa, Benoit Bideau [contact], Brault Sébastien, Burns Anne-Marie.
In the past, we have worked on the interaction between two opponents in handball. We have designed a framework to animate virtual throwers in a reality center and to analyze the gestures of real goalkeepers whose objective was to intercept the corresponding virtual balls. This VR framework was then validated by showing that behaviors in real and virtual environment were similar. These works have been extended by using perception-action coupling and perception-only studies to evaluate the anticipation of opponents. In order to evaluate the importance of perceived parameters, the ball and/or the character animation was successively hidden to determine their importance and the same kind of study was done on the graphical level of details.

These works have been extended to the study of deceptive movements and gaps evaluation in rugby. Combining perceptual analysis based on the use of cutoffs with biomechanical analysis, we have extracted important kinematic information that could explain differences between experts and novices. Indeed, thanks to the cutoffs, it is possible to determine how early each of these two levels of practice can perceive the correct final direction of the opponent. Then this information is correlated to kinematical parameters of this player. Finally, we have embedding these knowledge on the evaluation of novices and expertsd to create models of rugby defenders. We are currently working on integrating these models in a VR experiment in which the real user is this time the attacker and our model the virtual defender.

Concurrently, studies are experimented to determine if VR can be used for training in sports [9]. The first step was to compare if trainees learned the same way in real situation, facing a video of the lesson or facing a virtual teacher that is animated from the motions of the real course. Based on evaluation of an expert, the results showed that the three groups evolved the same way and reached the same level of practice. The second step is then to have more experts to complete the evaluation but also to combine these results with objective analyses based on kinematics data.

This work is partially funded by the Biofeedback project (DGCIS "Serious Gaming" project) of the M2S laboratory, University Rennes 2. Its goal was to create a training tool that can be used and configured by coaches in order to train athletes to repetitive motions such as katas in karate. The evaluation is made by an automatic module that compares the kinematics of the trainee to a database of expert movements.

6.3. Crowds

Participants: Julien Pettré [contact], Richard Kulpa, Anne-Hélène Olivier, Samuel Lemercier, Yijiang Zhang, Jonathan Perrinet.

6.3.1. Perception of collision in crowds

We designed a level-of-detail (LOD) selection function to determine where collision avoidance constraints in crowd simulation can be relaxed without being perceived by spectators [4]. Collision avoidance is probably the most time consuming parts of crowd simulator. However, when only believable results are required, we argue that visually similar results can be obtained a low computational costs based on macroscopic crowd simulation. Based on a perception study, we determined the conditions for collision to be or not to be detected. We discovered that the camera tilt angle was playing a great effect on perception, whereas distance to camera (usually used in previous works) was only the third most important factor to be considered.

6.3.2. Mixed Reality Crowds

In the task of making virtual crowds and real people interact together, we explore a mixed reality solution [22]. The seamless integration of virtual characters into dynamic scenes captured by video is a challenging problem. In order to achieve consistent composite results, both the virtual and real characters must share the same geometrical space and their interactions must adhere to the physical coherence criteria. One essential question is how to detect the motion of real objects - such as real characters moving in the video - and how to steer virtual characters accordingly to avoid unrealistic collisions. We propose an online solution. First, by analysis of the input video, the motion states of the real objects are recovered into a common world 3D coordinate system. Meanwhile, a simplified accuracy measurement is defined to represent the confidence of the motion estimate. Then, under the constraints imposed by the real dynamic objects, the motion of virtual characters are accommodated by a uniform steering model. The final step is to merge virtual objects back the
real video scene by taking into account visibility and occlusion constraints between real foreground objects and virtual ones.

6.3.3. Experiments on crowds

Evaluating crowd simulation models is a difficult task. In the frame of the ANR PEDIGREE project, we put in a lot of effort to perform experiments on groups of walking people in order to dispose of a reference database on groups motion. In order to obtain high-quality data, we measure people locomotion by using optoelectronic motion capture systems. In 2011, we starting obtaining detailed analysis on such motion after large efforts on motion analysis and processing. We had to develop dedicated reconstruction techniques because of the challenging conditions in which we performed our motion capture [12]. We submitted two papers on following modeling and simulation stages (submitted to Eurographics 2012 and Physical Review E).

6.4. Interactive Virtual Cinematography

Participants: Marc Christie [contact], Christophe Lino.

The domain of Virtual Cinematography explores the operationalization of rules and conventions pertaining to camera placement, light placement and staging in virtual environments. In 2011, two major challenges were tackled (i) the proposition of intelligent interactive assistants integrating users in the process of selecting viewpoints and editing a virtual movie, with the capability of adapting to the user choices, and (ii) the design and implementation of evaluation functions for precisely ranking the quality of viewpoints of a virtual 3D environment.

Our intelligent assistant is designed around (i) an intelligent cinematography engine that can compute, at the request of the filmmaker, a set of suitable camera placements (called suggestions) for starting a shot, representing semantically and cinematically distinct choices for visualizing the current narrative, considering established cinema conventions of continuity and composition along with the filmmaker’s previous selected suggestions, and also his or her manually crafted camera compositions, by a machine learning component that adapts shot editing preferences from user-created camera edits, (ii) a user interface, where the suggestions are presented as small movie frames, arranged in a grid whose rows and columns correspond to visual composition properties of the suggested cameras, and (iii) a motion-tracked camera system that makes the user able of modifying the low-level parameters of the camera in shots in the same way a real operator would.

The result of this work [16] is a novel workflow based on interactive collaboration of human creativity with automated intelligence that enables efficient exploration of a wide range of cinematographic possibilities, and rapid production of computer-generated animated movies. A full prototype has been built and demonstrated at ACM Multimedia conference [15] as well as ParisFX conference. A patent protecting this technology is currently under evaluation [25].

The second challenge is related to the design of efficient and precise metrics for measuring the quality of viewpoints. For efficiency, we have proposed parallel GPU-based evaluation techniques for the estimation of multiple viewpoints [8] coupled within a Genetic Algorithm (Swarm Particle Optimization) to rapidly explore the space of possible viewpoints. For preciseness, we have designed a large range of quality functions relative to screen composition and transition between shots, and employed these functions to either automatically generate movies from actions occuring in the virtual environment [13] or interactively generating movies by letter the users select best shots and best transitions between shots [14].

Finally we have been exploring the use of tactile devices to the interactive construction of narratives following Prop’s computational model of stories [10].

6.5. Biomechanics and Motion Analysis

6.5.1. Balance in highly dynamic situations

Participants: Franck Multon [contact], Ludovic Hoyet.
Balance is a key problem in humans as people stand on two feet which leads to a small base of support area compared to the overall body volume. This unstable state has been widely analyzed in static situation but is still difficult to understand when velocity and acceleration reach ineligible values. We thus have proposed an experimental protocol in order to evaluate if criteria published in the literature for specific motions could be generalized to any dynamic motions (see figure 7). To this end, each studied criterion was tested on various dynamic motions and the number of false falling alarms was reported in each case: the number of frames where the criterion detects loss of balance while the subject is actually balanced. The tested criteria where: the projection of the center of mass on the ground which should remain in the base of support, the Zero Moment Point widely used in robotics, the Zero Rate of Angular Momentum, the Foot Rotation Index and the extrapolated center of mass which was introduced in biomechanics recently. The results demonstrate that none of the criteria succeeded in correctly predicting loss of balance in highly dynamic motions [7]. It thus demonstrate the need to continue some fundamental work on this topic which is a key problem in many applications, including robotics, detection and prevention of falls in the Elderly, understanding performance in sports, improving realism in virtual human simulation...

#### 6.5.2. Interaction strategies between two walkers to avoid collision
Participants: Armel Crétual, Julien Pettré [contact], Anne-Hélène Olivier, Jan Ondrej, Antoine Marin.

In the everyday life situation where two humans walk in the same nearness, each can be considered as a moving obstacle for the other one. They adapt their locomotion with respect to this external disturbance to avoid any collision. Collision avoidance between two humans has been largely neglected in the literature despite it lets us expect specific interactions. The main question we raised was to identify the conditions that induce avoidance manoeuvres in locomotor trajectories: what are the relations between the respective positions and velocities which induce motion adaptations? To answer this question, we proposed an original experiment: thirty participants were asked to walk two-by-two in a motion captured area. We assigned them locomotion tasks in order to provoke varied situations of potential future collisions (see figure 8 a). Following the hypothesis of a reciprocal interaction, we suggested a variable which is common to both of the walkers, the Minimum Predicted Distance (MPD), to predict the actual presence of physical interactions as well as to describe their properties. At each instant t, MPD was computed as the distance the walkers would meet if they did not perform motion adaptation after this instant t. Results showed that walkers adapted their motions only when required, i.e., when initial MPD was too low (<1m). We concluded that human walkers are able to accurately estimate future crossing distance and to mutually adapt it. The evolution of MPD enabled decomposing collision avoidance into 3 successive phases: observation, reaction, and regulation (see figure 8 b). Respectively, these phases corresponded to periods of time when, first, MPD was constant, second, increased to acceptable values by motion adaptation and, third, reached a plateau and even slightly decreased. This final phase demonstrates that collision avoidance is actually performed with anticipation. Future work is needed to inspect individual motion adaptations and to relate them with variation of MPD.

---

6.5.3. Quantification of pathological gait in adults

Participants: Armel Crétual [contact], Kristell Bervet.

Quantifying gait deviation is still a challenge in adults patient follow-up within a rehab process. This quantification can be done on several levels. Among them, the most useful for practitioners are surely kinematics and muscular activation. On the first one, Gillette Gait Index (GGI) has now become a common tool in rehabilitation centers to assess gait abnormalities. However, one limitation of this index is that it is based on some peak values and is thus sensitive to measurement noise. A new index, the Gait Deviation Index (GDI) which is based on joints angles patterns has been developed by the same team to avoid this problem. Nevertheless, both of them have only been validated in children with cerebral palsy. On the second level, no
satisfying global index has yet been developed. The first part of our study was to validate the GDI in adults. From a database of 74 healthy subjects and 48 patients we did demonstrate that GDI is a relevant index to quantify kinematic gait pattern in adults. Then, we developed a new index called KeR-EGI (for Kerappe-Rennes EMG-based Gait Index) which accounts for the muscular activation patterns of patients. There also, results were conclusive relying on a good correlation between GDI and KeR-EGI. Finally, our recommendation to practitioners was to use both of these two index as they account for complementary aspects of pathology. This allow to better understand if gait disorder is more due to neurological injury or on the opposite to mechanical constraints such as joint stiffness.

6.5.4. Modeling gesture in sports: tennis serve

Participants: Nicolas Bideau [contact], Guillaume Nicolas, Benoit Bideau, Caroline Martin, Richard Kulpa.

Most experimental studies on tennis focus on the segmental coordination in connection with the ball speed, but do not consider the resulting traumatisms. To this end, we currently develop an inverse dynamics modeling approach, based on musculoskeletal parameters. As a first step to this work, we calculated the joint constraints on the upper limb in the tennis serve, for professional and regional players. Eleven high level, professional players were compared to seven regional players during this specific motion. Each player was equipped with 42 reflecter markers and tennis serve was analyzed using an optoelectronical system composed of 12 infrared cameras cadenced at 300Hz. For each player, values of force, power and internal work (in absolute value) were calculated for the three joints (shoulder, elbow, wrist) using a musculoskeletal model. The results showed that professional players produced higher power and internal work for each joint in comparison with the regional players. Results also showed a decrease in the values of internal work from the distal (wrist joint) to the proximal joint (shoulder joint). These results may explain shoulder pain in tennis, which is commonly depicted for high-level players in epidemiological studies. A first perspective to this work is to better take individual parameters (inertia, muscle parameters, pre-constraint, etc.) into account. Another perspective is to test various objective functions in order to predict which parameter is optimized during tennis serve.

6.5.5. Modeling gesture in sports: fin swimming

Participants: Nicolas Bideau [contact], Guillaume Nicolas, Benoit Bideau, Richard Kulpa.

In swimming, experimental approaches are commonly used to analyze performance. However, due to obvious limitations in experimental approaches (impossibility to standardize any situations etc.), it is difficult to characterize surrounding fluid. To overcome this limitation, we currently develop analysis, modeling and simulation of aquatic locomotion, using CFD computer simulation and new methods based on animation of virtual characters.

A first application of this topic enables to evaluate the influence of swim fin flexibility on efficiency during swimming based on a CFD structure interaction model. Finite elements simulations are carried out for various material properties and various prescribed kinematics. Besides the significant effect of flexibility on propulsive forces, the results indicate that the propulsive efficiency is greatly influenced by the stroke frequency and the initial angle of attack. For the selected material properties, the results show that efficiency increases from 3.6 percents to 11.9 percents when the stroke frequency is increased from 0 to 1.7 Hz. Moreover efficiency is clearly increased from 5.0 percents to 24.2 percents when increasing the angle of attack from 0 to 45 degrees. Therefore, an interesting prospect of the present work could be an enhancement of the design of better performing swim fins.

A second application of this topic related to aquatic propulsion deals with a new method to evaluate cross-sectional area based on computer animation of swimming. Indeed, reducing cross sectional area (CSA) during starts and turns is a key part of performance optimisation. Different methods have been used to obtain this parameter without any standard: total human body volume to the power 2/3, wetted area or frontal area based on planimetry technique (PT). These different methods can lead to discrepancies in drag values. Recently, we used two synchronized camcorders to evaluate drag parameters during the different phases of an undulatory stroke cycle.
However, such a technique needs accurate synchronization and calibration of the different camcorders views. The aim of this study is to provide a new method based on animation of virtual characters to obtain instantaneous cross-sectional area in an undulatory stroke cycle. Its main advantage is to obtain cross-sectional area as well as biomechanical analysis with a single camcorder in a sagittal plane and without space calibration. From this, we intend to better understand swimming hydrodynamics and the way CSA influences active drag. More generally, this approach has been designed to provide new practical insights into swimming analysis protocols.

6.6. Path planning and environment analysis

6.6.1. Space-Time planning in dynamic environments
Participants: Fabrice Lamarche [contact], Thomas Lopez.

When automatically populating 3D geometric databases with virtual humanoids, modeling the navigation behavior is essential since navigation is used in most exhibited behaviors. In many application fields, the need to manage navigation in dynamic environments arises (virtual worlds taking physics laws into account, numerical plants in which step stools can be moved,...). This study focuses on the following issue: how to manage the navigation of virtual entities in such dynamic environments where topology may change at any time i.e. where unpredictable accessibility changes can arise at runtime. In opposition to current algorithms, movable items are not only considered as obstacles in the environment but can also help virtual entities in their navigation.

The proposed algorithm [17] splits that problem into two complementary processes: a topology tracking algorithm and a path planning algorithm. The aim of the topology tracking algorithm is to continuously detect and update topological relations between moving objects i.e. accessibility or obstruction, while storing temporal information when recurring relations are observed. The path planning algorithm uses this information to plan a path inside the dynamic environment. The coupling of those algorithms endows a virtual character with the ability to immediately use inserted / moved object to reach previously unreachable locations. Moreover, this algorithm is able to find a path through moving platforms to reach a target located on a surface that is never directly accessible.

6.6.2. Automated environment analysis
Participants: Fabrice Lamarche [contact], Carl-Johan Jorgensen.

To populate a virtual environment, modeling the navigation behavior is crucial. This behavior relies on the ability of planning a path inside a complex environment, which itself relies on an adequate representation of the environment structure. Most often, virtual environments are represented has 3D databases that are analyzed to produce data structures that are suitable for path planning and navigation. However, without any user intervention, those data structures lack of information about the nature of identified navigable zones that are crucial for navigation credibility.

We proposed an environment analysis algorithm [11] that automatically extracts a meaningful spatial representation of 3D virtual environments, suitable for spatial reasoning. This algorithm automatically differentiates indoor, outdoor and covered parts of the environment. It separates buildings into floors linked by stairs and represent floors as rooms linked by doorsteps. On this basis, we propose a natural hierarchical representation of the environment. This representation is used for spatial reasoning including zone selection and multi-criterion path planning that enhances path credibility.
6. New Results

6.1. Improvement of the force-feedback in a 1-ddl device

**Participants:** Michel Amberg, Frédéric Giraud, Betty Lemaire-Semail.

Traveling Wave Ultrasonic Motor have many advantages compared to the classical electromagnetic motors: they are lightweight, they don’t need any speed reducer and they make no noise. In a 1-ddl force feedback device, they can help to reduce the bulk size of the mechanism by simplifying the kinematic chain. However, their control has to be very precise because the torque produced is not a straightforward function of the electrical parameters. Previously, we proposed several control algorithms and we obtained good results. But at low speed, problems still remains, like a stick-slip phenomena which makes the motor producing a cogging torque.

To cope with this problem, we first proposed an accurate modeling of the motor and its torque production [24]. We introduced a friction torque $T_f$ which holds the non linearity of the torque production. The evolution of this friction torque has been identified through an experimental study. Then we obtained by inversion a control scheme [13]. The basic idea is to compensate the virtual friction torque. In order to achieve a more accurate control of the torque, we proposed to identify on-line the parameters of the equation of $T_f$.

A one-degree-of-freedom force feedback lever was built to verify the control laws. The experiment involves use of the lever of the digitracker which is free to rotate about the horizontal axis, and is presented in figure 1. In the same figure, we plotted the output torque of the motor, compared to its reference. Both are consistent, showing a good accuracy of the torque controller. To achieve that, the estimator’s parameters are time-varying.

![Figure 1](image_url)

**Figure 1.** (a) The 1-ddl haptic device; (b) experimental run of the torque controller with its parameter estimator; in $H$, results are plotted in the Torque-position plane, reference is in green and measurements is in blue while $C$, $D$ and $G$ show the estimator’s parameters.

6.2. Haptic Perception of Curvature through active touch

**Participants:** Michel Amberg, Frédéric Giraud, Betty Lemaire-Semail.
Interaction and Visualization - New Results - Team MINT

Figure 2.

Haptic perception of curvature can be achieved by passive or active finger touch. In this study we proposed a new haptic device that could independently orient, elevate and translate a flat plate. User is free to move his finger on the plate; by controlling plate’s orientation and position accordingly to the position of the finger, we can render a curved shape. The device is composed of two 6-dof haptic devices (Novint Falcon) on which we attached the plate (Figure 2). A force sensor is used to compute the position of the finger on the plate.

Several modelings have been proposed to calculate the orientation and position of the plate. We then measured how accurate simulations of curved shapes are. To achieve that work, we simulated several curved surfaces with different curvature. As the perception performance of curvature is dependent on local surface orientation, the plate was always kept tangent to a virtual shape at the contact point. We then asked people to compare simulated curvature to the real ones. We found that users are able to find the real shape (among five) corresponding to the simulated one [21].

6.3. Tactile input with programmable friction

Participants: Michel Amberg, Géry Casiez, Frédéric Giraud, Betty Lemaire-Semail, Paolo Olivo, Nicolas Roussel.

Our work on programmable friction relies on a particular technology we have been developing for several years. The STIMTAC is a touchpad device that supports friction reduction by means of a squeeze film effect [29]. It uses a controlled vibration at an ultrasonic frequency with a few micrometers amplitude to create an air bearing between a user’s finger and the device’s surface. As the frequency is outside skin mechanoreceptors’ bandwidth, one does not feel this vibration but its effect on tribological contact mechanisms: the touchpad feels more slippery as the amplitude is raised.

We have used this touchpad to create Surfpad, a pointing facilitation technique that operates in the tactile domain. Experiments comparing this technique to semantic pointing [30] and constant control-display gain with and without distractor targets clearly show the limits of traditional target-aware control-display gain.
adaptation in the latter case, and the benefits of the tactile approach in both cases [17]. Surfpad leads to a performance improvement close to 9% compared to unassisted pointing at small targets with no distractor. It is also robust to high distractor densities, keeping an average performance improvement of nearly 10% while semantic pointing can degrade up to 100%. Our results also suggest the performance improvement is caused by tactile information feedback rather than mechanical causes, and that the feedback is more effective when friction is increased on targets using a simple step function.

This year’s work on the hardware aspects of the STIMTAC resulted in a compact and quiet prototype powered by the USB cable used for data communication and supporting precise and reliable finger tracking based on multiple force sensors (Figure 3, left). Within the context of the 3DTOUCH project, efforts have also been targeted at the adaptation of the STIMTAC operating principles to off-the-shelf transparent touch sensors. Our latest prototypes demonstrate the compatibility of our approach with resistive (Figure 3, right) and capacitive technologies. In order to facilitate the design and evaluation of novel interaction techniques taking advantage of these prototypes, we have started developing a specific library, tIO, that supports all of them in a unified way.

Figure 3. Compact opaque STIMTAC and transparent resistive prototype

6.4. Methods and tools to characterize, replicate and compare pointing transfer functions

Participants: Géry Casiez, Damien Marchal, Nicolas Roussel.

Transfer functions are the only pointing facilitation technique actually used in modern graphical interfaces involving the indirect control of an on-screen cursor. But despite their general use, very little is known about them. We developed EchoMouse, a device we created to characterize the transfer functions of any system, and libpointing, a toolkit that we developed to replicate and compare the ones used by Windows, OS X and Xorg [16]. We described these functions and reported on an experiment that compared the default one of the three systems. Our results show that these default functions improve performance up to 24% compared to a unitless constant CD gain. We also found significant differences between them, with the one from OS X improving performance for small target widths but reducing its performance up to 9% for larger ones compared to Windows and Xorg. These results notably suggest replacing the constant CD gain function commonly used by HCI researchers by the default function of the considered systems.

6.5. Multimodal pen input for interactive multitouch surfaces

Participant: Géry Casiez.
Touch interaction is arguably more immediate and natural in many situations, but fingers are imprecise and difficult to write with. Alternatively, using a pen (or stylus) makes writing more natural and pointing more precise. Luckily, this does not need to be a unilateral choice; pen and touch can be used simultaneously. However, without non-dominant hand coordination or graphical buttons, the pen itself supports few modes. This makes single-handed mobile usage difficult and reduces the number of combined touch and pen modes. When frequently switching between pen-oriented modes, such as drawing, handwriting, gestures, and lasso selection, this can hurt performance. Inferring modes is difficult, and most users prefer explicit control. Schemes for squeezing multiple explicit modes from a pen include adding barrel buttons and classifying pressure, tilt, barrel rotation, or grip. But these can be error-prone and ambiguous. A simple way to add a second mode is by adding an “eraser,” a second contact point. The pencil analogy lends intuition and users have explicit control.

Conté is a small input device inspired by the way artists manipulate a real Conté crayon. By changing which corner, edge, end, or side is contacting the display, the operator can switch interaction modes using a single hand. Conté’s rectangular prism shape enables both precise pen-like input and tangible handle interaction. Conté also has a natural compatibility with multi-touch input: it can be tucked in the palm to interleave same-hand touch input, or used to expand the vocabulary of bimanual touch. Inspired by informal interviews with artists, we catalogue Conté’s characteristics, and use these to outline a design space. We describe a prototype device using common materials and simple electronics. With this device, we demonstrate interaction techniques in a test-bed drawing application [19].

![Figure 4. Illustration of different modes defined by Conté: (left) freehand drawing and annotating with the corner; (middle) revealing attribute palettes using a thick side face; (right) contextual commands using the end contact.](image)

### 6.6. Perceived difficulty of pen gestures

**Participants:** Géry Casiez, Laurent Grisoni.

There are three primary factors which contribute to a successful gesture-based interface: the acquisition technology, the recognizer, and the design of the gesture set. Technologies to acquire gestures, and gesture recognition algorithms, are now quite robust and widely available. However, developing techniques and criteria to help designers create an intuitive and easy-to-perform gesture set remain an active area of research. The challenge is that in order to successfully integrate into an application, a gesture has to satisfy multiple criteria: it must be unambiguously recognized; fit well with its associated function; be easy to learn and recall; and be efficient to perform.
Our empirical results show that users perceive the execution difficulty of single stroke gestures consistently, and execution difficulty is highly correlated with gesture production time. We use these results to design two simple rules for estimating execution difficulty: establishing the relative ranking of difficulty among multiple gestures; and classifying a single gesture into five levels of difficulty. We confirm that the CLC model does not provide an accurate prediction of production time magnitude, and instead show that a reasonably accurate estimate can be calculated using only a few gesture execution samples from a few people. Using this estimated production time, our rules, on average, rank gesture difficulty with 90% accuracy and rate gesture difficulty with 75% accuracy. Designers can use our results to choose application gestures, and researchers can build on our analysis in other gesture domains and for modeling gesture performance [18].
MISTIS Project-Team

5. New Results

5.1. Mixture models

5.1.1. Taking into account the curse of dimensionality

**Participant:** Stéphane Girard.

**Joint work with:** Bouveyron, C. (Université Paris 1), Celeux, G. (Select, INRIA).

In the PhD work of Charles Bouveyron (co-advised by Cordelia Schmid from the INRIA LEAR team) \[53\], we propose new Gaussian models of high dimensional data for classification purposes. We assume that the data live in several groups located in subspaces of lower dimensions. Two different strategies arise:

- the introduction in the model of a dimension reduction constraint for each group
- the use of parsimonious models obtained by imposing to different groups to share the same values of some parameters

This modelling yields a new supervised classification method called High Dimensional Discriminant Analysis (HDDA) \[4\]. Some versions of this method have been tested on the supervised classification of objects in images. This approach has been adapted to the unsupervised classification framework, and the related method is named High Dimensional Data Clustering (HDDC) \[3\].

In collaboration with Gilles Celeux and Charles Bouveyron, we have designed an automatic selection of the discrete parameters of the model \[12\]. Also, the description of the R package is submitted for publication \[44\].

5.1.2. A new family of multivariate heavy-tailed distributions with variable marginal amounts of tailweight: Application to robust clustering

**Participants:** Florence Forbes, Darren Wraith.

We proposed a family of multivariate heavy-tailed distributions that allow variable marginal amounts of tailweight. The originality comes from the eigenvalue decomposition of the covariance matrix in the traditional Gaussian scale mixture representation. By contrast to most existing approaches, the derived distributions can account for a variety of shapes and have a simple tractable form with a closed-form probability density function whatever the dimension. We examined a number of properties of these distributions and illustrate them in the particular case of Pearson type VII and $t$ tails. For these latter cases, we provided maximum likelihood estimation of the parameters and illustrated their modelling flexibility on clustering examples for several simulated and real data sets.

5.2. Markov models

5.2.1. Variational approach for the joint estimation-detection of Brain activity from functional MRI data

**Participants:** Florence Forbes, Lotfi Chaari, Thomas Vincent.

**Joint work with:** Michel Dojat (Grenoble Institute of Neuroscience) and Philippe Ciuciu from Neurospin, CEA in Saclay.
In standard fMRI within-subject analysis, two steps are generally performed separately: detection and estimation. Because these two steps are inherently linked, we proposed in this work a joint detection-estimation procedure. We adopt the so-called region-based Joint Detection Estimation (JDE) framework that deals with spatial dependencies between voxels belonging to the same functionally homogeneous parcel in the mask of the 3D brain. After building a spatially adaptive General Linear Model, prior information is introduced and a hierarchical Bayesian model is established. In contrast to previous works that use Markov Chain Monte Carlo (MCMC) techniques to approximate the resulting intractable posterior distribution, we recast the JDE into a missing data framework and derive a Variational Expectation-Maximization (VEM) algorithm for its inference. It follows a new algorithm that exhibits interesting properties compared to the previously used MCMC-based approach. Experiments on artificial and real data show that VEM-JDE is robust to model mis-specification and provides computational gain while maintaining good performance. Corresponding papers [27], [38], [26].

5.2.2. Adaptive experimental condition selection in event-related fMRI

Participants: Florence Forbes, Christine Bakhous, Lotfi Chaari, Thomas Vincent, Thomas Vincent.

Joint work with: Michel Dojat (Grenoble Institute of Neuroscience) and Philippe Ciuciu from Neurospin, CEA in Saclay.

Standard Bayesian analysis of event-related functional Magnetic Resonance Imaging (fMRI) data usually assumes that all delivered stimuli possibly generate a BOLD response everywhere in the brain although activation is likely to be induced by only some of them in specific brain areas. Criteria are not always available to select the relevant conditions or stimulus types (e.g. visual, auditory, etc.) prior to estimation and the unnecessary inclusion of the corresponding events may degrade the results. To face this issue, we propose within a Joint Detection Estimation (JDE) framework, a procedure that automatically selects the conditions according to the brain activity they elicit. It follows an improved activation detection that we illustrate on real data.

5.2.3. Finding Audio-Visual Events in Informal Social Gatherings

Participant: Florence Forbes.

Joint work with: Xavier Alameida-Pineda and Radu Horaud from the INRIA Perception team.

In this work [21] we addressed the problem of detecting and localizing objects that can be both seen and heard, e.g., people. This may be solved within the framework of data clustering. We proposed a new multimodal clustering algorithm based on a Gaussian mixture model, where one of the modalities (visual data) is used to supervise the clustering process. This was made possible by mapping both modalities into the same metric space. To this end, we fully exploited the geometric and physical properties of an audio-visual sensor based on binocular vision and binaural hearing. We proposed an EM algorithm that is theoretically well justified, intuitive, and extremely efficient from a computational point of view. This efficiency makes the method implementable on advanced platforms such as humanoid robots. We described in detail tests and experiments performed with publicly available data sets that yield very interesting results.

5.2.4. Spatial risk mapping for rare disease with hidden Markov fields and variational EM

Participants: Lamiae Azizi, Florence Forbes, Senan James Doyle.

Joint work with: David Abrial and Myriam Garrido from INRA Clermont-Ferrand-Theix.

We recast the disease mapping issue of automatically classifying geographical units into risk classes as a clustering task using a discrete hidden Markov model and Poisson class-dependent distributions. The designed hidden Markov prior is non standard and consists of a variation of the Potts model where the interaction parameter can depend on the risk classes. The model parameters are estimated using an EM algorithm and the mean field approximation. This provides a way to face the intractability of the standard EM in this spatial context, with a computationally efficient alternative to more intensive simulation based Monte Carlo Markov Chain (MCMC) procedures. We then focus on the issue of dealing with very low risk values and small numbers of observed cases and population sizes. We address the problem of finding good initial parameter values in
this context and develop a new initialization strategy appropriate for spatial Poisson mixtures in the case of not so well separated classes as encountered in animal disease risk analysis. Using both simulated and real data, we compare this strategy to other standard strategies and show that it performs well in a lot of situations. Corresponding papers and communications [43], [24], [37], [25].

5.2.5. Probabilistic model definition for physiological state monitoring

Participants: Laure Amate, Florence Forbes.

Joint work with: Catherine Garbay, Julie Fontecave-Jallon and Benoit Vettier from LIG.

Assessing the global situation of a person from physiological data is a well-known difficult problem. In previous work, we proposed a system that does not produce a diagnosis but instead follows a set of hypotheses and decides of an alarming situation with this information. In this work [22], we focus on data processing part of the system taking into account the complexity and the ambiguity of the data. We propose a statistical approach with a global model based on Hidden Markov Model and we present data models that rely on classical physiological parameters and expert’s knowledge. We then learn a model that depends on the person and its environment, and we define and compute confidence values to assess the plausibility of hypotheses.

5.2.6. Solder Paste Inspection

This is joint work with VI-Technology.

The majority of defects in PCB manufacture are attributed to the stencil printing process. Stencil printing is the process where solder paste bricks are deposited on the PCB pads. Solder paste deposition is required to be accurate and repeatable, however complex physical process make this problematic. Components are placed, and their leads are pushed into the solder paste. The solder paste is then melted using, for example, reflow soldering.

Inspection can be performed before the solder paste is melted, and it is more economical to identify defects at this stage.

The evaluation of solder paste joint quality involves the analysis of a number of indicative measurements. From these measurements, potential faults are identified and inspected manually. The general challenge is to reduce of the number of potential faults by better analyzing the indicative factor measurements. That is, to improve the first pass yield (FPY) which is the percentage of total solder deposits that are good, and that do not require manual inspection. However, the ability to catch defects must be retained. Another aspect to consider is the temporal nature of the process; The mechanism for identifying faults needs to be retrained after a period of time, and so a solution must be capable of using a small training dataset.

It is important to understand and identify the factors that influence quality. The industry standard factor for measuring quality is solder volume. The precise volume is not directly observable, and so is estimated. Often, height is used as a proxy measure for solder bricks of equal area and shape. There are many other contributing factors, however not all of these can be measured directly, making accurate quality determination difficult.

Stencil printing process control attempts to adjust machine parameters according to informative factors. Online printing process control faces a similar challenge of using a limited number of measurements to inform on the quality of solder paste deposition.

We used statistical techniques to analyze such measurements. The exact nature of the work is confidential.

5.2.7. PCB defect detection

Participants: Florence Forbes, Kai Qin, Huu Giao Nguyen.

This is joint work with VI-Technology.

The objective is to detect defective components in PC Boards from image data. The exact nature of the work is confidential.
5.2.8. **Statistical characterization of tree structures based on Markov Tree Models and multitype branching processes, with applications to tree growth modeling.**

**Participant:** Jean-Baptiste Durand.

**Joint work with:** Pierre Fernique (Montpellier 2 University and CIRAD) and Yann Guédon (CIRAD), INRIA Virtual Plants.

The quantity and quality of yields in fruit trees is closely related to processes of growth and branching, which determine ultimately the regularity of flowering and the position of flowers. Flowering and fruiting patterns are explained by statistical dependence between the nature of a parent shoot (e.g. flowering or not) and the quantity and nature of its children shoots – with potential effect of covariates. Thus, better characterization of patterns and dependencies is expected to lead to strategies to control the demographic properties of the shoots (through varietal selection or crop management policies), and thus to bring substantial improvements in the quantity and quality of yields.

Since the connections between shoots can be represented by mathematical trees, statistical models based on multitype branching processes and Markov trees appear as a natural tool to model the dependencies of interest. Formally, the properties of a vertex are summed up using the notion of vertex state. In such models, the numbers of children in each state given the parent state are modelled through discrete multivariate distributions. Model selection procedures are necessary to specify parsimonious distributions. We developed an approach based on probabilistic graphical models to identify and exploit properties of conditional independence between numbers of children in different states, so as to simplify the specification of their joint distribution. The graph building stage was based on a Poissonian Generalized Linear Model for the contingency tables of the counts of joint children state configurations. Then, parametric families of distributions were implemented and compared statistically to provide probabilistic models compatible with the estimated independence graph.

This work was carried out in the context of Pierre Fernique’s Master 2 internship (Montpellier 2 University and AgroParisTech). It was applied to model dependencies between short or long, vegetative or flowering shoots in apple trees. The results highlighted contrasted patterns related to the parent shoot state, with interpretation in terms of alternation of flowering (see paragraph 5.2.9). This work will be continued during Pierre Fernique’s PhD thesis, with extensions to other fruit tree species and other strategies to build probabilistic graphical models and parametric discrete multivariate distributions including covariates and mixed effects.

5.2.9. **Statistical characterization of the alternation of flowering in fruit tree species**

**Participant:** Jean-Baptiste Durand.

**Joint work with:** Jean Peyhardi and Yann Guédon (Mixed Research Unit DAP, Virtual Plants team), Evelyne Costes and Baptiste Guitton (DAP, AFEF team), Catherine Trottier (Montpellier University)

The aim of this work was to characterize genetic determinisms of the alternation of flowering in apple tree progenies. Data were collected at two scales: at whole tree scale (with annual time step) and a local scale (annual shoot or AS, which is the portions of stem that were grown during the same year). Two replications of each genotype were available.

To model alternation of flowering at AS scale, a second-order Markov tree model was built. The ASs were of two types: flowering or vegetative. Generalized Linear Mixed Models (GLMMs) were used to model the effect of year, replications and genotypes (with their interactions with year or memories of the Markov model) on the transition probabilities. This work was the continuation of the Master 2 internship of Jean Peyhardi (Bordeaux 2 University) and was carried out in the context of the PhD thesis of Baptiste Guitton.

This PhD thesis also comprised the study of alternation in flowering at individual scale, with annual time step. To relate alternation of flowering at AS and individual scales, indices were proposed to characterize alternation at individual scale. The difficulty is related to early detection of alternating genotypes, in a context where alternation is often concealed by a substantial increase of the number of flowers over consecutive years. To separate correctly the increase of the number of flowers due to aging of young trees from alternation in flowering, our model relied on a parametric hypothesis on the base effect random slopes specific to genotype
and replications), which translated into mixed effect modelling. Different indices of alternation were then computed on the residuals. Clusters of individuals with contrasted patterns of bearing habits were identified. Our models highlighted significant correlations between indices of alternation at AS and individual scales. The roles of local alternation and asynchronism in regularity of flowering were assessed using an entropy-based criterion, which characterized asynchronism.

As a perspective of this work, patterns in the production of children ASs (numbers of flowering and vegetative children) depending on the type of the parent AS must be analyzed using branching processes and different types of Markov trees, in the context of Pierre Fernique’s PhD Thesis (see paragraph 5.2.8).

5.3. Semi and non-parametric methods

5.3.1. Harmony Search with Differential Mutation Based Pitch Adjustment

Participants: Kai Qin, Florence Forbes.

Harmony search (HS), as an emerging metaheuristic technique mimicking the improvisation behavior of musicians, has demonstrated strong efficacy of solving various numerical and real-world optimization problems. This work [36] presents a harmony search with differential mutation based pitch adjustment (HSDM) algorithm, which improves the original pitch adjustment operator of HS using the self-referential differential mutation scheme that features differential evolution - another celebrated metaheuristic algorithm. In HSDM, the differential mutation based pitch adjustment can dynamically adapt the properties of the landscapes being explored at different searching stages. Meanwhile, the pitch adjustment operator’s execution probability is allowed to vary randomly between 0 and 1, which can maintain both wild and fine exploitation throughout the searching course. HSDM has been evaluated and compared to the original HS and two recent HS variants using 16 numerical test problems of various searching landscape complexities at 10 and 30 dimensions. HSDM consistently demonstrates superiority on most of test problems.

5.3.2. Dynamic Regional Harmony Search Algorithm with Opposition and Local Learning

Participants: Kai Qin, Florence Forbes.

To deal with the deficiencies associated with the original Harmony Search (HS) such as premature convergence and stagnation, a dynamic regional harmony search (DRHS) algorithm incorporating opposition and local learning is proposed [35]. DRHS utilizes the opposition-based initialization, and performs independent HS with respect to multiple groups that are randomly recreated on a fixed period basis. Besides the traditional harmony improvisation operators, an opposition based harmony creation scheme is introduced to update the group memory. Any prematurely converged group will be restarted with the doubled size to further augment its exploration capability. Local search is periodically applied to exploit promising regions around top-ranked candidate solutions. The performance of DRHS has been evaluated and compared to HS using 12 numerical test problems at 10D and 30D, which are taken from the CEC2005 benchmark. DRHS consistently demonstrate superiority to HR over all the test problems at both 10D and 30D.

5.3.3. Evolutionary algorithms with CUDA

Participants: Kai Qin, Federico Raimondo.

Evolutionary algorithms (EAs), inspired by natural evolution processes, have demonstrated strong efficacy for solving various real-world optimization problems, although their practical use may be constrained by their computation efficiency. In fact, EAs are inherently parallelizable due to the operations at the individual element level and population-wise evolution. However, most of the existing EAs are designed and implemented in the sequential manner mainly because hardware platforms supporting parallel computing tasks and software platforms facilitating parallel programming tasks are not prevalently available.
In recent years, the graphics processing unit (GPU) has emerged as a powerful general-purpose computation device that can favorably support massively data parallel computing tasks carried out on its hundreds of cores. The compute unified device architecture (CUDA) technology invented by NVIDIA provides an intuitive way to express parallelism and to implement parallel programs using some popular programming languages, such as C, C++, and FORTRAN. Accordingly, we can simply write a program for one data element, which gets automatically distributed across hundreds of cores for thousands of threads to execute. Although the CUDA programming model is easy-to-use, the computation efficiency of CUDA parallel programs crucially depends on careful consideration of hardware characteristics of GPUs during algorithmic design and implementation, especially about memory utilization and thread management (to maximize the occupancy of streaming multi-processors). Without proper considerations, the parallel programs may even run slower than their sequential counterparts.

The objectives of our project are to: 1. Redesign state-of-the-art EAs using CUDA under thorough consideration of GPU’s hardware characteristics. 2. Develop a generic hardware-self-configurable EA framework, which allows automatically configuring available hardware computing resources to maximize the computation efficiency of the EA.

Currently, we had developed a memory-efficient parallel differential evolution algorithm, which features maximally utilizing the available shared memory in GPU while maximally reducing the use of the global memory in GPU considering its very limited access bandwidth. Compared with two recent parallel differential evolution algorithms implemented with CUDA in 2010 and 2011, our algorithm demonstrated significantly faster computation speed. We had also investigated the parallel implementation of test problems and provided a guideline on how to implement any user-defined test problem and combine it with an existing parallel EA framework. To the best of our knowledge, this is the first research work on this topic.

5.3.4. Modelling extremal events

Participants: Stéphane Girard, Laurent Gardes, Jonathan El-methni, El-Hadji Deme.

Joint work with: Guillou, A. (Univ. Strasbourg).

We introduced a new model of tail distributions depending on two parameters $\tau \in [0, 1]$ and $\theta > 0$ [16]. This model includes very different distribution tail behaviors from Fréchet and Gumbel maximum domains of attraction. In the particular cases of Pareto type tails ($\tau = 1$) or Weibull tails ($\tau = 0$), our estimators coincide with classical ones proposed in the literature, thus permitting us to retrieve their asymptotic normality in an unified way. The first year of the PhD work of Jonathan El-methni has been dedicated to the definition of an estimator of the parameter $\tau$. This permits the construction of new estimators of extreme quantiles. The results are submitted for publication [48]. Our future work will consist in proposing a test procedure in order to discriminate between Pareto and Weibull tails.

We are also working on the estimation of the second order parameter $\rho$ (see paragraph 3.3.1). We proposed a new family of estimators encompassing the existing ones (see for instance [62], [61]). This work is in collaboration with El-Hadji Deme, a PhD student from the Université de Saint-Louis (Sénégal). El-Hadji Deme obtained a one-year mobility grant to work within the Mistis team on extreme-value statistics. The results are submitted for publication [46].

5.3.5. Conditional extremal events

Participants: Stéphane Girard, Laurent Gardes, Gildas Mazo, Jonathan El-methni.

Joint work with: J. Carreau, A. Lekina, Amblard, C. (TimB in TIMC laboratory, Univ. Grenoble I) and Daouia, A. (Univ. Toulouse I)

The goal of the PhD thesis of Alexandre Lekina is to contribute to the development of theoretical and algorithmic models to tackle conditional extreme value analysis, i.e., the situation where some covariate information $X$ is recorded simultaneously with a quantity of interest $Y$. In such a case, the tail heaviness of $Y$ depends on $X$, and thus the tail index as well as the extreme quantiles are also functions of the covariate. We combine nonparametric smoothing techniques [58] with extreme-value methods in order to obtain efficient
estimators of the conditional tail index and conditional extreme quantiles. When the covariate is random (random design) and the tail of the distribution is heavy, we focus on kernel methods [14]. We extension to all kind of tails in investigated in [45].

Conditional extremes are studied in climatology where one is interested in how climate change over years might affect extreme temperatures or rainfalls. In this case, the covariate is univariate (time). Bivariate examples include the study of extreme rainfalls as a function of the geographical location. The application part of the study is joint work with the LTHE (Laboratoire d’étude des Transferts en Hydrologie et Environnement) located in Grenoble.

More future work will include the study of multivariate and spatial extreme values. With this aim, a research on some particular copulas [1] has been initiated with Cécile Amblard, since they are the key tool for building multivariate distributions [64]. The PhD theses of Jonathan El-methni and Gildas Mazo should address this issue too.

5.3.6. Level sets estimation

Participants: Stéphane Girard, Laurent Gardes.

Joint work with: Guillou, A. (Univ. Strasbourg), Stupfler, G. (Univ. Strasbourg), P. Jacob (Univ. Montpellier II) and Daouia, A. (Univ. Toulouse I).

The boundary bounding the set of points is viewed as the larger level set of the points distribution. This is then an extreme quantile curve estimation problem. We proposed estimators based on projection as well as on kernel regression methods applied on the extreme values set, for particular set of points [10].

In collaboration with A. Daouia, we investigate the application of such methods in econometrics [41]: A new characterization of partial boundaries of a free disposal multivariate support is introduced by making use of large quantiles of a simple transformation of the underlying multivariate distribution. Pointwise empirical and smoothed estimators of the full and partial support curves are built as extreme sample and smoothed quantiles. The extreme-value theory holds then automatically for the empirical frontiers and we show that some fundamental properties of extreme order statistics carry over to Nadaraya’s estimates of upper quantile-based frontiers.

In the PhD thesis of Gilles Stupfler (co-directed by Armelle Guillou and Stéphane Girard), new estimators of the boundary are introduced. The regression is performed on the whole set of points, the selection of the “highest” points being automatically performed by the introduction of high order moments. The results are submitted for publication [51].

5.3.7. Quantifying uncertainties on extreme rainfall estimations

Participants: Laurent Gardes, Stéphane Girard.

Joint work with: Carreau, J. (Hydrosciences Montpellier) and Molinié, G. from Laboratoire d’Etude des Transferts en Hydrologie et Environnement (LTHE), France.

Extreme rainfalls are generally associated with two different precipitation regimes. Extreme cumulated rainfall over 24 hours results from stratiform clouds on which the relief forcing is of primary importance. Extreme rainfall rates are defined as rainfall rates with low probability of occurrence, typically with higher mean return-levels than the maximum observed level. For example Figure 2 presents the return levels for the Cévennes-Vivarais region obtained in [14]. It is then of primary importance to study the sensitivity of the extreme rainfall estimation to the estimation method considered.

The obtained results are published in [13].

5.3.8. Retrieval of Mars surface physical properties from OMEGA hyperspectral images.

Participant: Stéphane Girard.

Joint work with: Douté, S. from Laboratoire de Planétologie de Grenoble, France and Saracco, J (University Bordeaux).
Visible and near infrared imaging spectroscopy is one of the key techniques to detect, to map and to characterize mineral and volatile (e.g., water-ice) species existing at the surface of planets. Indeed, the chemical composition, granularity, texture, physical state, etc., of the materials determine the existence and morphology of the absorption bands. The resulting spectra contain therefore very useful information. Current imaging spectrometers provide data organized as three-dimensional hyperspectral images: two spatial dimensions and one spectral dimension. Our goal is to estimate the functional relationship $F$ between some observed spectra and some physical parameters. To this end, a database of synthetic spectra is generated by a physical radiative transfer model and used to estimate $F$. The high dimension of spectra is reduced by Gaussian regularized sliced inverse regression (GRSIR) to overcome the curse of dimensionality and consequently the sensitivity of the inversion to noise (ill-conditioned problems). We have also defined an adaptive version of the method which is able to deal with block-wise evolving data streams [28].

5.3.9. Statistical modelling development for low power processor.

**Participant:** Stéphane Girard.

**Joint work with:** A. Lombardot and S. Joshi (ST Crolles).

With scaling down technologies to the nanometer regime, the static power dissipation in semiconductor devices is becoming more and more important. Techniques to accurately estimate System On Chip static power dissipation are becoming essential. Traditionally, designers use a standard corner based approach to optimize and check their devices. However, this approach can drastically underestimate or over-estimate process variations impact and leads to important errors.

The need for an effective modeling of process variation for static power analysis has led to the introduction of Statistical static power analysis. Some publication state that it is possible to save up to 50% static power using statistical approach. However, most of the statistical approaches are based on Monte Carlo analysis, and such methods are not suited to large devices. It is thus necessary to develop solutions for large devices integrated in an industrial design flow. Our objective is to model the total consumption of the circuit from the probability distribution of consumption of each individual gate. Our preliminary results are published in [18].
6. New Results

6.1. Kaapi

New version of Kaapi, called X-Kaapi, has been released. The kernel is written in C for hypothetical required from embedded system. On top of the kernel, several APIs co-exist: a template based C++ library called Kaapi++; a C API; a Fortran API; and a compiler that transform a source code annotated with pragma directive to a source code with calls to the runtime library function. The compiler works with C and a subset of C++. http://kaapi.gforge.inria.fr

6.2. Multi-criteria optimization

The main idea is the development of a methodology to generate a reasonable set of approximated Pareto’ solutions (closed to the best achievable solutions). Especially, we have applied this methodology to better take into account users’ criteria than the other existing methods offer. We have also studied the problem of selection of best algorithms in a portfolio. This research axis is currently enforced by the INRIA postdoc position of Joachim Lepping where we have started to include a learning process to select the best algorithm on a given instance.

6.3. Stochastic models for optimizing checkpoint protocol

After our past studied on design of origin checkpoint protocols, we have proposed a new stochastic performance model of the parallel execution in presence of failures. Thanks to this formulation, we are able to optimize several criteria (the time lost due to failure; the expected completion time) by making right decision of the date of each checkpoint. The model is general and it does not take into account the failure distribution law and accept variable checkpoint time estimation, which is important for dynamic parallelism applications.

6.4. Work stealing scheduling algorithm taking care of communication

On some applications, the amount of data transfers can be high. To minimize the amount of data transfers during the execution, Jean-Noel Quintin has developed an algorithm called WSCOM which uses the DAG structure of the application. For each steal request, the work-stealing algorithm tries to balance the load between the thief and the stolen processor. Thus, WSCOM tries to divide the work on the stolen processor into two parts with a small number of edges between the two parts. This cutting is done with a negligible overhead at each steal request. This algorithm has been implemented in a tool called DSMake. This tool executes the set of tasks described by a Makefile on a distributed platform. In addition, I have developed a simulator to validate algorithm performance and its behavior. We compared WSCOM and several static list-scheduling algorithms. The comparison shows that WSCOM outperforms list-scheduling algorithms, on clusters with some network congestion.

Besides, based on SIPS analysis of work stealing, Stefano Mor in his thesis compared the influence of the choice of the stolen tasks on the number of steal operations, distinguishing unsuccessful and successful steals. While standard bounds are related to unsuccessful steals, they are pessimistic with respect to the number of successful steals that define intensive data communications.
6.5. Homomorphic coding for soft error resilience

We extended our results for fault-tolerant modular computations in two directions. To improve the correction rate of Reed-Solomon codes, power-decoding techniques consist in augmenting the number of syndrome equations by raising the received word to successive powers. The correction is done by a generalization of Berlekamp-Massey algorithm acting on multiple sequences. This method is, if not equivalent, at least very close to the list-decoding proposed by Sudan in its first version, in particular, error correction rates are identical. We improve the power-decoding method by reformulation into a vector rational function reconstruction, with benefit from fast polynomial matrix arithmetic. Besides, for basic exact linear algebra computations (eg dense linear system), we designed interactive protocols between a trusted platform and a non trusted one for resilience to soft-errors.

6.6. Chimeric algorithms design

To reach provable multicriteria performance, we used the coupling of various algorithms that adapt in several contexts: recursive cascading of both sequential and parallel algorithms with work-stealing; coupling specific algorithms on heterogeneous platforms (eg CPU/GPU); interactive distributed computations; fault-tolerant computations by coupling both a trustfully platform with low computation bandwidth and and an unreliable computing platform with high bandwidth. A unification work is currently developed for the design of a chimeric algorithms that is composed of the parts of multiple algorithms, interactively cascaded to achieve provable multicriteria performance.
MODAL Team

6. New Results

6.1. Intermediate dependency generative models

Participants: Christophe Biernacki, Matthieu Marbac-Lourdelle, Vincent Vandewalle.

Defining generative models for dealing with possibly correlated categorical variables is at the core of the MODAL activity. We start by noticing that it is straightforward to build a full independent distribution \( \hat{p} \) and also a full dependent one \( \hat{p} \) in the categorical situation. However, both are usually too crude for modeling most of real situations.

Our idea is to combine both extreme distributions \( \hat{p} \) and \( \hat{p} \) in order to obtain a new distribution called \( \tilde{p}^{(i)} \) which is an intermediate dependent situation between full independence and full dependence and \( (ii) \) which is not degenerate. As a consequence, \( \tilde{p} \) is a meaningful distribution because its particular “positioning” between \( \hat{p} \) and \( \hat{p} \) directly models and reveals strength of dependency between variables.

In addition, since both \( \hat{p} \) and \( \hat{p} \) are easily available for most variables types, we expect to be able to design a distribution \( \tilde{p} \) for most variables types, and not also the categorical ones.

A PhD thesis started on October’11 on this topic in continuation of the Master’s thesis of Matthieu Marbac-Lourdelle [37].

6.2. Transfer learning in model-based clustering

Participants: Christophe Biernacki, Alexandre Lourme.

In many situations one needs to cluster several datasets, possibly arising from different populations, instead of a single one, into partitions with identical meaning and described by similar features. Such situations involve commonly two kinds of standard clustering processes. The samples are clustered traditionally either as if all units arose from the same distribution, or on the contrary as if the samples came from distinct and unrelated populations. But a third situation should be considered: As the datasets share statistical units of same nature and as they are described by features of same meaning, there may exist some link between the samples.

We propose a linear stochastic link between the samples, what can be justified from some simple but realistic assumptions, both in the Gaussian and in the \( t \) mixture model-based clustering context ([15] and a paper in revision). In the general context (categorical or heterogeneous variables), we propose to use alternatively an entropic link between populations [17]. All these works are related to the Lourme’s PhD thesis [11].

A chapter of book about transfer learning (including clustering, classification and regression) is currently submitted for publication (joint work with Julien Jacques and Alexandre Lourme).

6.3. Block regression for variable clustering: Application to genetic data

Participants: Christophe Biernacki, Julien Jacques, Loïc Yengo.

Genome Wide Association (GWA) studies have proved the implication of numerous single nucleotides polymorphisms (SNP) in the etiology of common diseases. Nevertheless, only a small part of the expected heritability of those diseases is explained by the most significantly associated SNPs. Many researches that have been lately investigating this missing heritability have considered interactions between genes and/or environmental factors as a plausible and promising explanation. Considering all if not a large number (hundreds of thousands) of variants altogether stresses the problem of the high dimensionality that most regression-based methods cannot afford. To solve this issue one either reduces the number of variants to be analyzed (shrinkage approaches) or groups them according to a certain similarity. We introduce here a regression model that simultaneously clusterizes the variants sharing close effect size while selecting the most informative clusters. The estimation of the model parameters is proposed by maximizing the likelihood. The challenges of this research rely on finding efficient algorithms for the clustering part while studying the consistency of our estimators for which the classical asymptotic theory does not apply [33], [40].
6.4. Label switching in mixtures

**Participants:** Christophe Biernacki, Vincent Vandewalle.

During the last fifteen years there has been an increasing interest for using Bayesian methods in mixtures models. However, one of the principal issues of these methods is the non-identifiability of components caused by symmetric prior (whatever be the kind of variables), which makes the Gibbs outputs useless for inference; this problem is known as label switching. We propose to condition the posterior distribution by a particular numbering, not on the parameter as it is usually done, but rather on a latent partition, for which the posterior distributions are not any more strictly invariant up to a renumbering of the partition [26], [19], [32]. The importance of this asymmetry depends on the choice of partition space cutting. The challenge we address is to choose a particular cutting which is justified and also easy to compute. The idea is to use some properties of the (unavailable) completed posterior distribution.

6.5. Degeneracy in Gaussian mixtures

**Participant:** Christophe Biernacki.

In the case of Gaussian mixtures, unbounded likelihood is an important theoretical and practical problem. Using the weak information that the latent sample size of each component has to be greater than the space dimension, we derive a simple non-asymptotic stochastic lower bound on variances. We prove also that maximizing the likelihood under this data-driven constraint leads to consistent estimates. Currently, such results are proved in the univariate case [34]. The challenge is now not only to extend them in the multivariate situation but also to complete these theoretical results with some practical strategies for properly avoiding degeneracy in softwares devoted to such mixture estimations.

This is a joined work with Gwënaëlle Castellan.

6.6. Wavelet based clustering using mixed effects functional models

**Participant:** Guillemette Marot.

Curve clustering in the presence of inter-individual variability has longly been studied, especially using splines to account for functional random effects. However splines are not appropriate when dealing with high-dimensional data and can not be used to model irregular curves such as peak-like data. We propose a wavelet based clustering procedure [23] and apply it to high dimensional data. We suggest a dimension reduction step based on wavelet thresholding adapted to multiple curves and using an appropriate structure for the random effect variance, we ensure that both fixed and random effects lie in the same functional space even when dealing with irregular functions that belong to Besov spaces. In the wavelet domain our model resumes to a linear mixed-effects model that can be used for a model-based clustering algorithm and for which we develop an EM algorithm for maximum likelihood estimation. An R package curvclust implementing this procedure is under building and should be posted to the CRAN, the official website of the R software, before Dec. 2011. An article has been submitted once to Biometrics and received good reports. This paper should also be submitted again to Biometrics once curvclust is on the CRAN.

6.7. Comparison of normalisation procedures in RNA-sequencing before differential analysis

**Participant:** Guillemette Marot.

The continuing technical improvements and decreasing cost of next-generation sequencing technologies have made RNA sequencing (RNA-seq) a popular choice for gene expression studies in recent years. Because the data collected from such studies differ considerably from those measured using microarray technology, the statistical tools used for analysis must be adapted accordingly. In particular, several methods for the normalization of RNAseq data (removal of errors due to the small number of samples, corrections for sequence composition) have been proposed in recent years. With the Statomique Consortium, we have compared seven normalisation methods. First results are given in [28].
6.8. Comparison of peak finding methods applied to tiling array experiments

**Participant:** Guillemette Marot.

Scan statistics are widely used to detect peaks in tiling array experiments. An extensive analysis study of real biological data is being performed with Florent Sebbane and David Hot teams (Institut Pasteur, Lille) for the study of the Yersinia Pestis bacteria in order to find new small RNAs. First results have been presented in [31]. Given a signal composed of intensities ordered along the genome, the statistical problem is to detect peaks, taking into account the irregular design of the chips, which the biologists had chosen a few years ago. A master student (D. Thuillier) has compared different normalisation methods during a 6 months internship and improved the first analysis results presented in [31]. We also propose a local score procedure, which seems promising according to first biological results obtained. The next step is to work with Alain Célisse in order to choose a generative model on the normalised data which would enable to give appropriate initial values to the local score procedure and associate p-values to local scores.

6.9. Model-based clustering for functional data

**Participants:** Julien Jacques, Cristian Preda.

Two procedures for clustering functional data have been developed.

The first one, published in [14], is based on a functional latent mixture model which fits the functional data in group-specific functional subspaces. By constraining model parameters within and between groups, a family of parsimonious models is exhibited which allows to fit onto various situations. An estimation procedure based on the EM algorithm is proposed for estimating both the model parameters and the group-specific functional subspaces. Experiments on real-world datasets show that the proposed approach performs better or similarly than classical clustering methods while providing useful interpretations of the groups.

The second procedure, currently submitted, is a model-based clustering procedure, defined on the basis of an approximation of the density of functional random variables [36]. As previously, the EM algorithm is used for parameter estimation and the maximum a posteriori rule provides the clusters. Simulation study and real data application illustrate the interest of this methodology.

6.10. Generative models and random graphs

**Participant:** Alain Célisse.

The aim is to study consistency of variational and maximum likelihood estimates built from a particular generative model of random graph where independence between the ridges of the graph is not assumed. These results are established from concentration inequalities. They have a great practical interest since they justify a posteriori intensive use of variational methods in this context.

It is a joint collaboration with Jean-Jacques Daudin and a paper is submitted [35].

6.11. Resampling and learning

**Participant:** Alain Célisse.

This aim is to study the k nearest neighbors algorithm in binary classification in two different cases: Passive and active learning. The choice of k is addressed by cross-validation (resampling). In particular, we try to discover the influence of the cutting parameter on which depends the cross-validation with the retained k value.

It is a joined work with Tristan Mary-Huard [16].
6. New Results

6.1. Theoretical results

6.1.1. Theory of competition for one limited resource

Participants: Claude Lobry, Tewfik Sari, Radhouene Fekih-Salem.

In the paper [24], we give a global asymptotic stability result for a mathematical model of competition between several species in a chemostat, by using a new Lyapunov function. The model includes both monotone and non-monotone response functions, distinct removal rates for the species and variable yields, depending on the concentration of substrate.

In the paper [14], we consider the mathematical model of two species microbial competition on a single food resource in a chemostat, when one takes into account species interactions between the two populations of microorganisms and intraspecific interactions between individuals themselves, using strictly monotonic growth functions and distinct dilution rates.

6.1.2. Study of input/output maps of interconnected chemostats

Participants: Alain Rapaport, Ihab Haidar.

Patch or island models are popular in ecology, and are a convenient way to study the influence of a spatial structure of a geography on the distribution of the abundance of resources. Coupling such a structure with abiotic/biotic models and studying its input-output properties has been very rarely tackled in the literature. In biotechnology engineering, dead-zones models, that distinguish two sub-domains (a “living” and a “dead” one) are often used for approximating non perfectly mixed tanks. No more sophisticated representation, apart continuous space models (systems of partial differential equations), have been investigated.

We consider an hydric capacity and an nutrient flow that are fixed, and analyze the influence of different structures, having the same total hydric volume, on the output concentrations at steady-state. Three configurations are compared, under the assumption of a monotonic growth rate: perfectly-mixed, serial and parallel with diffusion rate. In each case, we show the uniqueness of a steady-state different to the washout equilibrium and its global asymptotic stability in the positive orthant. We prove the existence of a threshold on the input concentration of nutrient for which the benefits of the serial and parallel configurations over the perfectly-mixed one are reversed. In addition, we show that the dependency of the output concentrations on the diffusion rate can be non-monotonic, and give precise conditions for the diffusion effect to be advantageous [19], [33]. The study encompasses the dead-zone models.

The possibly non-monotonic influence of the diffusion parameter on the output steady state is not intuitive, and leaves further investigations open for understanding or taking benefit of this property for natural ecosystems (such as saturated soils or wetlands) as well as for bioprocesses (such as wastewater treatments). This result can be also of interest for reverse engineering when deciding which among serial or parallel configurations is a better fit for the modelling of chemostat-like ecosystems, providing that one has an estimation of the hydric capacity of the system.

This work is part of the material thesis of I. Haidar [11].

6.1.3. Aggregation models in the chemostat

Participants: Claude Lobry, Alain Rapaport, Jérôme Harmand, Tewfik Sari, Radhouene Fekih-Salem.
Bacteria aggregation often occurs in bioprocesses, creating flocks or biofilms (the latter being attached to the tank walls). At a macroscopic level with large populations of aggregated and non-aggregated individuals, a simple way of modelling this phenomenon in the chemostat is to distinguish explicitly two populations: planktonic or free bacteria and attached ones. The main differences between flocks and biofilms rely in the attachment/detachment terms and the effective dilution rate (assumed to be zero or very small for biofilms). Typically, the specific growth rate of free bacteria is expected to be larger than the attached one (that have in average a restricted access to nutrient and use part of their energy to glue together).

Based on former works of the team and the main assumption that attachment and detachment dynamics are much faster than the biological one, we have shown that a significant difference between the specific dilution rates of the free and attached populations can surprisingly lead to bi-stability, even for a single species and monotonic growth rates [30], [42], [43].

A work in progress addresses the case of two species, one of them having a non-monotonic growth rate (due to substrate inhibition) and the ability to form flocks. Without flock, the Competitive Exclusion Principle extended by G. Wolkowicz and her co-authors [47] shows the possibility to have one of the two species winning the competition depending on their initial repartition. Here, the presence of flocks may lead on the contrary to a single winner.

6.1.4. Neutral community models for microbial ecology

Participant: Bart Haegeman.

Hubbell’s neutral model [50] describes the dynamics of an ecological community in terms of random birth, death, immigration and speciation events, attributing equivalent characteristics to all species. Despite the absurd simplicity of these assumptions, remarkable agreement between neutral model predictions (e.g., the distribution of the abundance of the species present in the community) and empirical observations has been reported for some, mostly rather diverse, ecological communities.

There is some evidence that also certain aspects of microbial communities can be well described by the neutral model. Highly diverse microbial communities have been difficult to deal with using more traditional modelling approaches from community ecology. The neutrality assumption could lead to an effective global description, without requiring quantitative species data (growth characteristics, interaction strengths, etc). We are actively participating in the development of neutral community models, with a focus on microbial systems.

(1) Effect of speciation process

It has been argued that the neutral model predictions are rather insensitive to its assumptions. However, we have found that the details of the way new species appear in the community (i.e., the speciation process) do matter, and can drastically change the model predictions. In particular, we have studied the neutral community model with random fission speciation. This speciation model is quite different from the point mutation model usually considered in neutral community model, and is generally believed to be more realistic.

Using a technique from theoretical physics, we have obtained the stationary distribution of species abundances for the random fission model. We have compared our solution with the well-known stationary distribution of species abundances for the point mutation model on empirical data (tree communities in tropical forests) [13]. Surprisingly, we found that the point mutation model fits the data better than the random fission model, although the latter is believed to be more realistic.

(2) Comparison with niche models

Neutral community models challenge more traditional, niche-based models in community ecology. Niche theory states that species can coexist only if they differ sufficiently in their characteristics (for example, their use of available substrates). Neutral theory assumes that all species have approximately equal characteristics. Hence, the two theories describe species coexistence in fundamentally different ways.

We have tried to narrow the gap between the two theories. We have proposed a mathematical model that combines essential features of niche-based and neutral community models [17]. It integrates species niches, described as Lotka-Volterra interactions, in the standard neutral community model. The analysis of this model
indicates that the addition of species interactions has a limited effect on the species abundance distribution. We have further clarified this result using a slightly different model that also combines niche and neutral features [16]. For the latter model we have proved that the niche structure does not affect at all the species abundance distribution.

6.1.5. Quantifying genetic diversity of bacteria

Participant: Bart Haegeman.

With the wide availability of DNA sequencing, microbiologists are now able to rapidly sequence entire bacterial genomes. Comparison of these genomes has revealed a large genetic diversity within bacterial species. For example, one genome of the bacterium *E. coli* has about 4000 different genes, but a set of 10 genomes of *E. coli* has typically over 10000 different genes. Some of these genes are shared by all or almost all of the genomes, but many other genes are only present in one or a few of the genomes. This observation has important implications for the definition of bacterial species and for the description of the functional characteristics of bacteria.

We have been dealing with the problem of how to quantify this observed genetic diversity. Microbiologists have introduced notions like the pan genome of a bacterial species (that is, the set of genes that are present in at least one of the organisms from the species) and the core genome of a bacterial species (that is, the set of genes that are present in every organisms from the species). However, we have argued that both the pan and core genome are difficult to estimate, and should not be used for quantitative purposes [21]. Instead, we have proposed a measure of genetic diversity that has much better estimation properties. It is based on the average number of genes shared by a pair of genomes when sequencing two randomly sampled organisms from the species under consideration. We have applied our estimator on six bacterial species (about 100 sequenced genomes in total). Software for our robust estimation procedure of genetic diversity is freely available, see http://ecotheory.biology.gatech.edu/downloads/genomic-fluidity-scripts.

6.1.6. Individual-based modelling

Participants: Fabien Campillo, Chloé Deygout, Coralie Fritsch, Marc Joannides, Claude Lobry.

In terms of computational modelling of ecosystems, individual-based models (IBMs) are an interesting path to explore. We can outline two types of IBMs. On the one hand “detailed IBM” attempt to integrate in an ad-hoc way all the knowledge available about an ecosystem. On the other hand, “simplified IBM” are limited to one or several mechanisms to simplify the analysis. The former may be more realistic but are often difficult to analyze. Although the latter are too simplistic in realistic situations they lend themselves to the analysis and numerical analysis. We focus on the latter.

The IBMs offer an interdisciplinary language between biologists, biotechnologists, mathematicians, and computer scientists, to develop models in the form of relatively simple rules. In the case of simplified IBMs it is possible to translate these rules in the form of a branching Markov process with values in a space of measures. Using scaling methods, the IBMs can be approximated by integro-differential equations; using model simplification methods IBMs can be reduced to stochastic or ordinary differential equations. The mathematical interpretation of the IBMs and their analysis is relatively recent and still very few studies exist [48]. The numerical analysis of these models is yet to be built. Under certain conditions, IBMs themselves can be simulated through adapted Monte Carlo procedures.

The MODEMIC project-team develops three studies in the field of IBMs. The first is part of the ANR MODECOL on the modelling of clonal plant growth (see Section 7.5); the second is part of the ANR DISCO on modelling of biofilms (see Section 7.4); the last one is a starting thesis.

In all cases, we aim at developing the Monte Carlo simulation of the IBM as well as analyzing their links with integro-differential models. We also seek to make connections with non-IBM models proposed in Section 6.1.8.
In October 2011, Coralie Fritsch started a thesis at the École Doctorale I2E of the University of Montpellier 2, under the supervision of Fabien Campillo, Jérôme Harmand and Marc Joannides. This thesis is supported by a grant of the MESR and a grant of INRA from the MEM Meta-program (Méta-omiques des écosystèmes microbiens). The thesis aims at developing and analyzing individual-based microbial ecosystems models that capture both the spatial, biodiversity and function of these ecosystems. The thesis received the Agreenium label in December.

### 6.1.7. Hybrid modelling of biofilms in plug-flow reactors

**Participants:** Fabien Campillo, Chloé Deygout, Annick Lesne, Alain Rapaport.

Within the DISCO project of the SYSCOMM program founded by the ANR, we have proposed a multi-scaled modelling that combines three scales: a microscopic one for the individual bacteria, a mesoscopic or “coarse-grained” one that homogenises at an intermediate scale the quantities relevant to the attachment/detachment process, and a macroscopic one in terms of substrate concentration (see the Section 7.4).

Such an “hybrid” approach allows for modelling and understanding in plug-flow reactors [41] the interplay between

- the formation of the biofilm at a microscopic scale, that starts from a small number of bacteria (thus a stochastic individual based description),
- the limitation of the biofilm, due the carrying capacity of the wall attachment, at a mesoscopic scale,
- the consumption of nutrient along the flow at a macroscopic level, as a solution of a coupled transport-reaction partial differential equation.

The numerical computation of such a model requires a software architecture that allows the simultaneous simulation of stochastic events at the bacteria scale and the continuous evolution (in space an time) of the substrate density.

Experiments on real tubular plug-flow reactors are currently driven at Cemagref HBAN with the perspective of comparison with numerical simulations. After spending one year at Montpellier for deriving and simulating the theoretical model, our post-doctoral fellow C. Deygout is presently participating to the real experiments at Cemagref Antony.

The multi-species case with different bacteria specialized in different environments (poor or rich in nutrient) is a work in progress.

### 6.1.8. Stochastic modelling for biotechnology

**Participants:** Fabien Campillo, Marc Joannides, Claude Lobry.

This year we continue to study stochastic models for the chemostat [12], [39], [27]. Starting from the well-known ordinary differential equation systems, we propose first a pure jump process model at the microscopic scale that leads to a stochastic differential equation at the intermediate scale and to an ordinary differential equation at the macroscopic level (fluid limit model). After developing the model, we establish the Fokker-Planck partial differential equation for the diffusion model. This PDE integrates a specific washing-out term.

We proposed an ad hoc numerical integration scheme for the simulation of this PDE [39].

In [40], we consider a stochastic version of the basic predator-prey differential equation model. The model, which contains a parameter $\omega$ which represents the number of individuals for one unit of prey – if $x$ denotes the quantity of prey in the differential equation model $x = 1$ means that there are $\omega$ individuals in the discontinuous one – is derived from the classical birth and death process. It is shown by the mean of simulations and explained by a mathematical analysis based on results in singular perturbation theory (the so called theory of Canards) that qualitative properties of the model like persistence or extinction are dramatically sensitive to $\omega$. For instance, in our example, if $\omega = 10^7$ we have extinction and if $\omega = 10^8$ we have persistence. This means that we must be very cautious when we use continuous variables in place of jump processes in dynamic population modelling even when we use stochastic differential equations in place of deterministic ones.
6.1.9. Minimal time control of batch bioprocesses  
**Participants:** Denis Dochain, Alain Rapaport.

Minimal time control problems often occur in biotechnology when one has to fill tanks. Typically, the objective to be reached is to have the tank full with a prescribed value of substrate or product concentrations, the tank being filled with a high concentration of nutrient.

When a single reaction occurs, the optimal solution is already known and has been rigorously proved by J. Moreno in 1999 [51] using the Green’s theorem: it consists in a “bang-bang” strategy (fill as fast as possible or do not fill) and possibly a singular arc when the growth function presents an inhibition (i.e. a maximum growth for a precise concentration of nutrient). When impulse controls in addition to regular control are allowed, an extension of this result has been recently proposed with a different technique that do not use the Green’s theorem [4]. This technique has also allowed to solve partially the problems when several species compete for the degradation of the substrate, but when all of them have a monotonic growth.

In the presence of complex non monotonic kinetics, typically characterized by the combination of two non-monotonic growth functions, aimed at emphasizing the presence of two parallel metabolic pathways to transform the limiting substrate into the biomass, the candidate singular arcs are multiple and determining which singular arc is eventually optimal is clearly a crucial issue. The local optimality conditions based on the Pontryagin Maximum Principle allow to characterize the geometric structure of the extremal trajectories, in which there may be singular arcs, but these necessary conditions are not always sufficient for determining which extremals are (globally) optimal. Then one has to compute the cost of each extremal or use global optimization methods such as dynamic programming or Hamilton-Jacobi-Bellman equation. The extremals are traditionally determined numerically by considering shooting methods, but for bang-bang control, it is well known that one may face numerical troubles because the shooting function is in general not smooth. For this problem, we have used an approximation technique first proposed and studied by C. Lobry and his students [53] and later by C. Silva and E. Trélat [52], that consist in adding an artificial control. In [22], we have proposed a new proof of convergence based on differential inclusions arguments that allows to relax the assumption of the uniqueness of the optimal solution for the convergence of the optimal paths of [52]. Then we have shown how to apply numerically this approximation procedure for analyzing the field of extremals on the whole state space. This technique appears to be quite effective for the practical determination of optimal synthesis in the planar case even in presence of multiple singular arcs.

6.1.10. Optimal control of continuous bioprocesses  
**Participants:** Jérôme Harmand, Alain Rapaport, José Fernandez, Walid Bouhafs, Amel Ghouali.

In continuous bioprocesses, a usual objective is to stabilize the output of the bioreactors about a desired steady state (in wastewater industry, this value is typically chosen under the norm of authorized discharge). It happens more and more frequently that transient trajectories are expected also to maximize a product of interest.

We have begun to study the maximization of the gaseous production of methane in anaerobic processes over a given period of time on specific problems. For the moment we have proved that the optimal trajectory consists in approaching a unique singular arc as fast as possible when only one limiting substrate has to be converted, but the problem is still open when involving several substrates. These works are part of the PhD work of A. Ghouali and W. Bouhafs.

Reference points in batch processes can be mimicked by a series of continuously stirred bioreactors in series at steady state (see applications 6.2.2 and 7.2). We study the minimal time problem to drive the nutrients concentrations of a cascade of chemostats. The control variable is the dilution rates of each tank, under the constraint that each dilution rate is bounded by the one of the previous tank, that makes the system not locally controllable. For the particular case of two tanks with total mass at steady state, the planar feedback synthesis has been found but the problem is still under investigation for the general case.

6.1.11. Minimal time bioremediation of natural resources  
**Participants:** Jérôme Harmand, Alain Rapaport, Antoine Rousseau.
In biological wastewater treatment (batch or continuous bioprocesses), one has always to separate biomass from the purified liquid phase at the output of the tanks, that is not possible when tanks are rather natural reservoirs such as lakes or water tables.

We have proposed a new operation strategy that consists in treating with the help of a bioreactor aside. No bacteria are introduced in the reservoir but water is pumped and treated by microorganisms in a smaller tank, and treated water returns to the reservoir after being separated from the biomass. Consequently, there is no need of a separation operation for the reservoir.

The minimal time control problem consists in controlling the flow rate for having the substrate concentration of the whole reservoir below a given reference value as fast as possible.

Last year, we have determined analytical expressions of optimal feedback strategies for a general class of growth functions under the assumptions that the volume of the bioreactor is much smaller than the reservoir one, and that the spatial repartition of the concentration of the pollutant in the reservoir can be modelled by simple spatial representations: either perfectly mixed or discrete one directional gradient \cite{44}, \cite{15}. This year, we have studied more realistic spatial motifs:

- dead-zones: we have shown that the optimal synthesis is identical to the perfectly mixed case, even though the time to reach the target is larger \cite{31}.
- two parallel zones, allowing to control the repartition of the flow rate between the two zones. Without diffusion between the zones, the optimal solution is almost straightforward and under investigation in presence of lateral diffusion.

This work is mainly achieved in cooperation with Chilean researchers and PhD students within the associated team DYMECOS.

### 6.2. Applications

#### 6.2.1. Modelling and control of Anaerobic Digestion processes

**Participants:** Amine Charfi, Radhouene Fekih-Salem, Jérôme Harmand, Boumediene Benyahia, Tewfik Sari.

We consider the AM2 or AMOCO model developed in \cite{46} and extend both the model in itself and its analysis to the following cases:

- Depending on the AM2 model parameters, the steady states were analytically characterized and their stability were analyzed. Following this study, it was shown that the overloading tolerance, a parameter proposed in \cite{49} to on-line monitoring anaerobic processes, may be not adapted under certain operating conditions and even lead to bad operating decisions.
- Within the framework of the PhD theses of Amine Charfi and Boumediene Benyahia, we have included the fouling dynamics of membranes into the AM2 and we have analyzed the resulting model (called the AM2b).
- We actually work towards two directions: (i) we are extending these results in including into the AM2 an additional process, i.e. the hydrolysis step in order to study bioprocesses treating solid waste (the resulting model being called the AM3); (ii) we try to find links between complex models such as the ADM1 model and simple models such as the AM2b or the AM3.

#### 6.2.2. Modelling and control of cascade biosystems to mimic batch wine making processes

**Participants:** Jérôme Harmand, Alain Rapaport, José Fernandez.
An experimental setup of four tanks connected in series has been designed by the research unit SPO (Montpellier) for studying four physiological stages of yeast as steady state. The manipulated variables are the flow rates $Q_i$ of each tank with the constraint $Q_i \geq Q_{i-1} \geq 0$, and the objective is to reach simultaneously four set-points in the four tanks. We are studying two kinds of control strategies:

- a linearizing feedback law that drives exponentially the dynamics to the target. This is not the fastest strategy but is has good robustness properties. Nevertheless, the inputs constraint imposes to use saturation functions that provide satisfactory convergence in simulations but that is hard to prove mathematically.
- a minimal time feedback. Due to lack of local controllability imposed by the constraint on the inputs, the optimal synthesis is not smooth with the presence of “barriers” (see Section 6.1.10).

Those feedback laws will be implemented and tested on real pilot plant at SPO lab in the scope of the European project CAFE described in Section 7.2.

### 6.2.3. Modelling and simulating terrestrial plant ecological dynamics

**Participants:** Fabien Campillo, Ihab Haidar.

This study is part of the ANR Syscomm MODECOL that is done in collaboration particularly with the University of Rennes I, the University of La Rochelle and INRIA. This is the second year of the three years program. We propose a stochastic individual-based model for clonal plant dynamics in continuous time and space, focusing on the effects of the network structure of the plants on the reproductive strategy of ramets. This model is coupled with an explicit advection-diffusion dynamics for resources. We develop a partially exact simulation scheme of the model; the capacity of the model to reproduce specific features of clonal plants, such as their efficiency to forage resources over the field, is numerically studied. Next, we propose a large population approximation of the model for phalanx-type populations, taking the form of an advection-diffusion PDE for population densities, where the influence of the local graph structure of the plant takes the form of a nonlinear dependence in the gradient of resources. This year we improved the simulation code that was proposed last year and made three communications in international conferences [26] [36] [35].

### 6.2.4. Modelling and inferring agricultural dynamics

**Participants:** Fabien Campillo, Angelo Raherinirina.

The International Laboratory LIRMA supports this work that is done in collaboration with the University of Fianarantsoa in Madagascar and with Dominique Hervé (IRD, Fianarantsoa, Madagascar). The aim is to study the dynamics of agricultural plots on the edge of primary forest. In [38] we propose a Markov chain model where the transition matrix is estimated both by maximum likelihood and Bayesian approaches. We also test if the Markov chain model is adapted to this problem. In an ongoing work we develop semi-Markov models for an extended data set.

### 6.2.5. Modelling and simulating microbial ecosystems in soils

**Participants:** Ihab Haidar, Jérôme Harmand, Alain Rapaport.

The team studies simple representations of the spatial inhomogeneity for bioprocesses, in terms of networks of interconnected compartments. Each compartment is modelled as a perfectly mixed bioreactor. Simulation of such networks is performed with the software developed by the VITELBIO project (see 5.1). Comparisons of simple structures (cascade of bioreactors) with numerical simulators based on REV (Representative Elementary Volumes) have been performed. The objective is to understand the role of the topology of the network on the biological functions of the overall system. For the moment simple configurations with two to four nodes and one single species have been investigated.

In addition, we study in simulation how software implementations of transport reactions models such as MIN3P, can mimic such simple configurations. Transport reactions models are often used in the community of soil functioning modelling by simulation. Here we compare their numerical computation with the exact solutions that can be approximated with a good accuracy using classical o.d.e. solvers. We found that one has to be careful when the trajectories are close to a non-hyperbolic equilibrium [45], [18].
6.2.6. Numerical optimisation in non perfectly mixed tanks

Participants: Jérôme Harmand, Alain Rapaport, Antoine Rousseau.

The optimisation of series of bioreactors in terms of minimizing the total residence time have been already investigated in the literature. In such models, the space has a one-dimensional representation. There is comparatively much less work on 2D or 3D space models. We consider different shapes of reactors of the same volume, and simulate with the help of multi-physics numerical software the coupling of the hydrodynamics laws in 3D or 2D (under cylindrical symmetry), solved numerically by the Navier-Stokes equations, with the system of differential equations of biotic/abiotic concentrations [ 34 ].

We are studying the influence of the shape of the domain and possible obstacles on the output concentration at steady state.

With A. Rousseau (EPI MOISE, INRIA Rhône-Alpes) we study with simulation of 2D Navier-Stokes equations the benefits of having several pumping points and how to control the pumps speed to minimize the treatment duration for the bioremediation of natural reservoirs presented in Section 6.1.11. We evaluate the feedback strategies that are derived to be optimal for simple models of o.d.e. in the more realistic framework of hydrodynamics simulation.

6.2.7. Individual-based models for the bacterial degradation of the cellulose

Participants: Fabien Campillo, Chloé Deygout, Marc Joannides.

We propose an individual-based model for the degradation of one cellulose bead (dozens of micrometers in diameter) by cellulolytic bacteria. Our aim is to determine the macroscopic degradation behavior. The initial stages of the degradation process may involve a very limited number of bacteria that cannot be properly modelled by classical models based on deterministic equations. In the present work we only consider a two-dimensional model for the degradation of a cellulose disc.

6.2.8. Non-linear filtering for the chemostat

Participants: Boumediene Benyahia, Fabien Campillo, Jérôme Harmand.

We propose numerical non-linear filtering approaches for the identification of non-observed components of dynamical systems in the context of the chemostat. This recently started study relies on the work of the project-team in the stochastic modelling of the chemostat. In a preliminary work we consider the bootstrap particle filter.
6. New Results

6.1. Mathematical Modelling of the Ocean Dynamics

6.1.1. Beyond the traditional approximation on the Coriolis force

Participant: Antoine Rousseau.

Formerly, A. Rousseau has performed some theoretical and numerical studies around the derivation of quasi-hydrostatic models. With C. Lucas, he proved that it is sometimes necessary to take into account the cosine part of the Coriolis force (which is usually neglected, leading to the so-called Traditional Approximation). They have also shown that the non-traditional terms do not raise any additional mathematical difficulty in the primitive equations: well-posedness for both weak and strong solutions.

In 2011, A. Rousseau and J. McWilliams (UCLA) proposed in [62] a mathematical justification of the tilt of convective plumes in the quasi-geostrophic regime, thanks to the account of the complete Coriolis force in the so-called quasi-hydrostatic quasi-geostrophic (QHQG) model. The new model has been presented in several international conferences [26], [49].

6.1.2. Coupling Methods for Oceanic and Atmospheric Models

Participants: Eric Blayo, David Cherel, Laurent Debreu, Antoine Rousseau, Manel Tayachi.

6.1.2.1. Interface conditions for coupling ocean models

Many physical situations require coupling two models with not only different resolutions, but also different physics. Such a coupling can be studied within the framework of global-in-time Schwarz methods. However, the efficiency of these iterative algorithms is strongly dependent on interface conditions. As a first step towards coupling a regional scale primitive equations ocean model with a local Navier-Stokes model, a study on the derivation of interface conditions for 2-D $x - z$ Navier-Stokes equations is currently underway (D. Cherel’s PhD thesis). It has been shown theoretically that several usual conditions lead to divergent algorithms, and that a convergent algorithm is obtained when using transmission conditions given by a variational calculation. Moreover the impact of two numerical schemes (a projection method, and a direct method [67]) on the implementation of the domain decomposition method has been discussed.

Using the direct method in a 2D $x - z$ Navier-Stokes model, D. Cherel has implemented a Schwarz-based domain decomposition method, for which he used the so-called transmission boundary conditions that mix the velocity and pressure variables on an Arakawa-C grid. The numerical results confirm the rate of convergence that has been obtained theoretically, thanks to a Fourier analysis of the semi-discretized problem. A paper is in preparation.

6.1.2.2. Coupling dimensionally heterogeneous models

The coupling of different types of models is gaining more and more attention recently. This is due, in particular, to the needs of more global models encompassing different disciplines (e.g. multi-physics) and different approaches (e.g. multi-scale, nesting). Also, the possibility to assemble different modeling units inside a friendly modelling software platform is an attractive solution compared to developing more and more global complex models. More specifically one may want to couple 1D to 2D or 3D models, such as Shallow Water and Navier Stokes models: this is the framework of our partnership with EDF in the project MECSICO. In her PhD, M. Tayachi is aimed to build a theoretical and numerical framework to couple 1D, 2D and 3D models for river flows.

This year, she obtained both numerical and theoretical results on a Laplace equation in a domain that suggests a domain decomposition method with two sub-domains that do not have the same space dimension (see Figure 1). A paper is in preparation.
6.1.3. Numerical schemes for ocean modelling

Participants: Laurent Debreu, Jeremie Demange.

Reducing the traditional errors in terrain-following vertical coordinate ocean models (or sigma models) has been a focus of interest for the last two decades. The objective is to use this class of model in regional domains which include not only the continental shelf, but the slope and deep ocean as well. Two general types of error have been identified: 1) the pressure-gradient error and 2) spurious diapycnal diffusion associated with steepness of the vertical coordinate. In a recent paper [78], we have studied the problem of diapycnal mixing. The solution to this problem requires a specifically designed advection scheme. We propose and validate a new scheme, where diffusion is split from advection and is represented by a rotated biharmonic diffusion scheme with flow-dependent hyperdiffusivity satisfying the Peclet constraint.

In 2011, in collaboration with F. Lemarié at UCLA, this work has been extended in order to render the biharmonic diffusion operator scheme unconditionally stable (paper submitted to ocean modelling). This is particularly needed when the slopes between coordinates lines and isopycnals surfaces are important so that the rotation of the biharmonic leads to strong stability condition along the vertical coordinate where the grid size is relatively small. This work also extends more classical results on the stability of laplacian diffusion with mixed derivatives.

In his Ph’D, Jeremie Demange begins a work on advection-diffusion schemes for ocean models (Supervisors: L. Debreu, P. Marchesiello (IRD)). His work will focus on the link between tracers (temperature and salinity) and momentum advection and diffusion in the non hyperbolic system of equations typically used in ocean models (the so called primitive equations with hydrostatic and Boussinesq assumptions).

Salinity at 1000 m in the Southwest Pacific ocean is shown in figure 2. The use of traditional upwind biased schemes (middle) exhibits a strong drift in the salinity field in comparison with climatology (left). The introduction of high order diffusion rotated along geopotential surfaces prevents this drift while maintaining high resolution features (right).

6.2. Development of New Methods for Data Assimilation

6.2.1. Variational Data Assimilation with Control of Model Error

Participants: Bénédicte Lemieux-Dudon, Arthur Vidard.
One of the main limitations of the current operational variational data assimilation techniques is that they assume the model to be perfect mainly because of computing cost issues. Numerous researches have been carried out to reduce the cost of controlling model errors by controlling the correction term only in certain privileged directions or by controlling only the systematic and time correlated part of the error.

Both the above methods consider the model errors as a forcing term in the model equations. Trémolet (2006) describes another approach where the full state vector (4D field: 3D spatial + time) is controlled. Because of computing cost one cannot obviously control the model state at each time step. Therefore, the assimilation window is split into sub-windows, and only the initial conditions of each sub-window are controlled, the junctions between each sub-window being penalized. One interesting property is that, in this case, the computation of the gradients, for the different sub-windows, are independent and therefore can be done in parallel.

We are implementing this method in a realistic Oceanic framework using OPAVAR/ NEMOVAR as part of the VODA ANR project. An extensive documentation is being produced and should be available along with a first prototype early 2012.

6.2.2. Variational Data Assimilation and Control of the Boundary Conditions

Participant: Eugène Kazantsev.

A variational data assimilation technique applied to the identification of the optimal discretization of interpolation operators and derivatives in the nodes adjacent to the boundary of the domain is discussed in the context of the shallow water model. It was shown in [8] that control of approximation of boundary derivatives and interpolations can increase the model’s accuracy in boundary regions and improve the solution in general. On the other hand, optimal schemes obtained in this way may not approximate derivatives in a common sense. This may lead to another model physics, violating, for example, impermeability boundary condition.

Experiments with a full non-linear shallow water model in [7] show that controlling the discretization of operators near a rigid boundary can bring the model solution close to observations as in the assimilation window and beyond the window. This type of control allows also to improve climatic variability of the model. These properties have been studied in two different configurations: an academic case of assimilation of artificially generated observational data in a square box configuration and assimilation of real observations in a model of the Black sea [30].
The sensitivity of the shallow water model in the previously described configurations has been studied in detail in [9]. It is shown in both experiments that the boundary conditions near a rigid boundary influence the solution higher than the initial conditions. This fact points out the necessity to identify optimal boundary approximation during a model development.

In order to illustrate the influence of optimal discretization of operators near the boundary we compare this influence with now classical data assimilation for identification of the optimal initial conditions of the model. The norm of the difference between the model solution and real observational data is plotted in figure 3. Observed sea surface elevation of the Black sea was assimilated during 50 days (May–June 1992) to identify optimal initial and boundary conditions. After that, models have been integrated forward for 500 days and their solutions have been compared with data. One can see that, starting from optimal initial point, the model remains close to observations during less than 100 days while optimal optimal discretization of operators allows the model to be always closer than the model with default parameters.

Adjoint models, necessary to variational data assimilation have been produced by the TAPENADE software, developed by the TROPICS team.

6.2.3. A Nudging-Based Data Assimilation Method: the Back and Forth Nudging

Participants: Didier Auroux, Jacques Blum, Maëlle Nodet.

The Back and Forth Nudging (BFN) algorithm (see [63]) has been recently introduced for simplicity reasons, as it does not require any linearization, nor adjoint equation, or minimization process in comparison with variational schemes. Nevertheless it provides a new estimation of the initial condition at each iteration.

Previous theoretical results [65] showed that BFN was often ill-posed for viscous partial differential equations. To overcome this problem, we proposed a new version of the algorithm, which we called the Diffusive BFN [2], and which showed very promising results on one-dimensional viscous equations. Experiments on more sophisticated geophysical models, such as Shallow-Water equations and NEMO ocean model are still in progress, in collaboration with University of Nice.

6.2.4. Variational Data Assimilation for locally nested models.

Participants: Eric Blayo, Laurent Debreu, François-Xavier Le Dimet, Emilie Neveu.
The objectives are to study the mathematical formulation of variational data assimilation for locally nested models and to conduct numerical experiments for validation.

The state equations of the optimality system have been written for the general case of two embedded grids, for which several kinds of control (initial conditions, boundary conditions) have been proposed. Both one way and two way interactions have been studied. This last year, we worked on integration of non linear grid interactions in the algorithm. Additionally, the problem of specification of background error covariances matrices has been studied (see [85]).

In the ANR MSDAG project and Emilie Neveu’s PhD, we continue to work on the subject. Our main interest is on the use of multiscale optimization methods for data assimilation. The idea is to apply a multigrid algorithm to the solution of the optimization problem. The work includes the analysis of the ellipticity of the optimization problem [12], the comparison of different multigrid methods (Gauss-Newton multigrid method and Full Approximation Scheme) and specific developments for highly non linear problems. To extend previous work on Burgers equation, the Full Approximation Scheme (FAS) and the Newton Multigrid algorithm have been compared in a more complex shallow water model. The results shows good performance of the FAS and also put more interest in the design of the background error covariance matrix.

6.3. Data Assimilation for Ocean Models

6.3.1. Development of a Variational Data Assimilation System for OPA9/NEMO

We are heavily involved in the development of NEMOV AR (Variational assimilation for NEMO). From 2006, we built a working group (coordinated by A. Vidard) in order to bring together various NEMOV AR user-groups with diverse scientific interests (ranging from singular vector and sensitivity studies to specific issues in variational assimilation), and to get technical and scientific support from Inria Sophia (Automatic adjoint derivation, TROPICS project-team) and ECMWF (Parallelization). This project aimed at avoiding duplication of effort, and at developing a common NEMOV AR platform. It has led to the creation of the VODA (Variational Ocean Data Assimilation for multi scales applications) ANR project.

The project aims at delivering a common NEMOV AR platform based on NEMO platform for 3D and 4D variational assimilation. Following 2009-10 VODA activities, a fully parallel version of NEMOTAM (Tangent and Adjoint Model for NEMO) is now available for the community in the standard NEMO version. This version is based on the released 3.0 version of NEMO. Two upgrades were done to follow NEMO standard development race. As a consequence, NEMOV AR is also available for NEMO version 3.2, 3.2.1 and 3.2.2 both offer fully parallel features. The local group has developed a python interface engine (PIANO) to perform test and run on NEMO. A constant support to NEMOV AR project is ensured to deliver a focused response on dedicated issue (internal and external interaction).

We are also investigating variational data assimilation methods applied to high resolution ocean numerical models. This part of the project is now well advanced and encouraging preliminary results are available on an idealized numerical configuration of an oceanic basin (see Figure 4).

A new topic has been explored this year in the framework of VODA: data assimilation in a framework of nested models. It makes full use of the AGRIF capabilities of NEMO and follows previous work done on a toy model during the PhD thesis of E. Simon. Some early results are available with a global ocean 2 degrees configuration including a 1/2 degree zoom on the Agulhas region (see Figure 5).

As a side project we collaborate with Mercator-Ocean in order to use the adjoint to perform sensitivity analysis with the fourth of a degree global model used for the reanalysis. This collaboration that includes both heavy software developments and challenging scientific investigation, has been going on for 2 years now and is producing interesting results for both part that still need to be published.

Apart from the VODA ANR project, the NEMOV AR working group gets additional financial support by LEFE-Assimilation and the Mercator National Programs.

Figure 5. Temperature increment at 200m around the zoom on the Agulhas region
6.3.2. Variational data assimilation into highly nonlinear ocean models
Participants: Pierre-Antoine Bouttier, Eric Blayo, Jacques Verron.

The purpose of this study is to explore the behaviour of variational data assimilation methods in a non-linear ocean model. In an eddy-permitting or eddy-resolving ocean model, controlling mesoscale eddies activity is crucial for data assimilation methods. Our goal is to highlight the impact of these non-linearities on the assimilation system. To illustrate this, test experiments are performed with a double-gyre NEMO configuration at different resolutions (1/4°, 1/12°) which mimics Gulfstream-like behaviour in term of eddy system, and an incremental 4D-V AR formulation for the assimilation system.

First, we are mainly interested in observing the impact of the length of assimilation window on the quality of the analyzed trajectory. For that, we are doing twin experiments with 1/4° model, using simulated altimeter data, for different lengths of assimilation window. Helped by diagnoses on error scales, we also attempt to link the non-linear phenomena and error structures observed after assimilation quantitavely and qualitatively.

Then, by increasing the model resolution (and consequently mesoscale eddy activity), we bring to light the sensitivity of our assimilation system to non-linearity by repeating the same experiments on the length of assimilation window, and the same diagnoses about error structures.

6.3.3. Assimilation of Lagrangian Data
Participants: Claire Chauvin, Maelle Nodet, Arthur Vidard.

When an observation is given at a sequence of positions along the fluid flow, then it can be defined as Lagrangian, from a mathematical point of view. From this sequence of positions (for instance the profiling drifting floats of Argo program), one can deduce important information on the stream that transports the drifters. Such an information has not yet been exploited in an operational framework, although previous works [82] have shown the interest of assimilating this new type of data.

A task of the ANR VODA has thus been defined in order to develop the tools for the variational assimilation of Lagrangian data in the context of NEMOVAR. C. Chauvin is an engineer working on this task. She first constructed the observation operator, which requires the interpolation of the velocity at any point of the domain. This interpolation operator is not linear for the general grids used in NEMO, implying heavy tangent and adjoint operators.

Tangent and adjoint procedures associated to this interpolation method have been developed, as well as the tests of these procedures on the main test configurations GYRE and ORCA2. Their implementation in NEMOVAR has required a specific application, in order to be consistent with the conventions and data structures already present in NEMOVAR. We also performed extensive numerical experiments to assess the impact of Lagrangian data assimilation, and its complementarity with other types of data, and we prepare an article to sum up the results. Preliminary results have been presented at EGU [34].

6.4. Assimilation of Image Data
6.4.1. Direct assimilation of sequences of images

At the present time the observation of Earth from space is done by more than thirty satellites. These platforms provide two kinds of observational information:

- Eulerian information as radiance measurements: the radiative properties of the earth and its fluid envelops. These data can be plugged into numerical models by solving some inverse problems.
- Lagrangian information: the movement of fronts and vortices give information on the dynamics of the fluid. Presently this information is scarcely used in meteorology by following small cumulus clouds and using them as Lagrangian tracers, but the selection of these clouds must be done by hand and the altitude of the selected clouds must be known. This is done by using the temperature of the top of the cloud.
MOISE was the leader of the ANR ADDISA project dedicated to the assimilation of images, and is a member of its current follow-up GeoFluids (along with EPI FLUMINANCE and CLIME, and LMD, IFREMER and Météo-France).

During the ADDISA project we developed Direct Image Sequences Assimilation (DISA) and proposed a new scheme for the regularization of optical flow problems \cite{86}, \cite{90}. Thanks to the nonlinear brightness assumption, we proposed an algorithm to estimate the motion between two images, based on the minimization of a nonlinear cost function \cite{45}. We proved its efficiency and robustness on simulated and experimental geophysical flows \cite{64}. As part of GeoFluids, we are investigating new ways to define distance between a couple of images. One idea was to define this distance as the norm of the apparent motion between two images. This has been done thanks to optical flow methods which turned out to need a specific parametrization for each couple of images. Another idea, currently under investigation, consists in comparing mains structures within each image. This can be done using, for example, a wavelet representation of images. We are also part of TOMMI, another ANR project started mid 2011, where we are investigating the possibility to use optimal transportation based distances for images assimilation.

### 6.4.2. Assimilation of ocean images

**Participants:** Vincent Chabot, Maëlle Nodet, Nicolas Papadakis, Arthur Vidard.

In addition with the direct assimilation approach previously described, a particular attention has been given to the cloud occlusion and the representation of the observation errors in the context of ocean image data. Such works will be intensified with the post-doctorate Alexandros Makris that will start his activities in December. The assimilation of images (SST and chlorophyll) provided by geostationary satellites is also studied with the oceanographers of the Laboratoire des Écoulements Géophysiques et Industriels. The objective is here to take benefit from the correlation that exists between image gradients and ocean flow discontinuities that can be exhibited through the computation of Lyapunov coefficients and vectors from numerical ocean models \cite{70}.

### 6.5. Quantifying Uncertainty

#### 6.5.1. Propagation of uncertainties

**Participants:** François-Xavier Le Dimet, Victor Shutyaev.

Basically, geophysical models are suffering of two types of errors:

- errors in the model itself due to approximations of physical processes and their subgrid parametrization and also errors linked to the necessary numerical discretization;
- errors in the observation because of errors of measurements and also errors due to sampling. For instance, many remote sensings observe only radiances, which are transformed into the state variables thanks to complex processes like the resolution of an inverse problem. This is, of course, a source of errors.

Estimating the propagation of errors is an important and costly (in term of computing resources) task for two reasons:

- the quality of the forecast must be estimated
- the estimation of the statistics of errors has to be included in the analysis to have an adequate norm, based on these statistics, on the forecast and also on the observation.

In the variational framework, models, observations, statistics are linked into the optimality system which can be considered as a “generalized” model containing all the available estimation. The estimation of error covariances are estimated both from the second order analysis and the Hessian of the cost function. Numerical experiments have been carried out on a non-linear model \cite{16}. We expect to extent the numerical experiments to a semi-operational model in cooperation with ECMWF.

#### 6.5.2. Sensitivity analysis for West African monsoon

**Participants:** Anestis Antoniadis, Céline Helbert, Clémentine Prieur, Laurence Viry.
6.5.2.1. Geophysical context

The West African monsoon is the major atmospheric phenomenon which drives the rainfall regime in Western Africa. Therefore, this is the main phenomenon in water resources over the African continent from the equatorial zone to the sub-Saharan one. Obviously, it has a major impact on agricultural activities and thus on the population itself. The causes of inter-annual spatio-temporal variability of monsoon rainfall have not yet been univocally determined. Spatio-temporal changes on the sea surface temperature (SST) within the Guinea Gulf and Saharian and Sub-Saharan Albedo are identified by a considerable body of evidences as major factors to explain it.

The aim of this study is to simulate the rainfall by a regional atmospheric model (RAM) and to analyze its sensitivity to the variability of these inputs parameters. Once precipitations from RAM are compared to several precipitation data sets we can observe that the RAM simulates the West African monsoon reasonably.

6.5.2.2. Statistical methodology

As mentioned in the previous paragraph, our main goal is to perform a sensitivity analysis for the West African monsoon. Each simulation of the regional atmospheric model (RAM) is time consuming, and we first have to think about a simplified model. We deal here with spatio-temporal dynamics, for which we have to develop functional efficient statistical tools. In our context indeed, both inputs (albedo, SST) and outputs (precipitations) are considered as time and space indexed stochastic processes. A first step consists in proposing a functional modeling for both precipitation and sea surface temperatures, based on a new filtering method. For each spatial grid point in the Gulf of Guinea and each year of observation, the sea surface temperature is measured during the active period on a temporal grid. A Karhunen-Loève decomposition is then performed at each location on the spatial grid [91]. The estimation of the time dependent eigenvalues at different spatial locations generates great amounts of high-dimensional data. Clustering algorithms become then crucial in reducing the dimensionality of such data.

Thanks to the functional clustering performed on the first principal component at each point, we have defined specific subregions in the Gulf of Guinea. On each subregion, we then choose a referent point for which we keep a prescribed number of principal components which define the basis functions. The sea surface temperature at any point in this subregion is modeled by the projection on this truncated basis. The spatial dependence is described by the coefficients of the projection. The same approach is used for precipitation. Hence for both precipitation and sea surface temperatures, we obtain a decomposition where the basis functions are functions depending on time and whose coefficients are spatially indexed and time independent. Then, the most straightforward way to model the dependence of precipitation on sea surface temperatures is through a multivariate response linear regression model with the output (precipitation) spatially indexed coefficients in the above decomposition and the input (SST) spatially indexed coefficients being predictors. A naive approach consists in regressing each response onto the predictors separately; however it is unlikely to produce satisfactory results, as such methods often lead to high variability and over-fitting. Indeed the dimensions of both predictors and responses are large (compared to the sample size). We apply a novel method recently developed by [83] in integrated genomic studies which takes into account both aspects. The method uses an $\ell_1$-norm penalty to control the overall sparsity of the coefficient matrix of the multivariate linear regression model. In addition, it also imposes a group sparse penalty. This penalty puts a constraint on the $\ell_2$ norm of regression coefficients for each predictor, which thus controls the total number of predictors entering the model, and consequently facilitates the detection of important predictors.

The dimensions of both predictors and responses are large (compared to the sample size). Thus in addition to assuming that only a subset of predictors enter the model, it is also reasonable to assume that a predictor may affect only some but not all responses. By the way we take into account the complex and spatio-temporal dynamics. This work has been published in [1].

6.5.2.3. Distributed Interactive Engineering Toolbox

An important point in the study described above is that the numerical storage and processing of model inputs/outputs requires considerable computation resources. They were performed in a grid computing environment with a middleware (DIET) which takes into account the scheduling of a huge number of
computation requests, the data-management and gives a transparent access to a distributed and heterogeneous platform on the regional Grid CIMENT (http://ciment.ujf-grenoble.fr/).

Thus, a different DIET module was improved through this application. An automatic support of a data grid software (http://www.irods.org) through DIET and a new web interface designed for MAR was provided to physicians.

These works involve also partners from the INRIA project/team GRAAL for the computational approach, and from the Laboratory of Glaciology and Geophysical Environment (LGGE) for the use and interpretation of the regional atmospheric model (RAM).

6.5.3. Tracking for mesoscale convective systems

Participants: Anestis Antoniadis, Céline Helbert, Clémentine Prieur, Laurence Viry, Roukaya Keinj.

6.5.3.1. Scientific context

In this section, we are still concerned with the monsoon phenomenon in western Africa and more generally with the impact of climate change. What we propose in this study is to focus on the analysis of rainfall system monitoring provided by satellite remote sensing. The available data are micro-wave and IR satellite data. Such data allow characterizing the behaviour of the mesoscale convective systems. We wish to develop stochastic tracking models, allowing for simulating rainfall scenari with uncertainties assessment.

6.5.3.2. Stochastical approach

The chosen approach for tracking these convective systems and estimating the rainfall intensities is a stochastic one. The stochastic modeling approach is promising as it allows developing models for which confidence in the estimates and predictions can be evaluated. The stochastic model will be used for hydro-climatic applications in West Africa. The first part of the work will consist in implementing a model developed in [88] on a test set to evaluate its performances, our ability to infer the parameters, and the meaning of these parameters. Once the model well fitted on toy cases, this algorithm should be run on our data set, and compared with previous results by [80] or by [79]. The model developed by [88] is a continuous time stochastic model to multiple target tracking, which allows in addition to birth and death, splitting and merging of the targets. The location of a target is assumed to behave like a Gaussian Process when it is observable. Targets are allowed to go undetected. Then, a Markov Chain State Model decides when the births, death, splitting or merging of targets arise. The tracking estimate maximizes the conditional density of the unknown variables given the data. The problem of quantifying the confidence in the estimate is also addressed. Roukaya Keinj started working on this topic with a two years postdoctoral position in November 2011.

6.5.4. Sensitivity analysis for forecasting ocean models

Participants: Eric Blayo, Maëlle Nodet, Clémentine Prieur, Gaëlle Chastaing, Alexandre Janon, Jean-Yves Tissot.

6.5.4.1. Scientific context

Forecasting ocean systems require complex models, which sometimes need to be coupled, and which make use of data assimilation. The objective of this project is, for a given output of such a system, to identify the most influential parameters, and to evaluate the effect of uncertainty in input parameters on model output. Existing stochastic tools are not well suited for high dimension problems (in particular time-dependent problems), while deterministic tools are fully applicable but only provide limited information. So the challenge is to gather expertise on one hand on numerical approximation and control of Partial Differential Equations, and on the other hand on stochastic methods for sensitivity analysis, in order to develop and design innovative stochastic solutions to study high dimension models and to propose new hybrid approaches combining the stochastic and deterministic methods.
6.5.4.2. Estimating sensitivity indices

A first task is to develop tools for estimated sensitivity indices. Among various tools a particular attention was paid to FAST and its derivatives. In [89], the authors present a general way to correct a positive bias which occurs in all the estimators in random balance design method (RBD) and in its hybrid version, RBD-FAST. Both these techniques derive from Fourier amplitude sensitivity test (FAST) and, as a consequence, are faced with most of its inherent issues. And up to now, one of these, the well-known problem of interferences, has always been ignored in RBD. After presenting in which way interferences lead to a positive bias in the estimator of first-order sensitivity indices in RBD, the authors explain how to overcome this issue. They then extend the bias correction method to the estimation of sensitivity indices of any order in RBD-FAST. They also give an economical strategy to estimate all the first-order and second-order sensitivity indices using RBD-FAST.

6.5.4.3. Intrusive sensitivity analysis, reduced models

Another point developed in the team for sensitivity analysis is model reduction. To be more precise regarding model reduction, the aim is to reduce the number of unknown variables (to be computed by the model), using a well chosen basis. Instead of discretizing the model over a huge grid (with millions of points), the state vector of the model is projected on the subspace spanned by this basis (of a far lesser dimension). The choice of the basis is of course crucial and implies the success or failure of the reduced model. Various model reduction methods offer various choices of basis functions. A well-known method is called proper orthogonal decomposition” or principal component analysis”. More recent and sophisticated methods also exist and may be studied, depending on the needs raised by the theoretical study. Model reduction is a natural way to overcome difficulties due to huge computational times due to discretizations on fine grids. In [61], the authors present a reduced basis offline/online procedure for viscous Burgers initial boundary value problem, enabling efficient approximate computation of the solutions of this equation for parametrized viscosity and initial and boundary value data. This procedure comes with a fast-evaluated rigorous error bound certifying the approximation procedure. The numerical experiments in the paper show significant computational savings, as well as efficiency of the error bound. The present preprint is under review. When a metamodel is used (for example reduced basis metamodel, but also kriging, regression, ...) for estimating sensitivity indices by Monte Carlo type estimation, a twofold error appears : a sampling error and a metamodel error. Deriving confidence intervals taking into account these two sources of uncertainties is of great interest. We obtained results particularly well fitted for reduced basis metamodels [61]. Alexandre Janon obtained a best poster award on the topic [40]. An ongoing work deals also with asymptotic confidence intervals in the double limit where the sample size goes to infinity and the metamodel converges to the true model. Implementations have to be conducted on more general models such as Shallow-Water models.

6.5.4.4. Sensitivity analysis with dependent inputs

An important challenge for stochastic sensitivity analysis is to develop methodologies which work for dependent inputs. For the moment, there does not exist conclusive results in that direction. Our aim is to define an analogue of Hoeffding decomposition [75] in the case where input parameters are correlated. A PhD started in October 2010 on this topic (Gaëlle Chastaing). We obtained first results which should be submitted soon, deriving a general functional ANOVA for dependent inputs, allowing defining new variance based sensitivity indices for correlated inputs.

6.5.5. Quantification of uncertainty with Multi-fidelity computer experiments

Participants: Federico Zertuche, Céline Helbert, Anestis Antoniadis.

Propagation of uncertainties through computer codes is a hard task when dealing with heavy industrial simulators. Confidence intervals announced on predictions are often huge because of the lack of data. The context of the study here is the case of simulations when multiple levels of analysis (fast and slow) are available. In most cases the fast (but less trustworthy) and the slow (but more accurate) response values can be obtained independently. Thus, we can learn more about the response by additionally measuring the cheap function(s) on a large number of x ’s. In most cases the relationship between cheap and expensive responses is modeled by an autoregressive Gaussian regression. This method is a natural extension of the kriging method...
in the sense that to build the surrogate one performs a Gaussian regression for the cheap data and one for the
difference vector defined by the autoregressive relationship. The prediction error depends on the prediction
error of the cheap and expensive surrogates. We can observe that this modeling greatly improves the traditional
kriging method when the actual relationship between the cheap and expensive responses is somewhat linear.
On another hand, this approach gives worse results when the relation between cheap and expensive is far to
be linear. Therefore some improvements must be made on the models to take into account a more precise link
between the two levels fidelity of the responses. Some other additional tasks concern the associated numerical
designs (must the designs be absolutely nested?) and the allocation of resources between low and fast runs.
The work is currently the object of the thesis of Federico Zertuche that has just begun in October 2011.

6.5.6. Impact of the thermodynamics and chemical kinetics parameters at different scales for
the models of CO2 storage in geological media

Participant: Céline Helbert.

In collaboration with Bernard Guy and Joharivola Raveloson (Ecole des Mines de Saint-Etienne) we study
the water-gas-rock interactions in the case of CO2 storage in geological environment. The focus is on the
scale of observation of geochemical phenomena while taking into account the heterogeneity of the reservoir.
This heterogeneity at small and large scale helps to maintain a local variability of the chemical composition
of the fluid and influence reaction rates at the pore as well as at the reservoir scale. We propose to evaluate
the geostatistical characteristics of local variability thanks to simulations of reactive transport on a small
scale in which parameters (namely the equilibrium constants log K and the rate constant k) are perturbed to
represent local processes. This contribution is the following of a precedent study of the impact of the reservoir
uncertainties on the CO2 storage [72].

6.6. Inverse methods for Glaciology

6.6.1. Dating ice matrix and gas bubbles

Participants: Eric Blayo, Bénédicte Lemieux-Dudon, Habib Toye Mahamadou Kele.

Dating ice matrix and gas bubbles of ice-cores is essential to study paleoclimates. Inverse modelling imple-
mented on 1D ice flow models is being applied for a few years to construct the ice chronology of several deep
ice cores. Such a method based on a Monte Carlo algorithm was implemented under the assumption of perfect
ice flow models, for one core at a time, and without including the inverse modelling of the densification mod-
els, which enables to construct the gas age scale. This approach faces three issues: 1) frequent discrepancies
between core chronologies (lack of stratigraphic links between cores as data constraints), 2) frequent failure
to verify relevant data constraints (perfect model assumption is too strong), and 3) frequent inconsistency
between gas and ice age scales.

A new approach was proposed during the B. Lemieux-Dudon’s PhD to circumvent these restrictions. It
introduces the model error in terms of correction functions on three key quantities from which one can calculate
both the ice and gas age scales: a) the accumulation rate, b) the total thinning function, and c) the close-off
depth in meters of ice equivalent (i.e. depth below the ice-sheet surface where the atmosphere is trapped). A
variational formulation of the inverse problem is constructed. It includes several ice cores with background
scenarios and paleo data as constraints, among which:

- stratigraphic links between pair of ice cores (methane, tephra, cosmogenic isotopes, etc.) to derive
  consistent dating between cores,
- ice and gas age markers, as well as delta-depth data (i.e., in situ depth interval between gas and ice
  of the same age), which enable to optimize the gas and ice age scales simultaneously.

The cost function includes covariance error matrices, and confidence intervals of the solution can be assessed.
This method was applied to derive simultaneously a common age scale for the North Grip core and for the two
EPICA cores (DML and DC) [76].
This method arouses some interest in the glaciological and paleo community ( [ 68 ], [ 87 ]). Some further developments are however mandatory to ensure the robustness of the dating solution: (i) code optimization, (ii) diagnostics on the assimilation system, and (iii) calibration of the background error covariance matrices.

H. Toye Mahamadou Kele (a 2-year INRIA young engineer contract) joined the MOISE team to modify the code. During the first year, he implemented a shared memory parallelization of the code, and he currently works on the calibration of the covariance error matrices by implementing a posteriori diagnostics.

6.6.2. Inverse methods for large scale ice-sheet models

Participants: Bertrand Bonan, Maëlle Nodet, Catherine Ritz.

In collaboration with C. Ritz (CNRS, Laboratoire de Glaciologie et Geophysique de l’Environnement (LGGE), Grenoble), we aim to develop adjoint methods for ice cap models.

In the framework of global warming, the evolution of sea level is a major but ill-known phenomenon. It is difficult to validate the models which are used to predict the sea level elevation, because observations are heterogeneous and sparse.

Data acquisition in polar glaciology is difficult and expensive. Satellite data have a good spatial coverage, but they allow only indirect observation of the interesting data. We wish to make the most of all available data and evaluate where/when/what we have to add new observations. Sensitivity analysis, and in particular the adjoint method, allows to identify the most influential parameters and variables and can help to design the observation network.

The ANR project ADAGe started one year ago on this subject, and B. Bonan started his PhD in September 2010. During his master internship, he implemented the adjoint code of a simplified ice-sheet flow-line model, Winnie, developed by C. Ritz at LGGE. We then performed twin experiments of data assimilation. These preliminary results have been presented at two international conferences [ 32 ], [ 33 ].

We then implemented Ensemble Kalman Filter (EnKF) on Winnie, which we would like to compare to variational assimilation methods. Coding and testing for the EnKF are still in progress.

6.6.3. Inverse methods for full-Stokes glaciology models

Participants: Olivier Gagliardini, Maëlle Nodet, Catherine Ritz.

We are also interested in inverse modelling for another class of glaciology models, called full-Stokes models. Such a model is developed by LGGE and CSC in Finland, called Elmer/Ice. Contrary to large scale models, Elmer/Ice is based on the full Stokes equations, and no assumptions regarding aspect ratio are made, so that this model is well adapted to high resolution small scale modelling, such as glaciers (and more recently the whole Greenland ice-sheet).

In collaboration with O. Gagliardini, F. Gillet-Chaulet and C. Ritz (Laboratoire de Glaciologie et Géophysique de l’Environnement (LGGE), Grenoble), we investigated a new method to solve inverse problems for a Full-Stokes model of Groenland, which consisted in solving iteratively a sequence of Neumann and Dirichlet problems within a gradient descent algorithm. We also compared this method to an approximate variational algorithm, using the fact that the full Stokes equations are almost self-adjoint. These results have been submitted for publication and presented at EGU and AGU [ 36 ], [ 37 ].

With O. Gagliardini, F. Gillet-Chaulet and M. Jay-Allemand (LGGE), we also implemented these methods to study a complex phenomenon: the surge of Variegated glacier (Alaska). This glacier is indeed known to surge periodically, that is to accelerate suddenly during 1-2 years, and then come back to a quiescent phase during 10-20 years. Inverse modelling allowed us to infer changes in basal conditions from surface velocities, and to come to a better understanding of the surge phenomenon, as seen in Figure 6 . These results have been published [ 6 ] and presented at AGU [ 42 ].

6.7. Image processing

6.7.1. Segmentation and assimilation of medical images

Participant: Nicolas Papadakis.
Observation and Modeling for Environmental Sciences - New Results - Project-Team MOISE

Figure 6. Distribution of the basal friction parameter along the central flow line for the 25 dates of measurements. Dotted curves indicate where measured surface velocities are missing. In the legend, \(W_{Y1-Y2}\) denotes the mean velocity for the winter from year \(Y1\) to year \(Y2\), \(S_Y\) denotes the mean velocity for the summer of year \(Y\) and \(\text{Surge}_{Y-M1-M2}\) the mean velocity for year \(Y\) from month \(M1\) to month \(M2\).

In collaboration with the Inria team MC2 of the Bordeaux-Sud-Ouest center, we investigate the application of image assimilation to medical issues. The objective is here to use MRI images in order to monitor EDP models dealing with tumor growth in lungs or brains. Using such images, we would like to define a patient specific process allowing to calibrate the numerical model with respect to the observed tumor. First works based on convex relaxation of the binary segmentation problem \([81]\) have been realized in this direction by proposing a 3D segmentation method dedicated to glioblastomas from a set of MRI brain images. The obtained automatic segmentation results are very close to specialist manual segmentations (errors of 5%) and will be used as pseudo-observations for an assimilation system based on the numerical model describing the tumor growth. The final issue will be to define an observation operator linking images with the model in order to realize a direct assimilation.

6.7.2. Optimal transport

Participants: Maëlle Nodet, Nicolas Papadakis, Arthur Vidard.

A new activity on optimal transport has been started in collaboration with the EDP and MGMI teams of the Laboratoire Jean Kuntzmann, Grenoble and the MAP5 Laboratory, Paris, through a project funded by the ANR white program. The purpose is to define metric between images involving the so-called Wasserstein distance. Such metric would be of particular interest in order to introduce pertinent observation operators for assimilating image data \([64]\). Other applications including image morphing and histogram equalization are also studied for image processing purposes. First results has been obtained by adding spatial regularity to the transport map computed by the Benamou-Brenier algorithm \([66]\).

6.7.3. Computer vision

Participant: Nicolas Papadakis.
In collaboration with Vicent Caselles (Pompeu Fabra University, Barcelona, Spain), different image processing works have been finalized: 3D reconstruction and novel view synthesis for soccer replays [13], stereo inpainting for 3D movie post-production [29]. Other works dedicated to object tracking in image sequences have also been proposed with Aurelie Bugeau (LABRI, Bordeaux) [14]. A main attention is now given to the problem of histogram equalization of different images [15]. Our aim is now to include spatial information on color repartition during the histogram transfer for inpainting and shadow removal purposes. A journal paper dealing with this issue has been recently accepted for publication.

6.8. Multivariate risk indicators

**Participant:** Clémentine Prieur.

In collaboration with Véronique Maume-Deschamps, Elena Di Bernardino (ISFA, Lyon 1) and Peggy Cenac (Université de Bourgogne), we are interested in defining and estimating new multivariate risk indicators. This is a major issue with many applications (environmental, insurance, ...). Two papers were accepted for publication and one other is submitted. The submitted one deals with the estimation of bivariate tails [56]. In [69] we propose to minimize multivariate risk indicators by using a Kiefer-Wolfowitz approach to the mirror stochastic algorithm. In [4] we present an estimation procedure for multivariate risk indicators making use of a plug-in estimation of level sets of bivariate cumulative distribution functions.

6.9. Stochastic Downscaling Method

**Participant:** Antoine Rousseau.

In collaboration with TOSCA (Inria Sophia-Antipolis), LMD (Ecole Polytechnique) and CETE (Clermont-Ferrand), we investigate a new method for the numerical simulation of the wind at small scales. In this work, we consider a new approach for the downscaling in CFD. The local model that we propose is inspired from S.B. Pope’s previous works on turbulence. We investigated a new numerical simulation method for the downscaling in CFD, with a strong orientation in applications to meteorology, particularly for the simulation of wind at small scales. The local model that we propose consists in modeling the fundamental equations of fluid motion by a stochastic Lagrangian model describing the behaviour of a fluid particle. Because of the both Lagrangian and stochastic nature of our model, it is discretized thanks to an interacting particle system, combining a time Euler scheme for stochastic differential equations and a Monte–Carlo approximation method. This model called SDM (Stochastic Downscaling Method) is adapted from previous works introduced by S.B. Pope [84] (see http://sdm.gforge.inria.fr/Accueil/index.en.php).

This year, we worked on the comparison of the SDM model (endowed with a physical geostrophic forcing and a wall log law) with simulations obtained with a LES method (Méso-NH code) for the atmospheric boundary layer (from 0 to 750 meters in the vertical direction), in the neutral case. This work allowed to deeply understand the contribution of each elements of the Lagrangian model in terms of the turbulence production and dissipation, we analyzed the returns of various closure parametrization approaches, including viscosity turbulent approach. We also investigated anisotropic effect, with the introduction of GLM model in SDM (see [84]), in particular the isotropic relaxation case. We gave our conclusions as a part of the final report for ADEME [58]. A paper is in preparation.

6.10. Mathematical modelling for CFD-environment coupled systems

**Participant:** Antoine Rousseau.

6.10.1. Minimal-time bioremediation of natural water resources

The objective of this work is to provide efficient strategies for the bioremediation of natural water resources. Based on a previous paper [74] that deals with an homogeneous resource in space (with a system of ODEs), we implement a coupled ODE-PDE system that accounts for the spatial non-homogeneity of pollution in natural resources. The main idea is to implement a Navier-Stokes model in the resource (such as a lake), with boundary conditions that correspond to the corresponding optimal discharge of a (small) bioreactor. A first mathematical model has been introduced (see [48]) and a journal paper is ready to be submitted.
6.10.2. Mathematical modelling for the confinement of lagoons

This work deals with the concept of confinement of paralic ecosystems. It is based on the recent paper [73] that presents a modelling procedure in order to compute the confinement field of a lagoon. In [59], A. Rousseau and E. Frénod (INRIA CALVI), improve the existing model in order to account for tide oscillations in any kind of geometry such as a non-rectangular lagoons with a non-flat bottom. The new model, that relies on PDEs rather than ODEs, is then implemented thanks to the finite element method. Numerical results confirm the feasibility of confinement studies thanks to the introduced model.
6. New Results

6.1. Mesh repair with topology control

**Participant:** Franck Hétroy.

This work is done in collaboration with Carlos Andújar, Pere Brunet and Álvar Vinacua from Universitat Politecnica de Barcelona, Spain, and has been published in the CAD journal [ 7 ]. The purpose is to propose an efficient method to create 2-manifold meshes from real data, obtained as soups of polygons with combinatorial, geometrical and topological noise (see Figure 3 ). We propose to use a voxel structure called a discrete membrane and morphological operators to compute possible topologies, between which the user chooses.

![Figure 3. Two topologically different 2-manifold mesh repairs, from the same polygon soup.](image)

6.2. Topology computation on simplicial shapes

**Participants:** Dobrina Boltcheva, Franck Hétroy.

This work is a part of the BQR project IDEAL (see Section 8.1.1 ) which is performed in collaboration with Leila de Floriani from the University of Genova in Italy. The main goal of this project is to study non-manifold geometrical models and to find out features allowing to classify these models and criteria for determining their shape. We are interested in non-manifold models such as idealized industrial CAD models, since they are still ill-understood even if they are frequently used in computer graphics and many engineering applications.

We have developed an efficient method to compute the homology of a large (non-manifold) simplicial complex, from the homologies of its sub-complexes. Computed topological invariants play a crucial role in the field of shape description and analysis. This work has been published in the CAD journal [ 5 ] and presented at the SIAM conference on geometric and physical modeling (GD/SPM’11).

6.3. Scale Space Representations on Manifolds

**Participant:** Edmond Boyer.
In collaboration with RaduHoraud and Andrei Zaharescu, we developed a novel approach for the scale-space representations of scalar functions defined over Riemannian manifolds. One of the main interest in such representations stems from the task of 3D modelling where 2D surfaces, endowed with various physical properties, are recovered from images. Multi-scale analysis allows to structure the information with respect to its intrinsic scale, hence enabling a wide range of low-level computations, similar to what is usually used for representing images. In contrast to the Euclidean image domain, where scale spaces can be easily obtained through convolutions with Gaussian kernels, surfaces require a more general approach that must handle non-Euclidean spaces. Such a generalized scale-space framework is the main contribution of this work, which builds on the spectral decomposition available with the heat-diffusion framework to derive a computational approach for representing scalar functions on 2D Riemannian manifolds using an intrinsic scale parameter. In addition, we proposed a feature detector and a region descriptor, based on these representations, extending the widely used DOG detector and HOG descriptor to manifolds. Experiments on real datasets with various physical properties, i.e., scalar functions, demonstrated the validity and the interest of this approach[16].

![Figure 4. Fine-to-coarse representations of scalar functions (color) defined over 2D Riemannian manifolds.](image)

6.4. Topologically-Robust 3D Shape Matching
Participant: Edmond Boyer.

3D Shape matching is an important problem in computer vision. One of the major difficulties in finding dense correspondences between 3D shapes is related to the topological discrepancies that often arise due to complex kinematic motions. In this work done in collaboration with Jan Cech, Radu Horaud and Avinash Sharma a shape matching method is proposed that is robust to such changes in topology. The algorithm starts from a sparse set of seed matches and outputs dense matching. We use a shape descriptor based on properties of the heat-kernel and which provides an intrinsic scale-space representation. This descriptor incorporates (i) heat-flow from already matched points and (ii) self diffusion. At small scales the descriptor behaves locally and hence it is robust to global changes in topology. Therefore, it can be used to build a vertex-to-vertex matching score conditioned by an initial correspondence set. This score is then used to iteratively add new correspondences based on a novel seed-growing method that iteratively propagates the seed correspondences to nearby vertices. The matching is further densified via an EM-like method that explores the congruency between the two shape embeddings. The method is compared with two recently proposed algorithms and we show that we can deal with substantial topological differences between the two shapes[15].

6.5. Motion-based segmentation of mesh sequences
Participants: Romain Arcila, Franck Hétroy.
Mesh animations, or sequences of meshes, represent a huge amount of data, especially when acquired from scans or videos. In collaboration with the University of Lyon (LIRIS lab), we address the problem of partitioning these sequences, in order to both recover motion information and be able to compress them. Following last year’s method, we proposed this year a second and third motion-based segmentation algorithm, which clusters mesh vertices into static or rigidly moving components (see Figure 5). These methods are based on spectral clustering of the vertex transformations and are more robust and general than the previous one. This work has been submitted for publication to a journal, and is part of the PhD thesis of Romain Arcila [1].

Figure 5. Temporally varying segmentation of a mesh sequence, into rigidly moving components. Right hand and arm are merged at some time since they start to move accordingly. They are later split, when they start to follow different motions.

6.6. Surface Flow

Participants: Antoine Letouzey, Benjamin Petit, Jean-Sébastien Franco, Edmond Boyer.

Recovering dense motion information is a fundamental intermediate step in the image processing chain upon which higher level applications can be built, such as tracking or segmentation. For that purpose, pixel observations in the image provide useful motion cues through temporal variations of the intensity function. We have studied the estimation of dense, instantaneous 3D motion fields over non-rigidly moving surfaces observed by multi-camera systems. The motivation arises from multi-camera applications that require motion information for arbitrary subjects, in order to perform tasks such as surface tracking or segmentation. To this aim, we have proposed a novel framework that allows to efficiently compute dense 3D displacement fields using low level visual cues and geometric constraints. The main contribution is a unified framework that combines flow constraints for small displacements with temporal feature constraints for large displacements and fuses them over the surface using local rigidity constraints. The resulting linear optimization problem allows for variational solutions and fast implementations. Experiments conducted on synthetic and real data demonstrated the respective interests of flow and feature constraints as well as their efficiency to provide robust surface motion cues when combined[14], [18].

As an extension of this work, we also studied the situation where a depth camera and one or more color cameras are available, a common situation with recent composite sensors such as the Kinect. In this case, geometric information from depth maps can be combined with intensity variations in color images in order to estimate smooth and dense 3D motion fields. We propose a unified framework for this purpose, that can handle both arbitrary large motions and sub-pixel displacements. The novelty with respect to existing scene flow approaches is that it takes advantage of the geometric information provided by the depth camera to define a surface domain over which photometric constraints can be consistently integrated in 3D. Experiments on real and synthetic data provide both qualitative and quantitative results that demonstrated the interest of the approach[13].
6.7. Learning Temporally Consistent Rigidities

Participants: Jean-Sébastien Franco, Edmond Boyer.

We present a novel probabilistic framework for rigid tracking and segmentation of shapes observed from multiple cameras. Most existing methods have focused on solving each of these problems individually, segmenting the shape assuming surface registration is solved, or conversely performing surface registration assuming shape segmentation or kinematic structure is known. We assume no prior kinematic or registration knowledge except for an over-estimate $k$ of the number of rigidities in the scene, instead proposing to simultaneously discover, adapt, and track its rigid structure on the fly. We simultaneously segment and infer poses of rigid subcomponents of a single chosen reference mesh acquired in the sequence. We show that this problem can be rigorously cast as a likelihood maximization over rigid component parameters. We solve this problem using an Expectation Maximization algorithm, with latent observation assignments to reference vertices and rigid parts. Our experiments on synthetic and real data show the validity of the method, robustness to noise, and its promising applicability to complex sequences. This work was presented at the CVPR 2011 conference [11].
6.8. Ontology-based mesh segmentation

Participants: Sahar Hassan, Franck Hétroy.

Patient-specific 3D virtual models of anatomical organs are becoming more and more useful in medicine, for instance for diagnosis or follow-up care purposes. These models are usually created from 2D scan or MRI images. However, small or thin geometrical features, such as ligaments, are sometimes not visible on these images. We propose to use an anatomical ontology, called MyCorporisFabrica http://www.mycorporisfabrica.org/, to add missing parts to reconstructed virtual organs. This ontology describes definitions of and relationships between organs: e.g., femur is part of the leg. The first step towards the full achievement of this process is to segment virtual models, often represented by 2D meshes, into meaningful parts. In our case, “meaningful” means “related to the ontology”: each part should refer to an organ defined in the ontology. An algorithm to decompose a given organ into sub-organs according to the ontology has been proposed in the PhD thesis of Sahar Hassan [2]: first, we approximate organ shapes by geometric primitives, then we segment a given organ mesh by optimizing objective functions which are related to these primitives.

6.9. Detection and quantification of brain aneurysms

Participants: Sahar Hassan, Franck Hétroy.

Aneurysms are excrescences on blood vessels. They can break, letting the blood propagate outside the vessel, which often leads to death. In some cases, the blood clots sufficiently fast so that people survive. However, a neurosurgeon or a neuroradiologist should intervene very quickly in order to repace the vessel before the aneurysm breaks once more.

The purpose of our research is to help neurosurgeons and neuroradiologists to plan surgery, by giving them quantitative information about the size, shape and geometry position of aneurysms. This work was part of the PhD of Sahar Hassan [2], and has presented at the International Conference on Computer Analysis of Images and Patterns (CAIP) [12]. The method we propose first extracts a centered skeleton from the input voxel set of the vascular tree, then detects aneurysms by studying variations of vessel diameters along the skeleton. The name of an aneurysm-carrying vessel is also given thanks to a partial graph matching technique, and accurate measures to decide the treatment are provided.

6.10. Dimensionality reduction for character animation

Participants: Maxime Tournier, Lionel Reveret.

This work investigates and proposes a mathematical framework to perform statistical analysis and dimensionality reduction on rotational trajectories derived from motion capture data. Motion capture data consists in a set of trajectories in the space of 3D rotations (SO(3)) and as such do not present properties of an Euclidian space. Consequently there is no easy to way to apply standard dimensionality reduction techniques on these data. Using the formalism of exponential maps and Principle Geodesics Analysis (PGA), it has been shown that it is possible to rigorously derive a dimensionality reduction analysis on such data. This reduction can be typically applied for compression of motion capture data and probabilistic implementation of the Inverse Kinematics problem. This approach has shown good properties in the context of physically-based animation with a Lagrangian formulation of rigid body dynamics coupled with geometric integrators. These integrators allow a good preservation of momentum using only first order equations, achieving both real-time and high level of realism. These works were developed through the PhD thesis of Maxime Tournier [4]. Early development of PGA on motion capture data had been published at Eurographics in 2009. Its integration into a GPLVM framework has been published this year in the IEEE CG&A journal [9]. Its extension into the context of physically-based animation is currently under preparation for publication.

6.11. Animation of quadrupeds locomotion

Participant: Lionel Reveret.
Following a study on locomotion of quadrupeds by a team in the National Museum of Natural History (MNHN), a new theory on motion planning has been proposed. This theory, the Antero-Posterior Sequences (APS), allows a characterization of the sequence of foot placement for quadrupeds for all regular gaits with very few parameters, as well as transition between gaits, starting from stop to full gallop. In collaboration with the MNHN and the robotics department of the University of Versailles-Saint Quentin en Yvelines (UVSQ), a rigorous software implementation has been specified and developed. This software allows automatically generating foot planning of quadrupeds locomotion according to a desired speed transition. Co-workers for this project were Ludovic Maes and Anick Abourachid at the MNHN and Vincent Hugel at the UVSQ. A patent has been written and finalized for this project.

In parallel, collaboration on physical simulation of quadrupeds locomotion has been carried on with Stelian Coros (previously at University of British Columbia (UBC), now at Disney Research) and Michiel van de Panne (UBC). Automatic video analysis of dog walking, trotting and running has been used to optimize parameters of physical controllers. This work has been published at SIGGRAPH 2011 [6].
6. New Results

6.1. Weak Memory Models, Litmus-PPC-WMM tools

Participants: Jade Alglave, Luc Maranget, Pankaj Pawan, Susmit Sarkar [U. of Cambridge], Peter Sewell [U. of Cambridge], Francesco Zappa Nardelli.

Shared memory multiprocessors typically expose subtle, poorly understood and poorly specified relaxed-memory semantics to programmers. To understand them, and to develop formal models to use in program verification, we find it essential to take an empirical approach, testing what results parallel programs can actually produce when executed on the hardware. We describe a key ingredient of our approach, our litmus tool, which takes small “litmus test” programs and runs them for many iterations to find interesting behaviour. It embodies various techniques for making such interesting behaviour appear more frequently. We presented a tool, litmus, to run “litmus tests” on real hardware at TACAS’11 [31].

An automated exploration of machine memory models (on the dont tool) is submitted to TACAS’12.

During a two month long internship, Pankaj Pawan (IIT Kanpur, India) ported the PPCMEM application from OCaml to JavaScript, and developed a suitable web-interface. This enabled a wide dissemination (including at IBM) of the PPCMEM tool. The tool is available online at: http://www.cl.cam.ac.uk/~pes20/ppcmem/help.html.

6.2. Operational semantics for the memory model of Power (IBM) machines

Participants: Jade Alglave, Luc Maranget, Susmit Sarkar [U. of Cambridge], Peter Sewell [U. of Cambridge], Derek Williams [IBM, Austin].

Exploiting today’s multiprocessors requires high-performance and correct concurrent systems code (optimising compilers, language runtimes, OS kernels, etc.), which in turn requires a good understanding of the observable processor behaviour that can be relied on. Unfortunately this critical hardware/software interface is not at all clear for several current multiprocessors.

We characterise the behaviour of IBM POWER multiprocessors, which have a subtle and highly relaxed memory model (ARM multiprocessors have a very similar architecture in this respect). We have conducted extensive experiments on several generations of processors: POWER G5, 5, 6, and 7. Based on these, on published details of the microarchitectures, and on discussions with IBM staff, we give an abstract-machine semantics that abstracts from most of the implementation detail but explains the behaviour of a range of subtle examples. Our semantics is explained in prose but defined in rigorous machine-processed mathematics; we also confirm that it captures the observable processor behaviour, or the architectural intent, for our examples with an executable checker. While not officially sanctioned by the vendor, we believe that this model gives a reasonable basis for reasoning about current POWER multiprocessors. Our work should bring new clarity to concurrent systems programming for these architectures, and is a necessary precondition for any analysis or verification. It should also inform the design of languages such as C and C++, where the language memory model is constrained by what can be efficiently compiled to such multiprocessors.

This work was presented at PLDI’11 [26]. This operational model is now being enriched for Power machine with loads and link/store conditionals (the Power primitives to write locks), and connected to C++ semantics. It is submitted to PLDI’2012 with many co-authors from Cambridge.

6.3. Restoring Sequential Consistency for x86 and Power machines

Participants: Jade Alglave, Luc Maranget.
Concurrent programs running on weak memory models exhibit relaxed behaviours, making them hard to understand and to debug. To use standard verification techniques on such programs, we can force them to behave as if running on a Sequentially Consistent (SC) model. Thus, we examine how to constrain the behaviour of such programs via synchronisation to ensure what we call their stability, i.e. that they behave as if they were running on a stronger model than the actual one, e.g. SC. First, we define sufficient conditions ensuring stability to a program, and show that Power’s locks and read-modify-write primitives meet them. Second, we minimise the amount of required synchronisation by characterising which parts of a given execution should be synchronised. Third, we characterise the programs stable from a weak architecture to SC. Finally, we present our offence tool which places either lock-based or lock-free synchronisation in an x86 or Power program to ensure its stability.

This work was presented at CAV’11 [30].

6.4. Relaxed-Memory Concurrency and Verified Compilation

We studied the semantic design and verified compilation of a C-like programming language for concurrent shared-memory computation above x86 multiprocessors. The design of such a language is made surprisingly subtle by several factors: the relaxed-memory behaviour of the hardware, the effects of compiler optimisation on concurrent code, the need to support high-performance concurrent algorithms, and the desire for a reasonably simple programming model. In turn, this complexity makes verified (or verifying) compilation both essential and challenging.

This project started in 2010, when we defined a concurrent relaxed-memory semantics for ClightTSO, an extension of CompCert’s Clight in which the processor memory model is exposed for high-performance code, and, building on CompCert, we implemented a certifying compiler from ClightTSO to x86, and proved in Coq several compilation phases. A paper describing our approach has been accepted in POPL [29] 2011.

During 2011 we completed this project by developing correctness proofs for all the compilation phases, and made a public distribution of the compiler, available from http://www.cl.cam.ac.uk/~pes20/CompCertTSO.

In 2011 Zappa Nardelli and Vafeiadis investigated the soundness of fence elimination optimisations for x86TSO. They implemented and proved correct two optimisations that remove redundant fence instructions as compiler passes over RTL in CompCertTSO. Despite an apparent simplicity, these optimisations generate almost optimal code for several standard concurrent algorithms (CompCertTSO does not implement escape analysis, which would enhance the effectiveness of the optimisations), and since they only perform data-flow analysis over the code of each thread (without analysing the full-system thread interactions) they do not suffer from the finite-state and finite control limitation of other approaches. The proof of correctness of one optimisation was challenging has required some for prophecy variable simulation. This work has been published in SAS 2011 [28] and the code is part of CompCertTSO.

A journal version, describing the correctness proof of all the phases of CompCertTSO (including the fence eliminations) as been submitted to the Journal of the ACM [35].

6.5. Compiling C/C++ Concurrency: from C++11 to POWER

Participants: Kayvan Memarian, Francesco Zappa Nardelli.

The upcoming C and C++ revised standards add concurrency to the languages, for the first time, in the form of a subtle relaxed memory model (the C++11 model). This aims to permit compiler optimisation and to accommodate the differing relaxed-memory behaviours of mainstream multiprocessors, combining simple semantics for most code with high-performance low-level atomics for concurrency libraries.

We studied the the correctness of two proposed compilation schemes for the C++11 load and store concurrency primitives to Power assembly, having noted that an earlier proposal was flawed. (The main ideas apply also to ARM, which has a similar relaxed memory architecture.)
This should inform the ongoing development of production compilers for C++11 and C1x, clarifies what properties of the machine architecture are required, and builds confidence in the C++11 and Power semantics. A paper describing this work will appear in POPL 2012 [22].

6.6. F*: Secure Distributed Programming with Value-Dependent Types

**Participants:** Nikhil Swamy [MSR Redmond], Juan Chen [MSR Redmond], Cédric Fournet [MSR Cambridge], Pierre-Yves Strub [MSR-INRIA], Karthikeyan Bhargavan [correspondent], Jean Yang [MIT].

Distributed applications are difficult to program reliably and securely. Dependently typed functional languages promise to prevent broad classes of errors and vulnerabilities, and to enable program verification to proceed side-by-side with development. However, as recursion, effects, and rich libraries are added, using types to reason about programs, specifications, and proofs becomes challenging.

We present F*, a full-fledged design and implementation of a new dependently typed language for secure distributed programming. Unlike prior languages, F* provides arbitrary recursion while maintaining a logically consistent core; it enables modular reasoning about state and other effects using affine types; and it supports proofs of refinement properties using a mixture of cryptographic evidence and logical proof terms. The key mechanism is a new kind system that tracks several sub-languages within F* and controls their interaction. F* subsumes two previous languages, F7 and Fine. We prove type soundness (with proofs mechanized in Coq) and logical consistency for F*.

We have implemented a compiler that translates F* to .NET bytecode, based on a prototype for Fine. F* provides access to libraries for concurrency, networking, cryptography, and interoperability with C#, F#, and the other .NET languages. The compiler produces verifiable binaries with 60-size overhead for proofs and types, as much as a 45x improvement over the Fine compiler, while still enabling efficient bytecode verification.

To date, we have programmed and verified more than 20,000 lines of F* including (1) new schemes for multiparty sessions; (2) a zero-knowledge privacy-preserving payment protocol; (3) a provenance-aware curated database; (4) a suite of 17 web-browser extensions verified for authorization properties; and (5) a cloud-hosted multi-tier web application with a verified reference monitor.

This paper was published at ICFP 2011 [27].

6.7. Security by Typing for Cryptographic Protocol Implementations

**Participants:** Karthikeyan Bhargavan [correspondent], Cédric Fournet [MSR Cambridge], Andrew D. Gordon [MSR Cambridge], Alfredo Pironti.

We propose to use refinement typing to verify the security of cryptographic protocol implementations. Our method is based on declaring and enforcing invariants on the usage of cryptography. We develop cryptographic libraries that embed a logic model of their cryptographic structures and that specify preconditions and postconditions on their functions so as to maintain their invariants.

We implement the method for protocols coded in F# and verified using F7, our SMT-based typechecker for refinement types, that is, types carrying formulas to record invariants. As illustrated by a series of programming examples, our method can flexibly deal with a range of different cryptographic constructions and protocols [24].

We are currently evaluating this method on a fully-fledged implementation of TLS. While previous uses of typing for cryptographic protocol implementations focused on the symbolic model of cryptography, we use a new technique by Fournet et al to develop computational proofs for our implementations. Our TLS implementation consists of 6000 lines of code. We have currently annotated and verified about half of this implementation.

We recently published a tutorial on our verification method as part of the proceedings of FOSAD 2010, and a journal paper on our type system at TOPLAS [20].
6.8. Authorization for the Social Web: from Formal Analysis to Concrete Attacks

**Participants:** Chetan Bansal [BITS Goa], Karthikeyan Bhargavan [correspondant], Sergio Maffeis [Imperial College].

Social sign-on and social sharing are becoming an ever more popular feature of web applications. This success is caused in part by the APIs support offered by leading websites such as Facebook, Twitter and Google, and by the openness of standards such as OAuth 2.0. A formal analysis of such protocols must account for malicious websites and their JavaScript, and common website vulnerabilities, such as cross site request forgery and open redirectors.

We present a formal model for web application protocols called WebSpi, implemented as a library for the protocol verification tool ProVerif. We use WebSpi to model and verify several configurations of the OAuth 2.0 protocol. We show that our formal analysis can be used to reconstruct concrete website attacks. Our approach is validated by finding dozens of previously unknown vulnerabilities in popular websites such as Yahoo and Wordpress, when they connect to social networks such as Twitter and Facebook.

We are in discussion with Facebook, Twitter and other websites to address the vulnerabilities found by our analysis. We have submitted a paper describing this work, and plan to release the WebSpi library in 2012.

6.9. Verified Android Cryptographic Applications

**Participants:** Karthikeyan Bhargavan [correspondant], Quentin Lefebvre [MPRI].

With the emergence of application markets for smartphones, hundreds of third-party applications now use cryptography to protect sensitive user data before storing it on disk or sending it out on the network. However, using cryptographic mechanisms correctly to fulfill a desired security goal is challenging and error-prone, even for experts. Our goal is to build verification tools that developers may use to develop security proofs for their applications.

We show how to verify the security of third-party cryptographic applications written in Java for the Android platform. We first develop symbolic security specifications for classes in the JCA. We can then verify that applications that use these libraries satisfy their security goals, even in the presence of a Dolev-Yao adversary who controls the network, the disk, and potentially other applications on the device. We report preliminary verification results using the Krakatoa verification tool for Java programs.

We presented this work at the ASA workshop 2011 [23].

6.10. Logical Auditing of JavaScript Programs for Security

**Participants:** Karthikeyan Bhargavan [correspondant], Sergio Maffeis [Imperial College], Ravinder Shankesi [UIUC].

Client side web applications are error-prone and hard to secure, as proven by frequent vulnerability reports. We experiment with using logical annotations as a means to specify inlined security policies for web pages, and we implement a run-time monitoring system that generates a logical trace of the program execution. Feeding the logical trace to external theorem provers, it is possible to detect, post-facto, violations of the security policies, helping the on-line debugging of web applications.

We present JSTY a browser-based logical auditing framework for JavaScript programs. We show how first-order logic contracts can be used to express cryptographic assumptions and security goals for JavaScript programs that use cryptography. We demonstrate our approach on realistic examples, including browser extensions for password management. We find security vulnerabilities in commercial products by logical auditing. This work is currently unpublished.

6.11. Secure Interpreters for Sessions

**Participants:** James Leifer, Jean Pichon [intern from ENST Telecom ParisTech].
We developed an interpreter for decentralised multi-party sessions. The interpreter takes a graph-based description of a session and provides a high-level interface for sending and receiving messages permissible in the session. The interpreter protects the integrity of session execution in a realistic security setting where an adversary has the ability to: (1) control the network to capture and reinject messages at will, and read and forge messages using leaked cryptographic keys; (2) compromise arbitrary session participants. By producing and verifying cryptographic signatures, the interpreter ensures that all non-compromised participants have consistent views of the session’s execution history.

We previously worked on a session compiler. The compiler took as input “local graphs” described in process-calculus fashion. It produced one F# library for each role, and an F7 interface/specification for this library. If the library typechecked (with the F7 type-checker) against its interface, then it was secure. However, the production of the library was not itself verified, and could fail.

By contrast, this present work is concerned with a session interpreter. This interpreter works like an ML functor (i.e. a compile-time function from modules to modules). It takes as input a module describing a global graph by exposing a specific interface. The application of the interpreter functor to a graph module yields an F$\#$ module that contains the interface/specification. The interpreter functor, being checked against an abstract description of a graph, is typechecked “once and for all”. Because the interpreter functor typechecks against its interface (that contains specifications), it is secure (through refinements). The interpreter functor can then be applied to a concrete session graph to be used.

The interpreter is written in F$\#$, a dialect of ML enriched with refinement types, and its correctness is proven by type annotations.

The interpreter consists of approximately 3000 lines of code.

### 6.12. Models of Audit Logs

**Participants:** Karthikeyan Bhargavan, Cédric Fournet [MSR Cambridge], Nataliya Guts, Francesco Zappa Nardelli.

This line of research was accurately described in last year activity report of Moscova. Here we just mention that Nataliya Guts defended her PhD [19] on "Auditability for security protocols" on January 11th, 2011.
6. New Results

6.1. Modeling XML document transformations

Participants: Joachim Niehren, Sophie Tison, Sławek Staworko, Aurélien Lemay, Anne-Cécile Caron, Yves Roos, Shunichi Amano, Camille Vacher, Benoît Groz, Antoine Ndione, Tom Sebastian.

Query answering on XML streams. In [16], Gauwin and Niehren introduce the notion of finite streamability for query languages, and classify fragments of XPath that are finitely streamable or not. They show that if a query language is finitely streamable, then its satisfiability problem can be solved in polynomial time, which in turn is known to fail for mostly all fragments of XPath. They also show that FXP, the fragment of ForwardXPath with child and descendant axis, conjunction, and negation becomes finitely streamable if bounding the number of conjunctions. Since 3 conjunctions are enough in many practical applications, FXP is most relevant in practice. Without any bound, FXP is not finitely streamable, since its satisfiability problem is DEXPTIME hard. The positive result for FXP with a bounded number of conjunctions is obtained by compilation of FXP to deterministic nested word automata. The compiler is in exponential time in the number of conjunctions, and thus polynomial if this parameter is bounded.

Answer enumeration for n-ary queries. Bagan, Filiot, Gauwin, and Niehren investigated answer enumeration algorithms for dialects of XPath with variables. The problem with n-ary queries is that answer sets may grow exponentially in |t|^n, so that algorithms depending polynomially on the size of the answer set might still be unfeasible. In such case, it might still be possible to enumerate elements of answer sets on need. The question is then whether enumeration can be done efficiently without duplicates and failures, that is with constant delay between subsequent answers and polynomial time preprocessing in the size of the query and the tree. We obtained positive results on answer enumeration with constant delay enumeration for acyclic conjunctive queries over so called X-doublebar structures that we introduce [24]. These subsume tree structures with child, next-sibling and next-sibling* axis, but not the descendant axis. Our result can be lifted to a dialect of ConditionalXPath with variables, that is FO-complete on trees of bounded depth, so that the descendant axis is not needed.

Tree automata global constraints. TAGEDs are a new class of tree automata with constraints that currently receive much interest from top conferences on theoretical computer science. During its postdoc in Lille, Vacher improved complexity bounds for some fragments of decidability results [12].

Sequential tree-to-word transducers. Laurence, Lemay, Niehren, Staworko, Tommasi considered deterministic sequential top-down tree-to-word transducers (STWa), that capture the class of deterministic top-down nested-word to word transducers. While reordering and copying are not allowed, STWa are nevertheless very expressive because they allow concatenation of outputs, deletion of inner nodes and they can produce context free languages as output. Their expressiveness is incomparable with DTOPs (plus concatenation, but minus copying). While objecting for learning algorithms, they study normalization of STWa in a first step and then develop unique minimalization algorithms for normalized STWa in a second step in [19]. The idea of normalization is to produce the output in an earliest manner, when reading the input in document order. This works only on binary trees, but can be lifted to unranked trees modulo the binary top-down encoding. The normalization algorithm is by far nontrivial. The natural continuation of this approach will be toward learning algorithms for earliest STWa.

Access control for XML views. The PhD project of Groz, supervised by Staworko and Tison, is centered on access control for XML databases, and in particular on security of user views over XML documents. He obtained results on query rewriting for read-only queries, and translation for update queries. More precisely, given an XML view definition and a user defined query (resp. update program) q, the problem is to find a source query (resp. update program) that is equivalent to q on the view. Caron, Groz, Roos, Staworko and Tison study update programs and views represented by recognizable tree languages in [15], and devise algorithms for update translation in different settings, namely without or with constraints on the authorised source updates.

Participants: Jérôme Champavère, Jean Decoster, Jean-Baptiste Faddoul, Antonino Freno, Gemma Garriga, Rémi Gilleron, Mikaela Keller, Grégoire Laurence, Aurélien Lemay, Joachim Niehren, Slawek Staworko, Marc Tommasi, Fabien Torre.

Induction of tree automata. Champavère, Gilleron, Lemay and Niehren proposed to use schemas for improving induction algorithms for monadic queries represented by tree automata [26]. The idea is to use pruning strategies to eliminate useless parts of trees when learning from partially annotated trees such that only the structure of relevant fragments is learned. This allows to avoid generalization errors and to learn from fewer annotations. They define schema-guided pruning strategies. They define stable queries w.r.t. a pruning strategy and show that stable queries are learnable.

Further Results. In [21], Staworko proposed learning twig and path queries. Prioritized repairing and consistent query answering in relational databases was tackled in [13] and Bounded repairability for regular tree languages in [20].

Torre and Terlutte explored the combination of automata and words balls for sequences classification in [14].

Tommasi participated in the writing of a chapter of a book on conditional Markov fields for information extraction [23].

Garriga and collaborators from the Fraunhofer Institute in Bonn, studied fixed parameter tractable algorithms for the discovery of maximal order preserving submatrices in bioinformatic applications in [17].

We begun a new activity on learning for social network and information network supported by the arrivals of Gemma GARRIGA, Mikaela KELLER and Antonino FRENO. Freno, Garriga and Keller [22] proposed a model for predicting new links in a network which exploit both the current structure of the network and the content of its node.
6. New Results

6.1. Introduction

Research results are presented according to the research directions of the MYRIADS team.

6.2. Autonomous Management of Virtualized Infrastructures

6.2.1. Cloud Federations

6.2.1.1. Virtual Execution Platforms in Cloud Federations

In the context of the Contrail European project, we have defined the overall architecture of the Contrail software stack for cloud computing on top of cloud federations [51]. We have focused on the design and the implementation of a first basic prototype of the Virtual Execution Platform (VEP) component [52]. It is in charge of provisioning hardware resources from Cloud providers and to deploy and run distributed applications submitted by users under the control of a negotiated Service Level Agreement (SLA) [16]. Within VEP software, REST interface, OVF parsing, SSL security, Authorization modules are under active development and at various levels of integration. A first demo version of VEP running on top of OpenNebula IaaS cloud has been successfully demonstrated at the first annual project review.

6.2.1.2. Efficient virtual cluster migration

We continued our work on Shrinker, a system providing efficient live migration of virtual clusters on wide area networks. The design has been improved to coordinate the deduplication on the source site of the migration. Deduplication is now performed only within an individual virtual cluster, in order to reduce security issues and avoid performance impact on virtual machines of other users. We performed a comprehensive performance evaluation of Shrinker. An article presenting the design, implementation, and performance of Shrinker was published in [28].

6.2.1.3. Elastic Map/Reduce over Cloud Federations

We worked on the development of Resilin, a system to easily create execution platforms over distributed cloud resources for executing MapReduce computations. Resilin implements the Amazon Elastic MapReduce web service API and uses resources from private and community clouds. Resilin takes care of provisioning, configuring and managing cloud-based Hadoop execution platforms, potentially using multiple clouds. An initial implementation of Resilin was presented at the CCA ’11 workshop [36]. Further development was performed in the context of Ancuta Iordache’s master internship. The results of this work were published as a research report [45].

6.2.1.4. Sky Computing Experiments

We continued our collaboration with the University of Florida on sky computing experiments, which led to the publication of a book chapter [38].

6.2.2. Infrastructure as a Service Clouds

Participants: Stefania Costache, Eugen Feller, Yvon Jégou, Christine Morin, Nikos Parlavantzas, Pierre Riteau.
6.2.2.1. Large scale Energy aware self-healing IaaS

The research done in 2011 was two fold. A prototype of the previously proposed scalable, fault-tolerant and energy-aware virtual machine (VM) management framework called Snooze was implemented and evaluated on the Grid5000 testbed [41]. In 2011, we have focused on the implementation of the self-healing mechanisms and protocols, and on integrating in Snooze the system-level mechanisms (e.g. for automatically switching on/off cluster nodes) to support energy aware resource management algorithms. Our experimental results show that the fault-tolerance features of the framework do not impact application performance. Moreover, negligible cost is involved in performing distributed VM management and the system remains highly scalable with increasing amounts of resources. A nature-inspired VM placement algorithm [24] based on the Ant Colony Optimization (ACO) meta-heuristic was developed and evaluated by means of simulations.

6.2.2.2. Resource Management in Private Clouds

We focused on the design of a resource management system for private clouds that provides support for different application SLAs while maximizing the resource utilization of the infrastructure. As we also considered the need of providing users the incentives to truthfully express their valuation for the performance of their application we investigated existing economic models of allocating resources. As a result, we proposed a novel resource management architecture based on a virtual economy. In this system, independent agents monitor the application’s performance and dynamically provision virtual machines from the infrastructure under user’s budget constraints. To provision virtual machines, a proportional share auction is used, allowing a fine-grain resource sharing at a low complexity cost. This work was done as part of a collaboration with EDF R&D and was published at the VHPC 2011 workshop [22]. We have also implemented a first prototype of this proposal. In collaboration with Vydia Rajagopalan (Master student at VU Amsterdam) we have implemented the proportional-share auction scheduler and integrated it with the OpenNebula Virtual Infrastructure Manager. Then, we have extended this work with the design of agents that execute scientific applications (MPI and Bag-of-Task applications) under deadline and budget constraints. Experimental evaluations are currently performed on Grid5000.

6.2.2.3. Resilience

We initiated a collaboration with Box Leangsuksun’s group on high availability of cloud infrastructures. We carried out a preliminary study on how the HA-OSCAR environment developed at the Louisiana Tech University could be used to ensure the high availability of critical services in Nimbus IaaS clouds [30].

6.2.3. XtreemOS Grid Distributed Operating System

**Participants:** Amine Belhaj, Jérôme Gallard, Rémy Garrigue, Yvon Jégou, Christine Morin, Yann Radenac.

6.2.3.1. Facilitating Experiments with XtreemOS Grid System

XtreemOS Grid system that has been developed in the framework of the XtreemOS European project is now evolving as an open source software in a community driven by INRIA in the framework of the XtreemOS Easy ADT. We have provided first level support to users and maintained XtreemOS website, wiki and mailing-lists. We have updated XtreemOS documentation to reflect the evolution of XtreemOS system. We facilitated the access to XtreemOS in three different ways: maintaining an open public testbed running XtreemOS, providing ready-to-use XtreemOS virtual machines and developing tools to automatically deploy XtreemOS Grid system on the Grid’5000 large-scale experimentation platform. In 2011, we have finalized a new 3.0 version of XtreemOS system and ported it on top of the OpenSuse 11.4 Linux distribution. We performed a number of tests to validate the installation, configuration and execution of the new XtreemOS version based on openSuSE Linux distribution. An incremental integration process has been set up to facilitate the integration of patches and bug fixes. We have run a number of experiments with XtreemOS 3.0 based on Mandriva Linux distribution: MPI programs, Salomé numerical simulation platform, bio-informatics applications. Yann Radenac, in the framework of the COOP project funded by ANR contributed to XtreemOS’s code by fixing bugs, cleaning the source code to improve maintainability, and adding a few minor features.
6.2.3.2. Resource Management for Dynamic Applications

In the framework of the COOP project funded by ANR, we compared the features offered by the CooRM resource manager for dynamic applications developed by Christian Perez and Cristian Klein at ENS Lyon with those provided by the XtreamOS Grid system. A plan has been set to adapt CooRM to XtreamOS system and to extend XtreamOS’s API to include a CooRM-like interface [53]. We worked on the definition of a variant of CooRM that can work in the context of XtreamOS Grid operating system.

6.3. Dynamic Adaptation of Service-based Applications

Participants: Françoise André, Djawida Dib, Erwan Daubert, Guillaume Gauvrit, André Lage, Christine Morin, Nikos Parlavantzas, Jean-Louis Pazat, Chen Wang, Mohamed Zouari.

6.3.1. Dynamic Adaptation in a Distributed Operating System

Participants: Françoise André, Djawida Dib, Christine Morin, Nikos Parlavantzas.

We have studied the feasibility to dynamic adapt the features of a distributed operating system using a framework for self-adaptation of service oriented distributed applications [46]. We have focused on the consistency protocols for replicated data in distributed shared memory systems. We have considered two strict consistency protocols, one based on invalidation and one based on broadcast on write operations. The adaptation framework selects one of these two algorithms based on the inter-node data transfer delay. We have implemented a prototype based on Kerrighed single system image operating system for clusters and the SAFDIS adaptation framework. We have integrated a broadcast based consistency protocol in Kerrighed that already implements a write invalidation consistency protocol. We have implemented the adaptation policy in the SAFDIS framework and the needed adaptation mechanisms in Kerrighed as well as a component for monitoring data transmission delays. An experimental evaluation is being carried out.

6.3.2. Adaptation for Data Management

Participants: Françoise André, Mohamed Zouari.

The usage of context-aware data management in mobile environments has been previously investigated by Françoise André in collaboration with Mayté Segarra and Jean-Marie Gilliot from Telecom Bretagne Brest (previously known as ENST Bretagne). This work focuses on data management in grid and mobile environments; an ambient assisted living application illustrates the approach. This work was realized in the context of the ALORAD project (Architecture LOgicielle pour la Réplication Adaptative de Données), financed by the Brittany council. Mayté Segarra from Telecom Bretagne Brest was co-adviser for the PhD thesis of M. Zouari [12].

6.3.3. Adaptation for Service-Oriented Architectures

Participants: Françoise André, Erwan Daubert, Guillaume Gauvrit, André Lage, Nikos Parlavantzas, Jean-Louis Pazat, Chen Wang.

Service-Oriented Computing is a paradigm that is rapidly spreading in all application domains and all environments - grids, clusters of computers, mobile and pervasive platforms. The following works take place in the context of the S-CUBE European Network of Excellence.

6.3.3.1. Services adaptation in distributed and heterogeneous systems

We are still studying service adaptation in distributed and heterogeneous systems. This work covers different aspects such as structural, behavioral and environmental adaptation, distributed decision and planification of adaptation actions, adaptive allocation of resources for services. A framework called SAFDIS for “Self Adaptation For Distributed Services” has been defined and implemented. It is built as a set of services, providing functionalities useful to build an adaptation system. The analysis phase can take reactive as well as proactive decisions. This gives the ability to either react fast or to take decisions for the long term. This implies the ability to analyze the context with a variable depth of reasoning. Our implementation of the SAFDIS analysis phase also distributes and decentralizes its analysis process to spread the computational
load and make the analysis process scalable. The planning phase seeks the set of actions (the plan) needed to
adapt the system according to the strategy chosen by the analysis phase. It also schedules the selected actions
to ensure a coherent and efficient execution of the adaptation. The planning topic is a well known subject in
AI research works and many algorithms already exist in that field to produce efficient schedules. With our
SAFDIS framework, the planning phase is able to reuse these algorithms. The resulting plan of actions can
have actions that can be executed in parallel.

6.3.3.2. Quality Assurance for Distributed Services

In the context of the service-centric paradigm, we have designed and developed the Qu4DS (Quality Assurance
for Distributed Services) research prototype. Qu4DS is a cloud PaaS solution which fills the gap between the
conception of higher-level SaaS service providers over the resource-level PaaS layer. Qu4DS provides an
automatic support for service execution management by aiming at increasing the service provider’s profit.
More specific, Qu4DS dynamically acquires resources according to the customer demand, deploys service
instances and implements QoS assurance mechanisms in order to prevent SLA violations. Moreover, Qu4DS
has been evaluated on Grid5000 and showed to be effective on reducing service provider’s costs [ 27 ].

6.3.3.3. Self-configuration for Cloud Platforms

By definition, cloud computing offers an abstraction to manage various needs and concepts such as distributed
software design, the deployment of such software on dynamic resources and the management of this kind of
resources. Thus it is possible to reconfigure (adapt) according to some needs the software as well as the use
of the resources. However these reconfigurations that are used on different layers may also have impacts on
the others. Moreover these layers are independent and so are able to adapt themselves independently of the
others. In our work, we propose to use some adaptation capabilities offered for example by the infrastructure
(IaaS) that manages the resources to adapt the software (SaaS). We also propose to use planning algorithms to
coordinate the adaptations between them to avoid inconsistency or inefficiency due to concurrent adaptations.

6.3.3.4. Dynamic Adaptation of Chemical services

We have proposed a QoS-aware middleware for dynamic service execution. In the context of dynamic
execution, a workflow is defined by composing a set of abstract activities as place holders. Each activity is
bound to a suitable partner service, which is selected at run-time from a set of functional equivalent candidates
with different non-functional properties such as quality of service (QoS). The service selection process is
modeled as a series of chemical reactions.

6.3.3.5. Prediction of SLA violations and dynamic adaptation in workflows

During execution, run-time QoS is determined by the dynamic execution environment and thus the expected
QoS is not always ensured. In addition, infrastructure failures can make a service undeliverable. The adaptive
execution reflects the capability to recompose a (part of a) workflow on-the-fly in case that global SLA
violation is predicted. Most techniques for predicting global SLA violation require past experiences on
executions of a business process. All historical execution instances have the same structure as well as the
same bindings. These solutions do not adapt to the case of dynamic execution, where for each execution,
partner services are selected and bound at run time.

In order to predict global SLA violation in the context of dynamic service execution, we proposed a 2-phase
prediction technique, which is fit for generic workflow composition. The prediction method works with a high
accuracy for simple workflows, but when the workflow composes complicated structures (such as loops and
exclusive branches), the performance degrades. The reason is that the estimation of global SLA is based on the
critical path, which is not definitely executed. To solve this problem, we propose to use data mining technique
to predict workflow branches and the number of loop execution. Based on predicted branches, the prediction
of global SLA violation is much more accurate. The numerical evaluation will be carried out in the near future.

6.4. A Chemical Approach for Autonomous Service Computing

Participants: Héctor Fernandez, Marko Obrovac, Thierry Priol, Cédric Tedeschi.
6.4.1. Chemistry-Inspired Workflow Management System for e-Science Applications

Participants: Héctor Fernandez, Cédric Tedeschi, Thierry Priol.

In the research track that aims at leveraging the properties of the chemical Programming models for autonomic computing, we have built a software based on the HOCL compiler (part of the HOCL-tools) that was actually deployed and experimented over the Grid'5000 platform. The experiments have shown, that envisioning the execution workflow as an autonomic chemical process is actually viable in practice. Experimeneted with different well known workflow-based e-Science applications, the software showed a performance level comparable to current top-rated scientific workflow management systems [25].

6.4.2. Solving Workflow Patterns Through Molecular Composition

Participants: Héctor Fernandez, Cédric Tedeschi, Thierry Priol.

In the same area, but on a more conceptual point of view, we have shown how the expressive power of the chemical model can be leveraged to solve complex workflow patterns. This aspect was also integrated into the HOCL-tools and experimented over the Grid'5000 platform, following two architectures with a different level of decentralization, showing the advantages and drawbacks of decentralizing the workflow execution using a chemical workflow engine [26].

6.4.3. Scalable Atomic Capture of Molecules

Participants: Marko Obrovac, Cédric Tedeschi.

Capturing the reactants involved in a reaction constitutes one of the main challenges in the execution of chemical programs. Doing it at large scale is one of the essential barriers hindering the actual execution of chemical programs at large scale. We proposed a protocol solving this issue on top of a distributed hash table (DHT). The DHT secures the scalability of the communications and provides a scalable discovery of reactants. Our protocol is triggered once reactants are found. It is made of two sub-protocols being used at different stages of the computation, according to the density of possible reactions. The protocol is validated through its proof of liveness and simulations showing that it is able to switch from one sub-protocol to the other efficiently, according to the execution’s conditions [18].
6. New Results

6.1. Discontinuous Galerkin methods for Maxwell’s equations

6.1.1. DGTD-$P_p$ method based on hierarchical polynomial interpolation

**Participants:** Loula Fezoui, Joseph Charles, Stéphane Lanteri.

The DGTD (Discontinuous Galerkin Time Domain) method originally proposed by the team for the solution of the time domain Maxwell’s equations [14] relies on an arbitrary high order polynomial interpolation of the component of the electromagnetic field, and its computer implementation makes use of nodal (Lagrange) basis expansions on simplicial elements. The resulting method is often denoted by DGTD-$P_p$, where $p$ refers to the interpolation degree that can be defined locally i.e. at the element level. In view of the design of a $hp$-adaptive DGTD method, i.e. a solution strategy allowing an automatic adaptation of the interpolation degree $p$ and the discretization step $h$, we now investigate alternative polynomial interpolation and in particular those which lead to hierarchical or/and orthogonal basis expansions. Such basis expansions on simplicial elements have been extensively studied in the context of continuous finite element formulations (e.g. [46]) and have thus been designed with global conformity requirements (i.e. $H_1$, $H$(rot) or (div)) whose role in the context of a discontinuous Galerkin formulation has to be clarified. This represents one of the objectives of this study.

![Figure 3. Scattering of a plane wave by a business aircraft geometry computed by DGTD-$P_1$ method on a tetrahedral mesh. Contour lines of the amplitude of the electric field.](image)

6.1.2. DGTD-$P_pQ_k$ method on multi-element meshes

**Participants:** Clément Durochat, Stéphane Lanteri, Claire Scheid, Mark Loriot [Distene, Pôle Teratec, Bruyères-le-Chatel].
In this work, we study a multi-element DGTD method formulated on a hybrid mesh which combines a structured (orthogonal) quadrangulation of the regular zones of the computational domain with an unstructured triangulation for the discretization of the irregularly shaped objects. The general objective is to enhance the flexibility and the efficiency of DGTD methods for large-scale time domain electromagnetic wave propagation problems with regards to the discretization process of complex propagation scenes. As a first step, we have designed and analyzed a DGTD-$P_pQ_k$ method formulated on conforming hybrid quadrangular/triangular meshes for the solution of the 2D Maxwell’s equations.

6.1.3. DGTD-$P_p$ method for dispersive materials

**Participants:** Claire Scheid, Maciej Klemm [Communication Systems & Networks Laboratory, Centre for Communications Research, University of Bristol, UK], Stéphane Lanteri.

This work is undertaken in the context of a collaboration with the Communication Systems & Networks Laboratory, Centre for Communications Research, University of Bristol (UK). This laboratory is studying imaging modalities based on microwaves with applications to dynamic imaging of the brain activity (Dynamic Microwave Imaging) on one hand, and to cancerology (imaging of breast tumors) on the other hand. The design of imaging systems for these applications is extensively based on computer simulation, in particular to assess the performances of the antenna arrays which are at the heart of these systems. In practice, one has to model the propagation of electromagnetic waves emitted from complex sources and which propagate and interact with biological tissues. In relation with these issues, we study the extension of the DGTD-$P_p$ method originally proposed in [14] to the numerical treatment of electromagnetic wave propagation in dispersive media. We consider an approach based on an auxiliary differential equation modeling the time evolution of the electric polarization for a dispersive medium of Debye type (other dispersive media will be considered subsequently). This work comprises both theoretical aspects (stability and convergence analysis) of the resulting DGTD-$P_p$ method for the time domain Maxwell equations for dispersive media, and application aspects [35].

6.1.4. DGFD-$P_p$ method for the frequency domain Maxwell equations

**Participants:** Victorita Dolean, Mohamed El Bouajaji, Stéphane Lanteri, Ronan Perrussel [Laplace Laboratory, INP/ENSEEIHT/UPS, Toulouse].

![Figure 4. Scattering of a plane wave by a perfectly conducting cylinder computed by a DGTD-$P_2Q_4$ method on a hybrid triangular-quadrangular mesh.](Image)
For certain types of problems, a time harmonic evolution can be assumed leading to the formulation of the frequency domain Maxwell equations, and solving these equations may be more efficient than considering the time domain variant. We are studying a high order Discontinuous Galerkin Frequency Domain (DGFD-$P_p$) method formulated on triangular meshes for solving the 2D time harmonic Maxwell equations [16]. This work is undertaken in the context of the ANR MAXWELL project whose objective is the development of an ultra wideband georadar system for imaging the subsurface. In this context, the DGFD-$P_p$ method that we have proposed is used as the forward solver in an inversion process for the electric permittivity [17].

6.1.5. Hybridized DGFD-$P_p$ method

Participants: Stéphane Lanteri, Liang Li, Ronan Perrussel [Laplace Laboratory, INP/ENSEEIHT/UPS, Toulouse].

One major drawback of DG methods is their intrinsic cost due to the very large number of globally coupled degrees of freedom as compared to classical high order conforming finite element methods. Different attempts have been made in the recent past to improve this situation and one promising strategy has been recently proposed by Cockburn et al. [40] in the form of so-called hybridizable DG formulations. The distinctive feature of these methods is that the only globally coupled degrees of freedom are those of an approximation of the solution defined only on the boundaries of the elements. This work is concerned with the study of such Hybridizable Discontinuous Galerkin (HDG) methods for the solution of the system of Maxwell equations in the time domain when the time integration relies on an implicit scheme, or in the frequency domain. As a first step, HDGTD and HDGFD [33] methods have been developed for the solution of the 2D propagation problems.

6.1.6. Exact transparent condition in a DGFD-$P_p$ method

Participants: Mohamed El Bouajaji, Nabil Gmati [ENIT-LAMSIN, Tunisia], Stéphane Lanteri, Jamil Salhi [ENIT-LAMSIN, Tunisia].

In the numerical treatment of propagation problems theoretically posed in unbounded domains, an artificial boundary is introduced on which an absorbing condition is imposed. For the frequency domain Maxwell equations, one generally use the Silver-Müller condition which is a first order approximation of the exact radiation condition. Then, the accuracy of the numerical treatment greatly depends on the position of the artificial boundary with regards to the scattering object. In this work, we have conducted a preliminary study aiming at improving this situation by using an exact transparent condition in place of the Silver-Müller condition. Promising results have been obtained in the 2D case and call for an extension of this work to the more challenging 3D case.

6.2. Discontinuous Galerkin methods for the elastodynamic equations

6.2.1. DGTD-$P_p$ method for the elastodynamic equations

Participants: Nathalie Glinsky, Fabien Peyrusse.

We continue developing high order non-dissipative discontinuous Galerkin methods on simplicial meshes for the numerical solution of the first order hyperbolic linear system of elastodynamic equations. These methods share some ingredients of the DGTD-$P_p$ methods developed by the team for the time domain Maxwell equations among which, the use of nodal polynomial (Lagrange type) basis functions, a second order leap-frog time integration scheme and a centered scheme for the evaluation of the numerical flux at the interface between neighboring elements. Recent results concern two particular points.

The first novelty is the extension of the DGTD-$P_p$ method initially introduced in [5] to the numerical treatment of viscoelastic attenuation. For this, the velocity-stress first order system is completed by additional equations for the anelastic functions describing the strain history of the material. These additional equations result from the rheological model of the generalized Maxwell body and permit the incorporation of realistic attenuation properties of viscoelastic material accounting for the behaviour of elastic solids and viscous fluids. In practice, one needs to add 3L additional equations in 2D and 6L in 3D, where L is the number of relaxation mechanisms of the generalized Maxwell body. This method has been implemented in 2D and validated thanks to comparisons with a FDTD method.
The second contribution is concerned with the numerical assessment of site effects especially topographic effects. The study of measurements and experimental records proved that seismic waves can be amplified at some particular locations of a topography. Numerical simulations are exploited here to understand further and explain this phenomenon. The DGTD-$P_p$ method has been applied to a realistic topography of Rognes area (where the Provence earthquake occurred in 1909) to model the observed amplification and the associated frequency. Moreover, the results obtained on several homogeneous and heterogeneous configurations prove the influence of the medium in-depth geometry on the amplifications measures at the surface [26], [25].

6.3. Time integration strategies and resolution algorithms

6.3.1. Hybrid explicit-implicit DGTD-$P_p$ method

**Participants:** Stéphane Descombes, Stéphane Lanteri, Ludovic Moya.

Existing numerical methods for the solution of the time domain Maxwell equations often rely on explicit time integration schemes and are therefore constrained by a stability condition that can be very restrictive on highly refined meshes. An implicit time integration scheme is a natural way to obtain a time domain method which is unconditionally stable. Starting from the explicit, non-dissipative, DGTD-$P_p$ method introduced in [14], we have proposed the use of a Crank-Nicolson scheme in place of the explicit leap-frog scheme adopted in this method [4]. As a result, we obtain an unconditionally stable, non-dissipative, implicit DGTD-$P_p$ method, but at the expense of the inversion of a global linear system at each time step, thus obliterating one of the attractive features of discontinuous Galerkin formulations. A more viable approach for 3D simulations consists in applying an implicit time integration scheme locally i.e. in the refined regions of the mesh, while preserving an explicit time scheme in the complementary part, resulting in an hybrid explicit-implicit (or locally implicit) time integration strategy. Such an approach, combining a leap-frog scheme and a Crank-Nicolson scheme, has been studied numerically in [6], showing promising results which have motivated further investigations on theoretical issues (especially, convergence in the ODE and PDE senses) [28].

6.3.2. Explicit local time stepping DGTD-$P_p$ method

**Participants:** Joseph Charles, Julien Diaz [MAGIQUE-3D project-team, INRIA Bordeaux - Sud-Ouest], Stéphane Descombes, Stéphane Lanteri.

We have initiated this year a collaboration with the MAGIQUE-3D project-team aiming at the design of local time stepping strategies inspired from [41] for the time integration of the system of ordinary differential equations resulting from the discretization of the time domain Maxwell equations in first order form by a DGTD-$P_p$ method. A numerical study in one- and two-space dimensions is underway.

6.3.3. Optimized Schwarz algorithms for the frequency domain Maxwell equations

**Participants:** Victorita Dolean, Mohamed El Bouajaji, Martin Gander [Mathematics Section, University of Geneva], Stéphane Lanteri, Ronan Perrussel [Laplace Laboratory, INP/ENSEEIHT/UPS, Toulouse].

We continued with the design of optimized Schwarz algorithms for the solution of the frequency domain Maxwell equations. In particular, we have analyzed a family of methods adapted to the case of conductive media [21]. Besides, we have also proposed discrete variants of these algorithms in the framework of a high order discontinuous Galerkin discretization method formulated on unstructured triangular meshes for the solution of the 2D time harmonic Maxwell equations.

6.4. High performance computing

6.4.1. High order DGTD-$P_p$ method on hybrid CPU/GPU parallel systems

**Participants:** Tristan Cabel, Stéphane Lanteri.
Modern massively parallel computing platforms most often take the form of hybrid shared memory/distributed memory heterogeneous systems combining multi-core processing units with accelerator cards. In particular, graphical processing units (GPU) are increasingly adopted in these systems because they offer the potential for a very high floating point performance at a low purchase cost. DG methods are particularly appealing for exploiting the processing capabilities of a GPU because they involve local linear algebra operations (mainly matrix/matrix products) on relatively dense matrices whose size is directly related to the approximation order of the physical quantities within each mesh element. We have initiated this year a technological development project aiming at the adaptation to hybrid CPU/GPU parallel systems of a high order DGTD-$p$ method for the numerical solution of the 3D Maxwell equations.
6. New Results

6.1. Algorithms for molecular modeling and simulation

6.1.1. Interactive quantum chemistry

Participants: Maël Bosson, Caroline Richard, Antoine Plet, Sergei Grudinin, Stéphane Redon.

We have proposed what appears to be the first algorithm for interactive quantum chemistry simulation at the Atom Superposition and Electron Delocalization Molecular Orbital (ASED-MO) level of theory. When drawing and editing molecular systems, interactive quantum chemistry provide immediate, intuitive feedback on chemical structures. Our method is based on the divide-and-conquer (D&C) approach, which we show is accurate and efficient for this non-self-consistent semi-empirical theory. The errors induced by the D&C approach have been studied empirically and via a theoretical study of two toy models. With this method, we have demonstrated interactive quantum chemistry simulations for systems up to a few hundred atoms on a current multicore desktop computer. As the number of cores on personal computers increases, and larger and larger systems can be dealt with, we believe such interactive simulations – even at lower levels of theory – should thus prove most useful to effectively understand, design and prototype molecules, devices and materials. This result has been published in Journal of Computational chemistry [4]. Figure 7 illustrates an interactive modeling session with a benzene molecule.

Figure 7. Interactive modeling session. After breaking a benzene cycle, the user moves a hydrogen atom closer to the top carbon atom to force them to bond (a). Then, the user pulls on a carbon atom to form a fulvene molecule (b-d). Interactive electronic structure calculations allow the user to easily build plausible topologies, and get immediate feedback on the chemical structure.

6.1.2. Adaptively Restrained Particle Simulations

Participants: Svetlana Artemova, Stéphane Redon.

Particle simulations are widely used in physics, chemistry, biology [17], [21], and even computer graphics [13]. However, many important problems still constitute significant computational challenges, including molecular docking, protein folding, diffusion across bio-membranes, fracture in metals, ion implantation, etc. Numerous methods have been developed to accelerate particle simulations, by e.g. increasing the simulation’s time step [18], [9], [14], [26], [27], [24], improving the computational complexity of the simulation [32], [15], [8], [10], [31], or simplifying the system under study [19], [29], [28], [16], [11], [31], in particular via coarse-graining methods [20], [33], [30] or multiscale and multiresolution methods [25], [22], [23], [12].
We have introduced a novel, general approach to speed up particle simulations that we call Adaptively Restrained Particle Simulations (ARPS).

Our approach works by adaptively switching positional degrees of freedom on and off repeatedly during a simulation, while letting momenta evolve. The benefits of this approach are that (a) it is mathematically grounded and is able to produce stable, energy-preserving simulations; (b) it does not require modifications to the simulated interaction potential, so that any suitable existing force-field can be directly used with ARPS; (c) under frequently-used assumptions on the interaction potential, ARPS make it possible to reduce the number of forces that have to be updated at each time step, which may significantly speed up simulations; (d) when performing constant-energy simulations, ARPS allow users to finely and continuously trade between precision and computational cost, and rapidly obtain approximate trajectories; (e) the trade-off between precision and cost may be chosen for each particle independently, so that users may arbitrarily focus ARPS on specific regions of the simulated system (e.g. a polymer in a solvent); (f) most important, when performing Adaptively Restricted Molecular Dynamics (ARMD) in the canonical (NVT) ensemble, unbiased statistics can be obtained.

We have illustrated ARPS on several numerical experiments, including a shock propagation example and a polymer-in-solvent study.

The shock propagation example demonstrates how ARPS make it possible to smoothly trade between precision and speed (Fig. 8). The polymer-in-solvent study shows how one may collect unbiased statistics with ARPS, and demonstrates that it can be done faster than with usual (reference) simulations, The results are shown in Fig. 9.

These results have been submitted for publication.

6.1.3. Adaptive interactive quantum chemistry

Participants: Maël Bosson, Sergei Grudinin, Stéphane Redon.

We are now working on applying the adaptive paradigm to the quantum chemistry methods, to allow for interactive editing of systems of any sizes and shapes. We are developing new methods and criteria to adaptively focus the computational resources on the most relevant parts of the system. Figure 10 illustrates our recent results in this direction. In this framework, we can already achieve interactive rates and efficient virtual prototyping for systems of size up to thousand atoms on a current desktop computer.

6.1.4. Interactive molecular modeling with haptic feedback

Participants: Aude Bolopion, Barthelemy Cagneau, Stéphane Regnier, Stéphane Redon.
Figure 9. Computing the hydrodynamic radius $R_H$ of a solvated polymer. Traditional simulations reduce the variance more at each time step (top), but adaptively restrained (AR) simulations perform many more time steps, so that they reduce the variance faster in wall-clock time (bottom). In this example, for any target precision, AR simulations compute the hydrodynamic radius four times faster than reference simulations.

Figure 10. Interactive electronic structure calculations in SAMSON. In this example the system is divided in four subsystems (for which the bounded boxes are displayed). The electronic structure is adaptively updated and the geometry is being optimized while the user edits the molecular system. Because the user pulls on one atom in the left part of the system, the electronic structure is accurately recomputed for the most left subsystem (atoms in red). In the neighboring subsystem, the electronic structure is updated with a cheaper model (carbon atoms are in black and hydrogen in white). In the right part of the system, the user force do not have a sufficiently large impact and atoms as well as the electronic structure are frozen (frozen atoms are displayed in blue).
In collaboration with ISIR in Paris and LISV in Versailles, we have developed a new approach for haptic interaction with molecular systems. Molecular interactions typically have a high dynamic range (HDR), combining short-range stiff repulsive effects with long-range, soft attractive and repulsive terms. As a result, faithful haptic rendering of such molecular interactions is both important and difficult, in particular in applications where the precise perception of molecular forces is necessary (e.g. in molecular docking simulations). Traditionally, teleoperation coupling using constant gain control schemes have limited applications since they are unable to transmit to users low attractive forces without truncating repulsive ones. Furthermore, constant scaling displacement induces either instability or time-consuming experiments (displacements are slow), which deteriorates the ease of manipulation. We have described a variable gain haptic coupling method specifically designed to render high dynamic range (molecular) forces. The proposed method has been evaluated by user tests on an experiment involving two water molecules. We have observed that variable force amplification is widely appreciated, whereas variable displacement scaling is appropriate only for users that are already familiar with haptic manipulation. A complex experiment on a HIV molecule has been carried out using this variable gain system. This approach has been published in the proceedings of the 2011 World Haptics Conference [7]. Figure 11 shows SAMSON being used with a haptic interface at ISIR.

6.2. Algorithms for molecular docking

6.2.1. Prediction of Interface Water Molecules Using a Knowledge Base

Participants: Georgiy Derevyanko, Sergei Grudinin.

We developed a method to predict positions for interface water molecules as part of the predicted protein-protein complex. For this purpose we used a previously developed knowledge-base scoring methodology. First, we constructed a training set of non-homologous protein complexes with interfacial water. Then, we deduced the water-protein interaction energy using this training set. And finally, we positioned water molecules around a test protein complex on a regular grid and optimized their positions according to the knowledge-based water-protein interaction energy. This method was validated in a recent CAPRI competition. Figure 12 illustrates our method on a test protein.
Figure 12. Densities of interface water molecules around a test protein computed using our water-protein knowledge-based potential.
6.2.2. Development of a Knowledge-Based Scoring Function

Participants: Georgiy Derevyanko, Sergei Grudinin.

We developed a new method to obtain a knowledge-based potential function for protein-protein interactions. To derive such a potential, we formulated a convex quadratic programming problem with about 1,000,000 of linear constraints and developed a fast iterative solver to solve it. We validated this scoring function in the CAPRI competition Round 24, where our prediction of the Target 50 was ranked 4th.

Figure 13 shows the use of Legendre polynomials to fit statistics obtained on the knowledge base.

6.2.3. Development of a Local Knowledge-Based Potential for Structure Optimization and Prediction of Point Mutations in a Protein

Participants: Petr Popov, Sergei Grudinin.

We developed and validated a method that reconstructs the shape of the binding potential function between two proteins by locations of its global minima. After, we used the obtained potential function for optimization of positions of two docking partners. We demonstrated that using our method we can significantly improve the quality of predictions of such widely-used docking algorithms as HEX and ZDOCK. We validated this method in the CAPRI competition Round 26, where our re-scoring prediction of the Target 53 was ranked 3rd.

We have also developed a method to predict the influence of point mutations on the binding affinity constant of a protein complex. First, we made point mutations and reconstructed the sidechain of the mutated residue. Then, we repacked the sidechains that are within a certain cutoff distance from the mutated residue. After, we optimized the structure of two proteins using a smooth pair-additive knowledge-based potential function. We iteratively repeated the two previous steps until convergence of the binding energy. Finally, we converted the obtained binding energy into the binding affinity constant of two proteins. We validated this method in the CAPRI competition Round 26 with the Targets 55 and 56.

Figure 14 shows an interactive docking session using a knowledge-based potential for CAPRI Round 26 Target 53.

6.3. Software engineering

6.3.1. SAMSON’s architecture

Participant: Stéphane Redon.
The data model of SAMSON has been expanded. The goal is to represent a nanosystem as the union of several interacting models: *structural models* (geometrical and topological information, to define relationships between structural elements), *dynamical models* (to define kinematical and dynamical relationships between structural components), *interaction models* (to define physical interactions between dynamical components, e.g. forces between atoms or rigid bodies), and *visual models* (visual representations, for user interaction).

All models are part of the *data graph*, which contains all the information related to the system being modeled. The referencing system has been significantly expanded, with data structures to safely handle objects creation and deletion. An *event mechanism* has been designed and added to SAMSON, so that nodes of the data graph may send messages to each other. These messages can be related to topological changes, structural changes, dynamical changes, etc.

### 6.3.2. SAMSON’s software engineering process

**Participants:** Jocelyn Gaté, Stéphane Redon.

SAMSON’s software development process has been much improved. CMAKE is used to ensure that all parts of SAMSON may easily be built on several platforms (Windows, Mac and Linux). Thanks to CMAKE, a variety of Integrated Development Environments may be used (Visual Studio, Eclipse, XCode, etc.).

CTEST and CDASH are used to test SAMSON, and the Pipol platform has been used to perform nightly builds.

### 6.3.3. Graphical User Interface design

**Participants:** Jocelyn Gaté, Stéphane Redon.

Several functionalities have been added to the graphical interface of SAMSON, including customizable toolbars (that plug-in developers will be able to modify), as well as a data graph view (Figure 15).
Also, because plug-ins might have complex interfaces and settings, a mechanism to save and load custom presets has been developed (Fig. 16).

6.4. Applications

Methods and tools developed in our group have been used in the following studies:

6.4.1. Building Blocks of Bacterial Chemoreceptor Arrays

Participant: Sergei Grudinin.
Bacterial chemoreceptors are known to cluster at the cell poles where they form partially hexagonally ordered arrays. This clusterisation is important for the function of chemotaxis system. In this study, we performed an analysis of the known structural and biochemical information on the components of chemoreceptor arrays: chemoreceptors themselves, histidine kinases and adapter proteins. Based on this analysis, we proposed a set of basic interactions within the chemotaxis system (the array building blocks) and constructed their atomistic models. The models resulting from these blocks are in agreement with experimental information and provide a basis for understanding the atomic-level structural organization of chemoreceptor arrays.

6.4.2. A Novel Dimerization Interface of Cyclic Nucleotide Binding Domain

Participant: Sergei Grudinin.

Cyclic nucleotide binding domain (CNBD) is a ubiquitous domain of effector proteins involved in signalling cascades of prokaryota and eukaryota. In this study, we described a novel CNBD dimerization interface found in crystal structures of bacterial CNG channel MlotiK1 and mammalian second messenger cAMP-activated guanine nucleotide-exchange factor Epac2. Using computational tools we demonstrated that the found interface is stable, in contrast to the dimerization interface reported previously. Comparisons with cN-bound structures of CNBD showed that the dimerization is incompatible with second messenger cAMP binding. Thus, the cAMP-dependent monomerization of CNBD may be an alternative mechanism of the cAMP sensing. Based on these findings, we proposed a model of the bacterial CNG channel modulation by cAMP.
6. New Results

6.1. Communication and control co-design for networked systems

6.1.1. Energy-aware communication and control co-design in wireless networked control systems

Participants: C. Canudas de Wit [Contact person], N. Cardoso de Castro, F. Garin.

This work is the topic of the PhD thesis of N. Cardoso de Castro. We have considered an event-based approach to energy-efficient management of the radio chip in the sensor node of a wireless networked control system [54], [66]. Indeed, as we had pointed out in the review paper [67], the radio is the main energy consumer, and intermittent data transmission allows one to reduce the use of the radio. While the existing literature in the control community on event-based control only addresses policies using two radio-modes (Transmitting/Sleep), our work follows some considerations on the radio-chip modes well-known in the communication networks literature, and introduces some intermediate radio-modes, which consume more energy than ‘Sleep’ but allow to reach the transmitting mode consuming less energy in the transition. We propose an event-based radio-mode switching policy, which allows to perform a trade-off between energy saving and performance of the control application. To this end, a switched model describes the system, taking into account control and communication. The optimal switching policy is computed using Dynamic Programming. This work is described in [66] and in a journal paper (in preparation). A further research direction is the exploration of receding-horizon techniques (Model Predictive Control), to solve a slightly modified formulation of the same problem. This research is in collaboration with Dr. Daniel Quevedo, senior lecturer at the University of Newcastle, Australia, in particular during a three-months visit of N. Cardoso de Castro at University of Newcastle.

6.1.2. Adaptive Delta Modulation in Networked Controlled Systems with bounded disturbances

Participants: C. Canudas de Wit [Contact person], F. Gomez-Estern [University of Sevilla], F. R. Rubio [University of Sevilla].

In the context of communication and control co-design for networked systems, this work investigates the closed-loop properties of the differential coding scheme known as Delta Modulation when used in feedback loops within the context of linear systems controlled through a communication network [19]. We propose a new adaptive scheme with variable quantization step, by defining an adaptation law exclusively in terms of information available at both the transmitter and receiver. With this approach, global asymptotic stability of the networked control system is achieved for a class of controllable (possibly unstable) linear plants. Moreover, thanks to the globally defined switching policy, this architecture enjoys a disturbance rejection property that allows the system to recover from any finite–time unbounded disturbance or communication loss.

6.1.3. Control, communication, computation (3C) co-design: Multi-level classification and formulation

Participants: C. Canudas de Wit [Contact person], A. Farhadi [University of Melbourne].

We introduce here an integration framework for Control/Communication/Computation (3C) co-design based on the motivating example of fleet control of Autonomous Underwater Vehicles (AUVs) [35], [75]. Specifically, we address the problem of almost sure stability of an unstable system with multiple observations over packet erasure channel, with emphasis on coding computational complexity. We look at the tradeoff between duty cycle for feedback channel use, coding computational complexity, and performance. We compare coding computational complexity and performance for two cases: a) No feedback channel at all, and b) Feedback channel all the time. It is shown that the strategy of using feedback channel results in a better performance.
6.2. Collaborative distributed consensus algorithms for control and estimation

6.2.1. Distributed Control

**Participants:** A. Seuret [Contact person], C. Canudas de Wit, L. Briñón Arranz, G. Rodrigues de Campos, K. H. Johansson [KTH].

The first contribution in this area deals with the source-seeking problem in which the task is to locate the source of some signal using a fleet of autonomous underwater vehicles. The objective is here to use the underwater vehicles equipped with appropriate sensors as a mobile sensors network. In [28] and [29], we present a method which allows estimating the gradient of the signal propagation using a distributed consensus filters [27]. To do so, we consider a group of vehicles uniformly distributed in a fixed circular formation. We then show that this distributed consensus algorithm converges to good approximation of the gradient of the signal propagation. The algorithm takes into account the communication constraints and depends on direct signal measurements. Our approach is based on the previous results in formation control to stabilize the fleet to elastic formations which can be time-varying [29] and in a collaborative source-seeking algorithm proposed earlier by members of the team. The results are supported through computer simulations.

The second contribution on collaborative control concerns the design and analysis of a distributed algorithm whose goal is symmetric robot deployment. This activity results from the collaboration between INRIA and KTH provided by the visit of G. Rodrigues de Campos (PhD student) at KTH during six month. The objective is here to propose a hierarchical control strategy composed of two stages. The first one corresponds to an algorithm for swarm dispersion and a second concerns the design of a additional algorithm which minimizes the inter-agent angles. In this context, the behavior of each vehicle depends only on the relative positions of agents it can sense. The article submitted to ICRA’12 [84], presents some simulation examples for different configuration support the derived theoretical results.

6.2.2. Distributed Estimation

- Collaborative protocols for estimation and control
  **Participants:** A. Kibangou [Contact person], A. L. F. Almeida [Universidade Federal do Ceara].

  In wireless communication systems, spatial diversity plays a key role in combating signal fading arising from multipath propagation. As long as the transmitter is equipped with multiple antennas, it is well known that spatial diversity can be exploited further at the transmitter by means of space-time coding [88]. In contrast to conventional (single-user) space-time coding/decoding, when dealing with cooperative wireless networks, spatial diversity must resort to distributed space-time coding/decoding, where a collection of distributed antennas belonging to multiple terminals work in a coordinated way to encode/decode the transmitted information [85].

  For this purpose, we have extended the Khatri-Rao Space time coding method proposed in [86] to cooperative networks (see Fig. 5). For cooperating nodes having a single antenna, these nodes constitute a virtual antenna array at both transmitting and receiving front-end. At each node, the received data can be viewed as slices of a third-order tensor. Therefore, retrieving the informative data is achieved by means of a CP tensor decomposition using an Alternating Least Squares (ALS) algorithm for example. When all the slices cannot be gathered at the same node, for storage resources limitations for example, a distributed ALS method can be used as in [77], which is an average consensus based method. In a consensus problem, a group of network nodes try to reach agreement on a given quantity of interest that depends on their local values [79]. Instead of using a standard consensus method where convergence is achieved asymptotically, we have proposed a finite time average consensus approach that relies on the knowledge of the graph topology. The proposed algorithm and its performance evaluation by means of simulations are described in [37].

- Kalman filtering based distributed fault detection and isolation
  **Participants:** A. Kibangou [Contact person], F. Garin, S. Hachour, A. Esna Ashari.

  This year, we have started a research activity related to distributed fault detection and isolation. Our first work has been the master thesis of S. Hachour on the monitoring of a solar farm.
Indeed, stimulated by increasing energy demand and ecological concerns, clean energy production with renewable resources is a key research topic that presents a largely unexplored potential of development.

For this purpose, solar farms constitute power plants of the future. In such systems, electricity is produced thanks to the combined action of a large number of interconnected modules (solar panels). Each module individually produces energy, but only their interconnection allows reaching the global task of a relevant energy production. Due to the interconnection topology, a local fault on a given module can induce damageable effects on the whole network. In order to detect and localize a fault, a sensor network can be deployed over the farm. Thanks to the recent advances in wireless communications, the sensors can be equipped with wireless devices, creating a network of communicating sensors. A classical way to exploit such a network would be to create a hierarchical (tree-like) structure which conveys all measurements to a centralized computer which would analyze all data. However, a failure in a communication link or in the centralized computer would result in breakdown of the whole fault detection system, which is an unacceptable risk in an application domain of strategic importance such as a power plant. Therefore we have proposed a decentralized approach that relies on local data aggregation using the computing and communicating resources of the sensor nodes. As a consequence, nodes cooperation produces a global decision, available at each point of the network, and computable even in the case where a few sensors or links are unavailable. The monitoring procedure is achieved in a distributed way using a Kalman filtering approach. Now, by considering the sensor network as the system of interest, we try to derive distributed estimation methods that are robust to malicious entities and monitoring methods to detect anomalies in the system due to these malicious entities or malfunctioning of the network. These issues are addressed by A. Esna Ashari during his post-doctoral stay in our team.

6.2.3. Distributed Consensus

- Finite-time distributed average consensus on sensor networks
  
  **Participant:** A. Kibangou [Contact person].

Nowadays, several distributed estimation algorithms are based on the average consensus concept. Average consensus can be reached using a linear iterations scheme where each node repeatedly
updates its value as a weighted linear combination of its own value and those of its neighbors. The main benefit of using a linear iterations scheme is that, at each time-step, each node only has to transmit a single value to each of its neighbors. Based on such a scheme, several algorithms have been proposed in the literature. However, in the majority of the proposed algorithms the weights are chosen so that all the nodes asymptotically converge to the same value. Sometimes, consensus can be embedded as a step of more sophisticated distributed algorithm as it is the case for the Distributed Kalman filter [80] and the Distributed Alternating Least Squares algorithm [77]. Obviously, asymptotic convergence is not suitable for these kinds of distributed methods. Even though, speed convergence of consensus algorithm have been explored in [78] and [91] with the goal to derive fast consensus algorithms, running standard consensus in finite-time constitute a source of errors not easily quantifiable. Sometimes, bounds can be derived. Therefore, it is interesting to address the question of exact consensus in finite-time.

For time-invariant network topologies and in the perfect information exchange case, i.e. without channel noise nor quantization, we have shown that the finite-time average consensus problem can be solved as a matrix factorization problem with joint diagonalizable matrices depending on the Graph Laplacian eigenvalues [38], [48]. Moreover, the number of iterations is equal to the number of distinct nonzero eigenvalues of the graph Laplacian matrix. Then, by periodically restarting the consensus algorithm, we have also shown that, in the noisy case, exact average consensus can be achieved asymptotically.

- Quadratic indices for performance evaluation of consensus algorithms

**Participants:** F. Garin [Contact person], S. Zampieri [Università di Padova], E. Lovisari [Università di Padova].

Traditional analysis of linear average-consensus algorithms studies, for a given communication graph, the convergence rate, given by the essential spectral radius of the transition matrix (i.e., the second largest eigenvalues’ modulus). For many graph families, such analysis predicts a performance which degrades when the number of agents grows, basically because spreading information across a larger graph requires a longer time. However, when considering other well-known quadratic performance indices (involving all the eigenvalues of the transition matrix), the scaling law with respect to the number of agents can be different. This is consistent with the fact that, in many applications, for example in estimation problems, it is natural to expect that a larger number of cooperating agents has a positive, not a negative effect on performance. It is natural to use a different performance measure when the algorithm is used for different purposes, e.g., within a distributed estimation or control algorithm. Examples of various relevant costs can be found in the book chapter [50] and in the references therein.

We are interested in evaluating the effect of the topology of the communication graph on performance, in particular for large-scale graphs. Motivated by the study of wireless sensor networks, our main objective is to understand the limitations which arise when agents are limited to truly local interactions, i.e., the neighborhoods are determined by being ‘near’ in a geometric (Euclidean) way, differently from graphs with few but possibly ‘distant’ connections, such as in small world models. At first [18] we consider graphs which are regular lattices (infinite lattices, or grids on tori, or grids on hyper-cubes), which are examples of geometrically local interactions, but also have a very rich structure: their symmetries allow to exploit powerful algebraic tools, such as the discrete Fourier transform over rings, to compute their eigenvalues, and then find bounds on the associated costs. Then, we extend the results to a more general class of graphs, thus showing that the behavior of lattices is mainly due to the local nature of interactions and not to the symmetries. To do so, we exploit the analogy between reversible Markov chains and resistive electrical networks. This latter work is part of the Ph.D. thesis of E. Lovisari at University of Padova, Italy.

- Distributed averaging over digital noisy networks

**Participants:** F. Garin [Contact person], R. Carli [Università di Padova], G. Como [MIT], P. Frasca [Politecnico di Torino].
We study iterative distributed averaging algorithms for networks whose nodes can communicate through memoryless erasure broadcast channels. In order to compare the performance of different algorithms, we define suitable complexity measures, which account for the number of channel transmissions (communication complexity), and, respectively, of in-node computations (computational complexity) required to achieve a desired precision. These performance measures are particularly relevant, as they allow for directly estimating the energy consumption of such distributed computation systems, as well as their time-complexity.

The algorithms we propose combine the classical iterative linear consensus algorithm (where at each iteration, each agent receives the states of its neighbors and takes a suitable convex combination of them), with source-channel coding schemes for the reliable transmission of real numbers on noisy channels. Our algorithms involve a sequence of transmission phases, of increasing duration, in which the agents attempt to broadcast their state, i.e. their current estimate of the global average, to their neighbors, alternated to averaging steps, in which the agents' states are updated. These algorithms are fully distributed, and they do not require the agents to have any global knowledge of the network structure or size. Our main result shows that such algorithms drive the agents to state agreement (consensus) which can be made arbitrarily close to the true average. The number of channel transmissions and in-node computations is shown to grow at most poly-logarithmically in the desired precision. We also show how communication feedback, when available, allows one to modify the algorithms, achieving asymptotic average consensus (i.e., state agreement on the average of the initial observations), and reducing the computational and communication complexities. This work is presented in the paper [15]. In the paper [22], we present and analyze a modified algorithm, which can be used when source coding (compression) and channel coding (error correction) are performed by two separate encoders. Such algorithm takes into the account the fact that, even without any channel feedback, the part of the error which is due to lossy compression and not to channel noise is perfectly known by the transmitter, and a compensation can be introduced, thus improving performance.

- Distributed Consensus algorithms
  **Participant:** A. Seuret [Contact person].

  Concerning this problem, we address the classical issues of the stability analysis of consensus algorithm in continuous-time. The objective of the present work is to show that the performances classical consensus algorithms can be improved using an appropriate memory of the controlled state. We want to design a novel type of consensus algorithm which uses not only the current state of the algorithm but also a sampled version of it. The key problems are here the design of the best parameters, i.e., the sampling period and the ratio between the contributions of the current and the sampled states. It has to be noticed that a usual intuition is to say that using past values of the state a reduction of performances or to instability. However, our contributions show that this is not always in single and double integrator consensus algorithms [41]. These contributions is based on an LMI framework and based on algebraic communication matrix structure. The efficiency of the method is tested for different network communication schemes.

### 6.2.4. Distributed real-time Simulation of numerical models

**Participants:** D. Simon [Contact person], A. Ben Khaled [IFPEN], M. Ben Gaid [IFPEN].

To allow real-time simulation of high fidelity engine models, different techniques have to be applied in order to fulfill the real-time constraints. Real-time simulation involves trade-offs between several aspects, such as real-time constraints, models computational complexity and integration accuracy. Traditionally HIL designers consider that every step of the simulation must be real-time and deterministic, leading to strongly synchronized systems, at the cost of ineffective computation burdens. It has been shown that adequately splitting the plant’s model into weakly synchronized sub-systems allows for efficiently using variable steps numerical integrators, simulation speed-ups and subsequent effective parallel versions of HIL systems [25].
6.3. Stability and control design of asynchronous interconnected systems

6.3.1. New approaches for stability conditions design

- Stability for asynchronous sampled data systems

  **Participants:** A. Seuret [Contact person], C. Briat [KTH], J. Gomès Da Silva Jr. [UFRGS], W. Jiang, M. M. Peet [Illinois Institute of Technology].

  During the last year an important effort has been devoted to controlled systems under communication constraints. In particular a novel approach to assess stability of continuous linear systems with sampled-data inputs has been provided for the first time in [21]. The main contribution of this article is to make the bridge between the discrete-time and the continuous-time approaches to ensure stability of the closed loop system. The interest of the method remains in the application of the discrete-time Lyapunov theorem using the continuous-time model without introducing exponential. This method suggests the introduction of particular types of functionals of several shapes: using an adaptation of classical time-delay functionals [21]; using a discretization method [26]; or using SOS [44].

  Then extensions to uncertain systems, time-varying parameter systems [21]; or non linear systems (for instance with saturations [36], [43]) become straightforward in comparison to the discrete-time approaches. The stability conditions are expressed in terms of linear matrix inequalities. Sufficient conditions for asymptotic and exponential stability are provided dealing with synchronous and asynchronous samplings and uncertain systems. An additional stability analysis is provided for the cases of multiple sampling periods and packet losses in [21]. Moreover this method has also been extended to the case of sampled-data systems with additional input delay [42], [46] and to the case of impulsive systems (several papers are submitted on this topic, for example [65]).

- Stability of control under weakened real-time constraints

  **Participants:** D. Simon [Contact person], A. Seuret, P. Andrianiaina [AIRBUS].

  A weakened implementation scheme for real-time feedback controllers is proposed to reduce the conservatism due to traditional worst-cases considerations. To save wasted computing resources, new real-time scheduling scenarios allowed for reducing the time slots allocated to control tasks below the value of the Worst Case Execution Time which is traditionally used to implement embedded control software. The stability of the control system under occasional deadlines miss is assessed using robustness arguments, using Lyapunov-Krasovskii functionals and LMIs solving based on [46]. The methodology has been successfully assessed for a fighter aircraft pitch controller, which show that the stability of the plant can be kept (and even improved) using the new scheduling schemes using less computing resources than traditional implementations [24], [63].

6.3.2. Control for asynchronous sampled data systems

- Control architecture and tools

  **Participants:** D. Simon [Contact person], R. Pissard [SED], S. Arias [SED].

  During the development of control systems, hardware-in-the-loop that is showed in Fig. 6 takes place between design level simulations and costly experiments with the real plant. Using the prototype of ORCCAD V4 several HIL real-time simulators have been set up. These simulators combine multi-threaded/multi-rate real-time controllers running control algorithms synchronized with a variable step numerical integrator running a model of the plant [49]. These simulators have been further used to implement and test several kind of feedback/flexible scheduling schemes related to the FeedNetBack project, in particular real-time controllers subject to (m,k)-firm scheduling, Kalman filters modified to account for data loss and varying sampling controllers [62]. Finally a collaboration with SARDES about the integration of discrete (logical) control loops on top of continuous control tasks has been carried on. In this architecture ORCCAD is used to design the low level continuous controllers while the reactive parts are designed and synthesized using the BZR language [23].
Event-based control algorithms

**Participants:** A. Seuret [Contact person], N. Marchand [Contact person], S. Durand.

Asynchronicity is becoming more and more meaningful in modern control architectures and some new control strategies are being developed by some research teams in the world. The principle of these control laws is to compute a new control signal only when some event occur, where a event characterizes a change in the system and therefore a need for a new control. These approaches are supposed to reduce the number of times the control is computed (and consequently the CPU utilization) and to remove the real-time hard constraint on the computational system. Some works around this domain have been proposed by some members of the NeCS team.

In [45], one may look at the problem of reducing the amount of information to be sent to the actuators through the Network. Indeed the controller may be able to trigger the information to be sent. The main idea is to let the controller decide if the system needs an update of its control input. This class of control algorithms is called event-triggered. An algorithm is suggested to sample the control input based on the behavior of a Lyapunov-like function in [45]. This algorithm is event-triggered since the Lyapunov-like function directly depends on the state of the systems.

In [69] and [73], we firstly proposed to remove the safety limit condition introduced by K-E. Årzén in his event-based PID controller [93]. In this paper, the control signal is updated only when required from a performance point of view, that is when the measurement crosses a given level. Årzén also suggested to enforce an event when the sampling interval achieves a given maximal amount of time. This safety limit was added to prevent the system to be sampled less than what Shannon theorem requires but, in fact, we showed that the Shannon sampling condition is no more consistent in the context of event-based systems. Moreover, a practical implementation of a cruise control mechanism on a small radio-controlled vehicle was recently suggested [34]. Moreover, we are interested on updating the control signal only when required from a stability point of view. Such a solution consists for instance in enforcing an event when a Lyapunov function crosses a given level. Based on the seminal work from M. Velasco in [90], we suggested a simple Lyapunov sampling in [33].

Control with adaptive sampling

**Participants:** D. Simon [Contact person], O. Sename, E. Roche.

Control and real-time computing have been associated for a long time, for the control of industrial plants and in embedded or mobile systems, e.g. automotive and robotics. However both parts, control and computing, are often designed with poor interaction and mutual understanding. We propose here an integrated control and scheduling co-design approach, where closing the loop between the control
performance and the computing activity is promising for both adaptivity and robustness issues. We developed during the last years a variable sampling control methodology based on the LPV (Linear Parameter Varying) framework and $H_\infty$ control synthesis, where the sampling interval is used as a known and controlled variable [8]. Few assumptions about sampling are needed for this control design: the main point is that the control interval is known and lies between the predefined bounds $[h_{min}, h_{max}]$, whatever the origin of the control interval variations, its speed and its frequency. Another approach is proposed now to design sampling varying gain-scheduled controller for LPV systems, based on the Linear Fractional Representation (LFR). This method has already been studied concerning the synthesis of discrete-time gain-scheduled controller, depending only on the sampling period. The method has been extended to deal with the design of a gain scheduled LFT controller w.r.t. the sampling interval and w.r.t system’s parameters, given a discrete-time Linear Fractional Representation (LFR) of the LPV varying sampling model [13]. The approach comes from the robust control theory and consists in separating the LTI part $P$ (not depending on the set of parameters) from the varying part $\Delta$ (parameters or uncertainties), as shown on Fig. 7. The matrix $\Delta$ represents the influence of the set of parameters $\rho(.)$ on the plant. From this model, a gain scheduled controller can be computed, depending on the same set of parameters $\Delta$, or a subset of $\Delta$. The LFT approach proposed in [83] has been extended to set a LFR model that accounts for system and sampling parameters. In that case the uncertainty matrix is as depicted in Fig. 7 on the right, where $\delta$ is the deviation of the sampling interval w.r.t. the nominal sampling rate and $\Delta$ account for the plant’s uncertainty. A controller is then synthesized using the $H_\infty$ framework, where weighting functions allow to shape the control system’s response [82].

In the framework of the FeedNetBack IST project, the LFR formulation previously presented is applied to an Autonomous Underwater Vehicle (AUV) for the control of its altitude $z$ [40]. The global control structure is presented on Fig. 8. To control the altitude, two controllers are considered ($\hat{K}_z(\delta)$ and $\hat{K}_\theta(\delta, \rho)$) based on two models ($\hat{G}_z(\delta)$ and $\hat{G}_\theta(\delta, \rho)$). The LFR formulation is used here to keep some varying parameters into the model formulation. Indeed, in previous works, the limits of a simple linearization around a fixed equilibrium point have appeared. When the pitch angle is too far from 0 (the value chosen for $\theta$ at equilibrium), the linearized model becomes too different from the linearized one, which leads to bad performances. The $\Delta$ block contains the varying part of the model, which depends on the linearization point ($\theta_{eq}$). The two considered varying parameters are $\rho_1 = \cos(\theta_{eq})$ and $\rho_2 = \sin(\theta_{eq})$. The model is then discretized and the sampling period is added to the $\Delta$ parameter block. Compared with the previous approach using a linearized plant model, the new one shows (in simulation) improved altitude tracking and a better utilization of the available range of the actuators [82].

**Figure 7. System under LFT form.**
6.4. Vehicular transportation systems

6.4.1. Traffic modelling, estimation and control

Participants: C. Canudas de Wit [Contact person], C. Irinel-Constantin [CRAN], D. Pisarski, L. Leon Ojeda.

This part is related to the developed work within the Network of Excellence HYCON2 (Highly-Complex and Networked Control Systems). It interested to problems of modelling, estimation and control in traffic.

In [81], the problem of equilibrium sets for the Cell Transmission Model is studied. The objective is to design the homogeneous distribution of density on the freeway, where the input flows are the decision parameters to be determined. For the proper design of the balanced density the extensive analysis on the structures of equilibria is crucial. The analysis is carried out for the two different cases, where all sections of the freeway are assumed to be free or congested, respectively. The necessary conditions for the existence of balanced equilibria are formulated. These conditions show, that the key for the design of the balanced states may be the variable speed limiting, which strictly cooperates with the ramp metering. The computational algorithm for the input flows in case of free balance is proposed. In order to illustrate the results, the numerical example is provided.

In [39], the authors are interested to the highway traffic model-based density estimation. A strategy is proposed for real-time density estimation for traffic networks. To this aim, we introduced a deterministic constrained macroscopic model which reduce the number of possible affine dynamics of the system and preserve the number of vehicles in the network. This model is used to recover the state of the traffic network and precisely localize the eventual congestion front. The state of the network is recovered using what we call forward/backward observers. We pointed out that during unobservable modes the estimation error is preserved due to vehicle conservation law. Numerical simulations show the efficiency of the proposed strategy.

In [30], the problem of front congestions control is treated. For this, we have introduced a new traffic lumped model with only two cells (one free, and another congested) the cells have variable length, and a variation law for the front congestion completes the 3-dimensional model. In opposition to fixed-length cell models that are commonly represented by a set of linear state-dependent switching systems, our model results in a lower dimensional nonlinear system which solutions are continuous. Based on this model, we have designed a “best-effort” control strategy using variable speed limits. The notion of best effort control is here linked to the physical variable speed limit constraints which limits its size and as well as its rate variation. This results in a relative simple control in closed-form that can be implemented by using only information about the front congestion location.

Other work is under development and is related to the traffic show case application and the achievements reached that correspond to the operation of the freeway network around the Grenoble area (Grenoble South Ring). We started by designing the general network architecture, after specifying sensors and actuators locations along the highway and finally setting the platform of an interface between Matlab and our micro simulator "Aimsun". We have also carrying out some simulations from a real life application on Grenoble South ring of a deterministic state estimation technique. Using constrained macroscopic model which in fact reduces the number of dynamic states and preserves the conservation law (number of vehicles in the network).
6.4.2. Vehicle control

- Tele-operated control
  
  **Participants:** C. Canudas de Wit [Contact person], W. Jiang, J. Dumon, O. Sename.

  A mathematical driver model in the spatial equation form has been introduced for analysis of drivers’ behavior [31]. In the model, a previewed distance is taken into account. First, optimal control is applied. For the ideal case without driver’s reaction delay concerned, for both long distance preview and shorter one, the vehicle tracks well the path. Whereas, when time-delay added into the system, too short preview distance cause the instability of the system. The simulation result corresponds with the real driving experience. Then, Lyapunov-Krasovskii functional approach is applied deal with stability problem with the driver’s delay. In this case, when the delay becomes greater, the longer preview distance will be needed. The average derivation of the steering input is calculated for different preview distance as well as the time-delay cases, which well verifies our driver model. The main contribution of this model is that the preview effect only depends on the path information and it does not affected by the vehicle speed, so the result is more neutral

- Electric Power Steering Systems
  
  **Participants:** C. Canudas de Wit [Contact person], V. Ciarla, J. Tordesillas Illán [UJF].

  This part presents several aspects of modeling, observation and control towards a new generation of Electrical Power Steering (EPS) systems [47]. In particular we design an optimal control to reject oscillations of the steering column, then we device a new observer to estimate the internal state variables of the steering column, the driver applied torque (steering wheel torque), and the load torque (tire/ground contact friction). Finally, we also revisited the LuGre tire dynamic friction model by improving the transient behavior between the sticking phases and the dynamic ones. Simulation of the proposed control and observer are shown at the end of the paper using the improved LuGre-tire friction model. Index Terms—Electric Power Steering systems (EPSs), LQ control, LuGre friction model, observer.

6.5. Energy-aware control of systems on chip

**Participants:** N. Marchand [Contact person], S. Durand.

Achieving a good compromise between computing power and energy consumption is one of the challenges in embedded architectures of the future. This management is especially difficult for 45 nm or 32 nm known to be at the limit of the scalability, i.e. with a high process variability. This is a key point in the ARAVIS project. Automatic control loops have therefore to be designed to minimize the energy consumption still making the performance fit the requirement in a context of highly technological uncertainties of the chip. This issue is notably discussed in [92]. Finally, the main objective is to dynamically control the computing activity and the energy consumption using the voltage and the frequency according to the requirements of the operating system. In this way, a robust control law was developed in [72] and [32] in order to minimize the high voltage running time with a predictive technique, i.e. to minimize the energy consumption while ensuring good computational performance. This control was initially done for one node (i.e. a processor) but in ARAVIS SoC, the chip is composed of several clusters with several nodes each (see Fig. 9). Thus, the energy controller has to manage the voltage level (one voltage domain by cluster) and the frequency for all nodes: a maximal frequency is performed for critical node and then a ratio of this frequency could be apply for the other nodes. Thus, a multicore control strategy with low computational needs was also proposed [71]. This work yields two patents: the first one for the monocoal case [70] and the second one for the multicore case [74].
Figure 9. Architecture du SoC ARAVIS.
5. New Results

5.1. Statistical analysis of spike trains

Modern advances in neurophysiology techniques, such as two-photons imaging of calcium signals or micro-electrode arrays (MEA) electro-physiology, have made it possible to observe simultaneously the activity of large assemblies of neurons. Such experimental recordings provide a great opportunity to unravel the underlying interactions of neural assemblies and to understand how neural populations dynamically encode information. The goal of the present project is to propose to the neuroscientists community statistical methods and numerical tools to analyzing the statistics of action potentials (spike trains) obtained from MEA recordings. Our work is grounded on one hand on theoretical results on Gibbs distributions in neural networks and the other hand on a C/C++ library of algorithms developed jointly with the CORTEX INRIA team, freely available at http://enas.gforge.inria.fr/. We have collaborations with several labs specialized in MEA recording from the retina: Centro Interdisciplinario de Neurociencia de Valparaiso, Universidad de Valparaiso, Chile http://www.cinv.cl/; Department of Molecular Biology and Princeton Neuroscience Institute, Princeton University, USA http://www.princeton.edu/neuroscience/; Institut de la Vision, Paris http://www.institut-vision.org/.

5.1.1. A discrete time neural network model with spiking neurons. Dynamics with noise.

Participant: Bruno Cessac [correspondent].

We provide rigorous and exact results characterizing the statistics of spike trains in a network of leaky Integrate-and-Fire neurons, where time is discrete and where neurons are submitted to noise, without restriction on the synaptic weights. We show the existence and uniqueness of an invariant measure of Gibbs type and discuss its properties. We also discuss Markovian approximations and relate them to the approaches currently used in computational neuroscience to analyse experimental spike trains statistics. This work has appeared in Journal of Mathematical Biology[ 17 ].

5.1.2. Statistics of spike trains in conductance-based neural networks: Rigorous results

Participant: Bruno Cessac [correspondent].

We consider a conductance-based neural network inspired by the generalized Integrate and Fire model introduced by Rudolph and Destexhe in 1996. We show the existence and uniqueness of a unique Gibbs distribution characterizing spike train statistics. The corresponding Gibbs potential is explicitly computed. These results hold in the presence of a time-dependent stimulus and apply therefore to non-stationary dynamics. This establishes a rigorous ground for the current investigations attempting to characterize real spike trains data with Gibbs distributions, such as the Ising-like distribution, using the maximal entropy principle. This work has appeared in Journal of Mathematical Neuroscience [ 18 ].

Participants: Bruno Cessac [correspondent]. Adrian Palacios [Centro de Neurociencia, Valparaiso, Chile].

This work focuses on methods from statistical physics and probability theory allowing the analysis of spike trains in neural networks. Taking as an example the retina we present recent works attempting to understand how retina ganglion cells encode the information transmitted to the visual cortex via the optical nerve, by analyzing their spike train statistics. We compare the maximal entropy models used in the literature of retina spike train analysis to rigorous results establishing the exact form of spike train statistics in conductance-based Integrate-and-Fire neural networks. This work is submitted in “Mathematical Problems in Computational Biology and Biomedicine” Springer, [ 54 ].
5.1.4. Gibbs distribution analysis of temporal correlations structure in retina ganglion cells

Participants: Michael Berry II [Department of Molecular Biology, Princeton University, USA], Bruno Cessac [correspondent], Olivier Marre, Adrian Palacios [Centro de Neurociencia, Valparaiso, Chile], Juan-Carlos Vasquez.

We present a method to estimate Gibbs distributions with spatio-temporal constraints on spike trains statistics. We apply this method to spike trains recorded from ganglion cells of the salamander retina, in response to natural movies. Our analysis, restricted to a few neurons, performs more accurately than pairwise synchronization models (Ising) or the 1-time step Markov models (Marre et al. (2009)) to describe the statistics of spatio-temporal spike patterns and emphasizes the role of higher order spatio-temporal interactions. This work has been accepted in Journal of Physiology, Paris [28] (in press).

5.1.5. A Markovian event-based framework for stochastic spiking neural networks

Participants: Olivier Faugeras, Jonathan Touboul.

In spiking neural networks, the information is conveyed by the spike times, that depend on the intrinsic dynamics of each neuron, the input they receive and on the connections between neurons. In this article we study the Markovian nature of the sequence of spike times in stochastic neural networks, and in particular the ability to deduce from a spike train the next spike time, and therefore produce a description of the network activity only based on the spike times regardless of the membrane potential process. To study this question in a rigorous manner, we introduce and study an event-based description of networks of noisy integrate-and-fire neurons, i.e. that is based on the computation of the spike times. We show that the firing times of the neurons in the networks constitute a Markov chain, whose transition probability is related to the probability distribution of the interspike interval of the neurons in the network. In the cases where the Markovian model can be developed, the transition probability is explicitly derived in such classical cases of neural networks as the linear integrate-and-fire neuron models with excitatory and inhibitory interactions, for different types of synapses, possibly featuring noisy synaptic integration, transmission delays and absolute and relative refractory period. This covers most of the cases that have been investigated in the event-based description of spiking deterministic neural networks.

This work has appeared in the Journal of Computational Neuroscience [26].

5.2. Coding by spikes

Our goal here is a better understanding of the extent to which computing and modeling with spiking neuron networks might be biologically plausible and computationally efficient. Based on a thorough characterization of the main constraints on spiking neural networks dynamics this has led us to propose new algorithms to infer the structure of the network from its spike trains and to propose an FPGA implementation of spiking neural networks.

5.2.1. Reverse-engineering of spiking neural networks parameters

Participants: Bruno Cessac [correspondent], Horacio Rostro-Gonzalez, Thierry Viéville [Cortex].

We consider the deterministic evolution of a time-discretized spiking network of neurons with connection weights having delays, modeled as a discretized neural network of the generalized integrate and fire (gIF) type. The purpose is to study a class of algorithmic methods allowing to calculate the proper parameters (synaptic weights) to reproduce exactly a given spike train generated by an hidden (unknown) neural network. This problem is linear (L) if the membrane potentials are observed and LP (Linear-Programming) if only spike times are observed, in the context of gIF models. The L or LP adjustment mechanism is local to each unit and has the same structure as an "Hebbian" rule. This paradigm is easily generalizable to the design of input-output spike train transformations. This means that we have a practical method to "program" a spiking network, i.e. find a set of parameters allowing us to exactly reproduce the network output, given an input.

This work has been submitted in the Journal of Neural Engineering, 2011[25].
5.2.2. Development of FPGA-based efficient reconfigurable architectures for spiking neural networks

Participants: Bruno Cessac, Bernard Girau [INRIA Cortex], Horacio Rostro-Gonzalez, Cesar Torres-Huitzil [Information Technology Department, Polytechnic University of Victoria (UPV), Tamaulipas, Mexico], Thierry Viéville [Cortex, correspondent].

Spiking neural networks are able to perform very powerful computations with precise timed spikes. We are developing an FPGA (Field Programmable Gate Array) reconfigurable platform that enables the simulation of in silico models of spiking neural networks. Since the model is directly mapped into a FPGA device, the neural processing is accelerated and the time consumption reduced. We use VHDL and Handel-C to design the reconfigurable architecture of a discrete time Integrate-and-Fire model coded in CUDA, running on GPU. This work has been accepted in Journal of Physiology, Paris [24].

5.2.3. Towards biologically inspired image coders

Participants: Marc Antonini [Laboratoire I3S, Sophia Antipolis, France], Pierre Kornprobst, Khaled Masmoudi [Laboratoire I3S, Sophia Antipolis, France].

In [51] we presented a novel bio-inspired and dynamic coding scheme for static images. Our coder aims at reproducing the main steps of the visual stimulus processing in the mammalian retina taking into account its time behavior. The main novelty of this work is to show how to exploit the time behavior of the retina cells to ensure, in a simple way, scalability and bit allocation. To do so, our main source of inspiration has been the biologically plausible retina model Virtual Retina described in Section 4.1. Following a similar structure, our model has two stages. The first stage is an image transform which is performed by the outer layers in the retina. Here it is modelled by filtering the image with a bank of difference of Gaussians with time-delays. The second stage is a time-dependent analog-to-digital conversion which is performed by the inner layers in the retina. Thanks to its conception, our coder enables scalability and bit allocation across time. Also, compared to the JPEG standards, our decoded images do not show annoying artefacts such as ringing and block effects. As a whole, this article shows how to capture the main properties of a biological system, here the retina, in order to design a new efficient coder.

5.3. Mean field methods

5.3.1. Noise-induced behaviors in neural mean field dynamics

Participants: Jonathan Touboul, Geoffroy Hermann, Olivier Faugeras.

The collective behavior of cortical neurons is strongly affected by the presence of noise at the level of individual cells. In order to study these phenomena in large-scale assemblies of neurons, we consider networks of firing-rate neurons with linear intrinsic dynamics and nonlinear coupling, belonging to a few types of cell populations and receiving noisy currents. Asymptotic equations as the number of neurons tends to infinity (mean field equations) are rigorously derived based on a probabilistic approach. These equations are implicit on the probability distribution of the solutions which generally makes their direct analysis difficult. However, in our case, the solutions are Gaussian, and their moments satisfy a closed system of nonlinear ordinary differential equations (ODEs), which are much easier to study than the original stochastic network equations, and the statistics of the empirical process uniformly converge towards the solutions of these ODEs. Based on this description, we analytically and numerically study the influence of noise on the collective behaviors, and compare these asymptotic regimes to simulations of the network. We observe that the mean field equations provide an accurate description of the solutions of the network equations for network sizes as small as a few hundreds of neurons. In particular, we observe that the level of noise in the system qualitatively modifies its collective behavior, producing for instance synchronized oscillations of the whole network, desynchronization of oscillating regimes, and stabilization or destabilization of stationary solutions. These results shed a new light on the role of noise in shaping collective dynamics of neurons, and gives us clues for understanding similar phenomena observed in biological networks.
5.3.2. Mean Field description of and propagation of chaos in recurrent multipopulation networks of Hodgkin-Huxley and FitzHugh-Nagumo neurons

Participants: Javier Baladron, Diego Fasoli, Olivier Faugeras, Jonathan Touboul.

We derive the mean-field equations arising as the limit of a network of interacting spiking neurons, as the number of neurons goes to infinity. The neurons belong to a fixed number of populations and are represented either by the Hodgkin-Huxley model or by one of its simplified version, the Fitzhugh-Nagumo model. The synapses between neurons are either electrical or chemical. The network is assumed to be fully connected. The maximum conductances vary randomly. Under the condition that all neurons initial conditions are drawn independently from the same law that depends only on the population they belong to, we prove that a propagation of chaos phenomenon takes places, namely that in the mean-field limit, any finite number of neurons become independent and, within each population, have the same probability distribution. This probability distribution is solution of a set of implicit equations, either nonlinear stochastic differential equations resembling the McKean-Vlasov equations, or non-local partial differential equations resembling the McKean-Vlasov-Fokker-Planck equations. We prove the well-posedness of these equations, i.e. the existence and uniqueness of a solution. We also show the results of some preliminary numerical experiments that indicate that the mean-field equations are a good representation of the mean activity of a infinite size network, even for modest sizes. These experiment also indicate that the McKean-Vlasov-Fokker-Planck equations may be a good way to understand the mean-field dynamics through, e.g., a bifurcation analysis.

This work has been submitted for publication in the Journal of Mathematical Neuroscience [55].

5.3.3. Three applications of GPU computing in neuroscience

Participants: Javier Baladron, Olivier Faugeras.

GPUs are low cost highly parallel devices that are now not only used for graphics but also for numerical simulation. We present three applications of a computer system with multiple GPUs to the domain of theoretical neuroscience. The first application is to a continuous model of the primary visual area, the second to the simulation of a stochastic neural network, and the third to the computation of the probability distribution on the possible states of a network. In all three cases we show that the speed-up obtained by the use of GPUs has considerably helped answering a scientific or technological question.

This work has been accepted for publication in Computing in Science and Engineering [63].

5.4. Neural Fields

5.4.1. Modelling the dynamics of contextual motion integration in the primate

Participants: Heiko Neumann [Institute of Neural Information Processing, Ulm University, Ulm, Germany], Pierre Kornprobst, Guillaume Masson [Institut de Neurosciences de la Timone, UMR 6193, CNRS, Marseille, France], Emilien Tlapale.

The dynamics of motion integration show striking similarities when observed at neuronal, psychophysical, and oculomotor levels. Based on the inter-relation and complementary insights given by those dynamics, our goal is to investigate how basic mechanisms of dynamical cortical processing can be incorporated in a dynamical model to solve several aspects of 2D motion integration and segmentation.

Thanks to Emilien Tlapale PhD [13] (see also [16]), we have obtained the following results:

- We proposed a recurrent model of motion integration. Proposing a simple readout mechanism, we reproduced not only motion perception but also the dynamics of smooth pursuit eye movements on various line figures and gratings viewed through different apertures. Our model can also solve various contextual problems where extrinsic junctions should be eliminated, without relying on complex junction detectors or depth computation [71]. Finally, we have also shown how our model can be rewritten in the neural fields formalism (see [52] and the Software MotionLib), which has opened new perspectives as detailed in Section 5.4.2.
We confronted our results to artificial and biological vision. To formalize the comparison against visual performance, we proposed a new evaluation methodology based on human visual performance by establishing a database of image sequences taken from biology and psychophysics literature [70], [69], [67]. We compared our results against the state of the art computer vision approaches and we found that our model also gives results comparable to recent computer vision approaches of motion estimation.

5.4.2. Neural fields models for motion integration: Characterising the dynamics of multi-stable visual motion stimuli

Participants: Olivier Faugeras, Pierre Kornprobst, Guillaume Masson [Institut de Neurosciences de la Timone, UMR 6193, CNRS, Marseille, France], Andrew Meso [Institut de Neurosciences de la Timone, UMR 6193, CNRS, Marseille, France], James Rankin, Emilien Tlapale, Romain Veltz.

In [57] we investigated the temporal dynamics of the neural processing of a multi-stable visual motion stimulus with two complementary approaches: psychophysical experiments and mathematical modelling. The so-called “barber pole” stimulus is considered with an aperture configuration that supports horizontal (H), diagonal (D) or vertical (V) perceived directions for the same input. The phenomenon demonstrates an interesting variable and dynamic competition for perceptual dominance between underlying neural representations of the three directions. We probe the early processing from stimulus presentation to initial perceived direction (before perceptual reversals). Starting from a simplified neural fields model inspired from [13], we constructed a model of the necessary motion integration that shows a shift in perceptual dominance from D to either H or V with increasing duration. Further, the timing of this shift is shown to be controlled by a stimulus gain parameter analogous to contrast. In psychophysics experiments with concurrent eye movement recordings, observers report their perceived direction of motion for presentation durations between 0.1s and 0.5s. There is a also consistent transition in perceptual dominance from D to H/V as duration is increased. This trend, seen in both perceived direction decisions and eye movement patterns, is consistent with previous experiments using similar stimuli with an aperture configured for two (D/H) rather than three (D/H/V) states. The basic dynamic properties of the early transition from D to H/V are well predicted by the model. The experimental work additionally reveals asymmetric data patterns that guide adjustments to the model’s input equations. Observers have an H bias over V, which is also reflected in faster reaction times for H. In order to capture the bias between H and V a separate weighting is attributed to the local input corresponding to each state. The work presented forms a solid foundation for future experimental and modelling work investigating the longer term dynamics for which perceptual reversals are known to occur.

5.4.3. Analysis of a hyperbolic geometric model for visual texture perception

Participants: Pascal Chossat, Grégory Faye, Olivier Faugeras.

We study the neural field equations introduced by Chossat and Faugeras in [64] to model the representation and the processing of image edges and textures in the hypercolumns of the cortical area V1. The key entity, the structure tensor, intrinsically lives in a non-Euclidean, in effect hyperbolic, space. Its spatio-temporal behaviour is governed by nonlinear integro-differential equations defined on the Poincaré disc model of the two-dimensional hyperbolic space. Using methods from the theory of functional analysis we show the existence and uniqueness of a solution of these equations. In the case of stationary, i.e. time independent, solutions we perform a stability analysis which yields important results on their behavior. We also present an original study, based on non-Euclidean, hyperbolic, analysis, of a spatially localised bump solution in a limiting case. We illustrate our theoretical results with numerical simulations.

This work has been published in the Journal of Mathematical Neuroscience [21].

5.4.4. Bifurcation of Hyperbolic Planforms

Participants: Pascal Chossat, Grégory Faye, Olivier Faugeras.
Motivated by a model for the perception of textures by the visual cortex in primates, we analyze the bifurcation of periodic patterns for nonlinear equations describing the state of a system defined on the space of structure tensors, when these equations are further invariant with respect to the isometries of this space. We show that the problem reduces to a bifurcation problem in the hyperbolic plane $\mathbb{D}$ (Poincaré disc). We make use of the concept of a periodic lattice in $\mathbb{D}$ to further reduce the problem to one on a compact Riemann surface $\mathbb{D}/\Gamma$, where $\Gamma$ is a cocompact, torsion-free Fuchsian group. The knowledge of the symmetry group of this surface allows us to use the machinery of equivariant bifurcation theory. Solutions which generically bifurcate are called “H-planforms”, by analogy with the “planforms” introduced for pattern formation in Euclidean space. This concept is applied to the case of an octagonal periodic pattern, where we are able to classify all possible H-planforms satisfying the hypotheses of the Equivariant Branching Lemma. These patterns are, however, not straightforward to compute, even numerically, and in the last section we describe a method for computation illustrated with a selection of images of octagonal H-planforms.

This work has been published in the Journal of Nonlinear Science [19].

5.4.5. Bifurcation diagrams and heteroclinic networks of octagonal H-planforms

Participants: Grégory Faye, Pascal Chossat [correspondent].

This paper completes the classification of bifurcation diagrams for H-planforms in the Poincaré disc $\mathbb{D}$ whose fundamental domain is a regular octagon. An H-planform is a steady solution of a PDE or integro-differential equation in $\mathbb{D}$, which is invariant under the action of a lattice subgroup $\Gamma$ of $U(1,1)$, the group of isometries of $\mathbb{D}$. In our case $\Gamma$ generates a tiling of $\mathbb{D}$ with regular octagons. This problem was introduced in [19] as an example of spontaneous pattern formation in a model of image feature detection by the visual cortex where the features are assumed to be represented in the space of structure tensors. Under “generic” assumptions the bifurcation problem reduces to an ODE which is invariant by an irreducible representation of the group of automorphisms $\mathfrak{g}$ of the compact Riemann surface $\mathbb{D}/\Gamma$. The irreducible representations of $\mathfrak{g}$ have dimension one, two, three and four. The bifurcation diagrams for the representations of dimension less than four have already been described and correspond to already well known group actions. In the present work we compute the bifurcation diagrams for the remaining three irreducible representations of dimension four, thus completing the classification. In one of these cases, there is generic bifurcation of a heteroclinic network connecting equilibria with two different orbit types.

This work has been accepted for publication in the Journal of Nonlinear Science [22].

5.4.6. Hopf bifurcation curves in neural field networks with space-dependent delays

Participant: Romain Veltz.

We give an analytical parametrization of the curves of purely imaginary eigenvalues in the delay-parameter plane of the linearized neural field network equations with space-dependent delays. In order to determine if the rightmost eigenvalue is purely imaginary, we have to compute a finite number of such curves; the number of curves is bounded by a constant for which we give an expression. The Hopf bifurcation curve lies on these curves.

This work has appeared in the Comptes Rendus Mathématiques de l’Académie des Sciences [30].

5.4.7. Stability of the stationary solutions of neural field equations with propagation delays

Participants: Olivier Faugeras, Romain Veltz.

We consider neural field equations with space-dependent delays. Neural fields are continuous assemblies of mesoscopic models arising when modeling macroscopic parts of the brain. They are modeled by nonlinear integro-differential equations. We rigorously prove, for the first time to our knowledge, sufficient conditions for the stability of their stationary solutions. We use two methods 1) the computation of the eigenvalues of the linear operator defined by the linearized equations and 2) the formulation of the problem as a fixed point problem. The first method involves tools of functional analysis and yields a new estimate of the semigroup of the previous linear operator using the eigenvalues of its infinitesimal generator. It yields a sufficient condition for stability which is independent of the characteristics of the delays. The second method allows us to find
new sufficient conditions for the stability of stationary solutions which depend upon the values of the delays. These conditions are very easy to evaluate numerically. We illustrate the conservativeness of the bounds with a comparison with numerical simulation.

This work has appeared in the Journal of Mathematical Neuroscience [29].

5.4.8. Neural Mass Activity, Bifurcations and Epilepsy

**Participants:** Patrick Chauvel [INSERM U751, Marseille, Assistance Publique-Hopitaux de Marseille Timone, and Universite Aix-Marseille, Marseille], Olivier Faugeras, Jonathan Touboul, Fabrice Wendling [INSERM, U642, Rennes].

We propose a general framework for studying neural mass models defined by ordinary differential equations. By studying the bifurcations of the solutions to these equations and their sensitivity to noise we establish an important relation, similar to a dictionary, between their behaviors and normal and pathological, especially epileptic, cortical patterns of activity. We then apply this framework to the analysis of two models that feature most phenomena of interest, the Jansen and Rit model, and the slightly more complex model recently proposed by Wendling and Chauvel. This model-based approach allows to test various neurophysiological hypotheses on the origin of pathological cortical behaviors and to investigate the effect of medication. We also study the effects of the stochastic nature of the inputs which gives us clues about the origins of such important phenomena as interictal spikes, inter-ical bursts and fast onset activity, that are of particular relevance in epilepsy.

This work has appeared in Neural Computation [27].
5. New Results

5.1. Model-free control

Participants: Cédric Join, Riachy Samer, Lotfi Belkoura.

After the successful implementation of model-free control [75], [81] for several concrete situations:

- Throttle control for IC engines (with APPEDGE and PSA) [94];
- Stop-and-go automotive control strategy (in collaboration with the École des Mines de Paris and PSA) [72], [114], [115];
- Hydroelectrical dams modeling and control (in collaboration with EDF) [92], [93];
- Shape memory actuators (collaboration with the team directed by Prof. E. Delaleau at the École Nationale des Ingénieurs de Brest [88], [89]);
- Model-free control involves the design of the so-called "intelligent" PID controllers [75], [82], and a mathematical explanation via "intelligent" PID controllers of the strange ubiquity of PIDs has been developed in [74], and the simulations confirm the superiority of the new intelligent feedback design;
- Application of model-free control method to set Delta hedging [76];
- Model-free control of "Planar Vertical Take-Off and Landing" (PVTOL) aircraft [108];
- Model-free control for power converters [103];
- The longitudinal control of the electrical vehicle by using model-free control technique [73];
- Model-free control for automatic water level regularization [93] and [92];
- [49] simplifies several aspects of the practical implementation of the newly introduced model-free control and of the corresponding intelligent PID controllers. Four examples with their computer simulations permit to test our techniques.

More achievements have been made in 2011, listed as follows:

- Shape Memory Alloys (SMA) are more and more integrated in engineering applications. These materials with their shape memory effect permit to simplify mechanisms and to reduce the size of actuators. Most of successful control strategies applied to SMA actuator are not often suitable for industrial applications. In [17], an application of the new framework of model-free control to a SMA spring based actuator was proposed. This control strategy is based on new results on fast derivatives estimation of noisy signals, its main advantages are: its simplicity and its robustness. Experimental results and comparisons with PI control are exposed that demonstrate the efficiency of this new control strategy.
- The regulation of freeway traffic flow, which is a complex nonlinear system, is achieved via the newly introduced model-free control in [39] and [64]. Several computer simulations are validating our control strategy, which is easy to implement and shows good robustness properties with respect to perturbations;
- After numerous successful applications, [36] has revisited some points of model-free control. The numerical differentiation of noisy signals may be replaced by a real time parameter identification which is much simpler. The strange ubiquity of classic PIDs is explained as well as the almost universal utilization of ultra-local models of order 1. We show that even with a partially known model the utilization of an intelligent PI controller remains profitable.
- The Ph.D. work of Y. El Afou allowed for experimental results on climate control in greenhouse.
5.2. Algebraic technique for estimation, differentiation and its applications

Participants: Cédric Join, Mamadou Mboup, Wilfrid Perruquetti, Lotfi Belkoura, Olivier Gibaru, Zoran Tiganj, Dayan Liu.

Elementary techniques from operational calculus, differential algebra, and noncommutative algebra lead to a new algebraic approach for estimation and detection. It is investigated in various areas of applied sciences and engineering. The following lists only some applications:

- [28] presents a partial derivatives estimation method for multidimensional signals. On a small interval the signal is represented by a truncated Taylor expansion. Then the application of multivariate Laplace transform together with adequate algebraic manipulations enabled us to express the desired partial derivative of any order as a function of iterated integrals of the noisy signal. Several recurrence relations and structural properties were provided. An interpretation of the estimators as least square minimization is also done by expressing the estimators in an orthogonal basis constituted by Jacobi polynomials. This projection enabled us not only to show a spacial shifting inherent to a specific class of estimators but also to synthesize a new class of estimators minimizing the truncation remainder of the Taylor local model. We provided also another class of estimators minimizing the noise influence. Finally we provided a numerical implementation scheme in the form of a finite impulse digital filters.

- A fast identification algorithm is proposed in [20] for systems with delayed inputs. It is based on a non-asymptotic distributional estimation technique initiated in the framework of systems without delay. Such a technique leads to simple realization schemes, involving integrators, multipliers and piecewise polynomial or exponential time functions. Thus, it allows for a real time implementation.

- A new approach to estimate vehicle tire forces and road maximum adherence is presented in [30]. Contrarily to most of previous works on this subject, it is not an asymptotic observer based estimation, but a combination of elementary diagnosis tools and new algebraic techniques for filtering and estimating derivatives of noisy signals. In a first step, instantaneous friction and lateral forces will be computed within this framework. Then, extended braking stiffness concept is exploited to detect which braking efforts allow to distinguish a road type from another. A weighted Dugoff model is used during these “distinguishable” intervals to estimate the maximum friction coefficient. Very promising results have been obtained in noisy simulations and real experimentations for most of driving situations.

- [27] proposes a diagnosis approach of sensor and actuator modeled as structured signals acting on a particular class of uncertain linear dynamical systems. The main advantage of this approach is that it is possible under certain assumptions, to detect, isolate and identify faults using only input and output measurements without having to identify model parameters. The method is based on the generation and analysis of analytical redundancy relations and exploits the fact that a structured signal satisfies a differential equation. The decision rule is based entirely on the temporal behaviour of the estimates of some fault characteristics.

- Numerical causal derivative estimators from noisy data are essential for real time applications especially for control applications or fluid simulation so as to address the new paradigms in solid modeling and video compression. By using an analytical point of view, [23] revisited the nth order algebraic derivative estimators. Thanks to a given noise level and a well-suitable integration length window, we analyzed the derivative estimator error.

- Recent algebraic parametric estimation techniques provide an estimate of the derivatives by using iterated integrals of a noisy observation signal. These algebraic parametric differentiation techniques give derivative estimations which contain two sources of errors: the bias term error and the noise error contribution. In order to reduce these errors, [25] extends the parameter domains used in the estimators, and studies some error bounds which depend on these parameters. This allows us to minimize these errors. It is shown that a compromise choice of these parameters implies an “optimized” error among the noise error contribution, the bias term error and the time delay.
The numerical differentiation by integration method based on Jacobi polynomials originally introduced by Mboup, Fliess and Join is revisited in [24] for the central case where the used integration window is centered.

[59] proposed new algebraic techniques to estimate the amplitude, frequency and phase of a biased and noisy sinusoidal signal. The methods which are popular today seem unable to obtain a robust estimation of those parameters within a fraction of the signal’s period. The efficiency of our approach is illustrated by several computer simulations;

A “practical” comparison between high-order sliding modes and the recently introduced model-free control is made in [56]. The perfect knowledge of the relative degree of the output variable, which is a standard assumption for sliding modes, is assumed. The comparisons are based on two concrete case-studies and on numerous computer simulations. The smoothness of the input variables, the robustness with respect to noises and the straightforward extendibility of the model-free controllers to MIMO systems are highlighted.

[43] and [66] present a parameter estimation algorithm for a magnetic bearing. Such process are inherently unstable systems with strongly nonlinear dynamics. A simplified model of the magnetic bearing is developed, which enables to obtain a linear expression with respect to the unknown parameters. These parameters are measurable with difficulties, and may slightly vary over time. The expression of the estimates is written as a function of integrals of the inputs and outputs of the system. The simulations and the experiments show a fast and robust on-line identification

Estimators of the frequency, amplitude and phase of a noisy sinusoidal signal with time-varying amplitude by using the algebraic parametric techniques is studied in [52], in which a similar strategy to estimate these parameters by using modulating functions method is applied. The convergence of the noise error part due to a large class of noises is studied to show the robustness and the stability of these methods. We also show that the estimators obtained by modulating functions method are robust to “large” sampling period and to non zero-mean noises.

In the framework of the SYSIASS project, a single landmark based localization algorithm for non-holonomic mobile robots is studied in [58]. In the case of a unicycle robot model, the localization problem is equivalent to the system observability. Based on this observation, the proposed localization method consists in finding a vector function which depends on the measurement vector and its derivatives, for which a numerical differentiation method is used in [58].

5.3. Observability and observer design for nonlinear systems

Participants: Jean-Pierre Barbot, Wilfrid Perruquetti, Lotfi Belkoura, Thierry Floquet, Gang Zheng.

Observability analysis and observer design are important issues in the field of control theory. Some recent results are listed below:

[32] investigates the observability and observer design for a class of single output switched systems with high frequency switching, where classical observers cannot be applied directly since the high frequency switching signals are not derivable. By assuming that these signals are integrable in the less restrictive way, and defining a new output, this study shows that algebraic observer can be adopted to estimate the states of the studied switched systems. Although the main idea is explained via normal forms, it can be easily extended to treat generic switched systems with high frequency switching.

Observability of a class of switched systems with Zeno phenomenon or high switching frequency is treated in [31]. Particularly, three observability forms are proposed and the observability for each form with knowledge of filtered switching signal is analyzed. Meanwhile, sufficient and necessary conditions for the existence of a diffeomorphism to transform a class of switched systems into one of such forms are presented.
• A triangular canonical form for a class of 0-flat nonlinear systems is studied in \cite{13}. Necessary and sufficient geometrical conditions are given in order to guarantee the existence of a local diffeomorphism to transform the studied nonlinear systems into the proposed 0-flat canonical form, which enables us to compute the flat output as well.

• A fault tolerant control for induction motors based on backstepping strategy is designed in \cite{44}. The proposed approach permits to compensate both the rotor resistance variations and the load torque disturbance. Moreover, to avoid the use of speed and flux sensors, a second order sliding mode observer is used to estimate the flux and the speed. The designed observer converges in a finite time and gives a good estimate of flux and speed even in the presence of rotor resistance variations and load torque disturbance.

• \cite{42} studies the observability problem of a general class of singular linear systems with unknown inputs. It is shown that, under some assumptions, the problem is equivalent to study the observability of a standard linear system with unknown inputs satisfying algebraic constraints. We obtain necessary and sufficient conditions for observability in terms of the zeros of the system matrix.

• \cite{53} is concerned with the study of observability properties of systems without inputs via homogeneous approximations. This approximation is induced by a filtration on the space of observation. A corresponding filtration on a Lie algebra of vector fields is defined and allows to construct the approximation that preserve observability properties. An explicit construction is given in \cite{53}.

5.4. Time-delay systems

Participants: Jean-Pierre Richard, Jean-Pierre Barbot, Thierry Floquet, Gang Zheng, Denis Efimov, Wilfrid Perruquetti.

• \cite{22} considers a networked control loop, where the plant is a "slave" part, and the remote controller and observer constitute the "master". Since the performance of Networked Control Systems (NCS) depends on the Quality of Service (QoS) available from the network, it is worth to design a controller that takes into account qualitative information on the QoS in realtime. The goal of the design is to provide a controller that guarantees two things: 1) high performances (here expressed by exponential decay rates) when the QoS remains globally the same; 2) global stability when the QoS changes. In order to guarantee the global stability, the controller will switch by respecting a dwell time constraint. The dwell time parameters are obtained by using the switched system theories and the obtained conditions are Linear Matrix Inequalities (LMI).

• Causal and non-causal observabilities are discussed in \cite{33} for nonlinear time-delay systems with unknown inputs. Using the theory of non-commutative rings and the algebraic framework, the nonlinear time-delay system is transformed into a suitable canonical form to solve the problem. A necessary and sufficient condition is given to guarantee the existence of a change of coordinates leading to such a form.

• The notion of homogeneity is extended to the time-delay nonlinear systems in \cite{45}. It is shown that under some conditions the stability of homogeneous functional systems on a sphere implies the global stability of the system. The notion of local homogeneity is introduced, the relations between stability of the locally approximating dynamics and the original time-delay system are established.

• \cite{38} addresses the problem of the position/force tracking in tele-operation system and proposes a haptic proxy control scheme, in which communication delays are assumed to be both time-varying and asymmetric, and the response of the synchronization and the transparency are improved. The control design is performed using Linear Matrix Inequality (LMI) optimization based on Lyapunov-Krasovskii functionals (LKF) and $H_1$ control theory.

• Stability and synchronization of systems with time-varying delays is studied in \cite{37}, in which a novel control scheme with position/velocity information channel on the basis of Lyapunov-Krasovskii functional (LKF) and $H_1$ control theory by using Linear Matrix Inequality (LMI) is proposed. The proposed solution is efficient for different working conditions, such as abrupt motion and wall contact illustrated by various simulations.
• Embedded systems can benefit from all results on variable sampling for delayed systems [18], [19] and [47].

OASIS Project-Team

6. New Results

6.1. Distributed Programming Models

6.1.1. Multi-active Objects

Participants:  L. Henrio, I. Zsolt, F. Huet.

The active object programming model is particularly adapted to easily program distributed objects: it separates objects into several activities, each manipulated by a single thread, preventing data races. However, this programming model has its limitations in terms of expressiveness – risk of deadlocks – and of efficiency on multicore machines. We proposed extends active objects with local multi-threading. We rely on declarative annotations for expressing potential concurrency between requests, allowing easy and high-level expression of concurrency. This year contribution includes

- publication of the basic principles of the new model [ 25 ]
- refinement of the proposal and adding dynamic compatibility
- operational semantic for multi-active objects
- extensive experiments

6.2. Component-oriented Distributed and Large-Scale Programming

6.2.1. Behavioural models for Distributed Components

Participants:  E. Madelaine, R. Halalai, A. Savu, M. Alexe, L. Henrio.

In the past, we defined the behavioural semantics of active objects and components, in [ 3 ]; we extended last year this work to take group communications. On the practical side, this work contributes to the Vercors platform; the overall picture being to provide tools to the programmer for defining his application, including its behavioural specification. Then some generic properties like absence of deadlocks, but also application specific properties can be validated on the composed model using an existing model-checker. We mainly use CADP model-checker, that also supports distributed generation of state-space. This year our main achievements are the following:

- We provided model for one-to-many component communication
- We provided a model for Byzantine failures, specified a component application supporting some Byzantine faults, and proved its correctness;
- We conducted heavy experiments on distributed model-checking in this context;
- We worked on the formal specification of the behavioural model generation for component systems.

Most of those results were published in [ 22 ] and [ 35 ].

6.2.2. Enacting large-scale service orchestration using a component-based approach

Participants:  F. Baude, V. Legrand.
The distribution of business processes encompasses the inclusion of external service providers in the overall process as well as the usage of external infrastructures like clouds. Both of these approaches lead to decentralization and outsourcing of a part of the global workflow, resulting in a complexified management of the global orchestration. As a matter of fact, the overall data are decentralized among different domains and must, most of the time, be gathered manually. To this extent, we continue our work on agile and distributed orchestration, showing that the framework we develop eases multidomain orchestration management. Our approach extracts, gathers and digests data from the decentralized processes in order to provide an unified and global view of a distributed orchestration. This year we focussed in particular on:

- The specification of the execution framework extending the SCA specification by adding temporal dependencies
- The definition of a use-case allowing the provisioning of a large set of OSGi gateways.

This work resulted in the PhD thesis of Virginie Legrand [12].

### 6.2.3. Autonomic Monitoring and Management of Components

**Participants:** F. Baude, C. Ruz, B. Sauvan, R. Dib.

We have completed the design of a framework for autonomic monitoring and management of component-based applications. We have provided an implementation using GCM/ProActive taking advantage of the possibility of adding components in the membrane, and we have tested it in simple applications. Our implementation allows the designer to describe in a separate way each phase of the MAPE autonomic control loop (Monitoring, Analysis, Planning, and Execution), and to plug them or unplug them dynamically [16].

- We presented the general description of the framework and its capability to support autonomic behaviour in [30]. This work takes advantage of the componentized membrane of GCM/ProActive, and of the PAGCMScript reconfiguration extensions made in our team.
- We used our proposition to design an integrated framework to cover the life-cycle of a service application from business and design level, to deployment and execution concerns in a Cloud environment, in a work done in conjunction with Adrian Mos and Alain Boulze formerly leading the INRIA ADT Galaxy from INRIA Rhône-Alpes. This work was presented in the SoEA4EE workshop [29].
- We experimented with the use of our autonomic framework to integrate autonomic behaviour into skeletons. This work was taken during the engineering internship of Rima Dib, and included the collaboration with Marco Danelutto from Università di Pisa.

### 6.3. Middleware for Grid and Cloud computing

#### 6.3.1. RDF Data Storage and Retrieval In P2P Systems

**Participants:** I. Filali, F. Huet, F. Baude, F. Bongiovanni, L. Pellegrino, B. Sauvan, I. Alshabani, A. Bourdin.

We have proposed in the context of the SOA4ALL FP7-IP project (8.3.1.1) the design and the implementation of a hierarchical Semantic Space infrastructure based on Structured Overlay Networks (SONS) [46],[10]. It aims at the storage and the retrieval of the semantic description of services at the Web scale [47]. This infrastructure combines the strengths of both P2P paradigm at the architectural level and the Resource Description Framework (RDF) data model at the knowledge representation level. As it is designed, the proposed infrastructure enables the processing of simple and complex queries. This year, the following achievements have been realised.

- A thorough survey of the existing works that have adapted the combination of RDF data model and the P2P communication model to build distributed infrastructures for RDF data storage and retrieval has been performed. This effort was published in a journal [34]. A previous but more complete version of this work can be found in a research report [45] and was used extensively in [39],[38],[36].
• We provided and presented in [23] an implementation of a three dimensional CAN overlay network for storing and retrieving RDF triples. At the implementation level, a modular and flexible architecture for the Semantic Space infrastructure has been proposed. The implementation relies on the ProActive Grid middleware and provides a clear separation between its sub-components (overlay, storage, query engine, etc.). The modularity of the architecture is combined with the decentralized aspect of the infrastructure enabling the RDF data storage and retrieval at large scale. The evaluation of the infrastructure through micro-benchmarks experiments on clusters and grids shows the impact of the architecture and data distribution on the performance of the storage and processing mechanisms.

In the context of the FP7 Strep PLAY (8.3.1.2) and French ANR SocEDA (8.2.2) research projects, we have extended the aforementioned work with a content-based Publish/Subscribe abstraction in order to support asynchronous queries for RDF-based events in large scale settings. In order to support these queries efficiently, we worked on an efficient broadcast primitive on top of CAN which we formalized and implemented (see section 6.3.2). We are also working towards a generalization of this broadcast algorithm to a multicast one, and contribute intensively to the general integration effort for offering such innovative semantic described event marketplace platform at cloud scale [41].

6.3.2. An algorithm for efficient broadcast over CAN-like P2P networks
Participants: L. Henrio, F. Bongiovani, A. Craciun.

The nature of some large-scale applications such as content delivery systems or publish/subscribe systems, built on top of structured overlay networks, demands application-level dissemination primitives which do not overwhelm the overlay and which are also reliable. Building such communication primitives in a reliable manner on top of such networks would increase the confidence regarding their behavior prior to deploying them in real settings. In order to come up with real efficient primitives, we take advantage of the underlying geometric topology of the overlay network and we also model the way peers communicate with one another. For this our objective is to design and prove an efficient and reliable broadcast algorithm for CAN-like P2P networks. To this aim, this year we:

• Formalised in Isabelle/HOL a CAN-like P2P system, devised formalised tools to reason on CAN topologies, and on communication protocols on top of CANs. We proved first completeness and correctness properties on some classes of broadcast algorithms.
• Designed an efficient broadcast algorithm on top of CAN and implemented it.

Preliminary results were presented at CFSE and published as a research report [37]; another publication is being written under way.

6.3.3. Matlab/Scilab parallel programming
Participant: F. Viale.

Matlab & Scilab, with millions of users around the world, are industry standards for numerical computing. They both lack a powerful and modern parallel computing framework to meet the industry’s growing demand in terms of parallel processing. This activity is intended to integrate into both softwares a toolbox for parallel processing, based on ProActive.

• This year, we implemented a ProActive Scilab toolbox with the same functionalities as the ProActive Matlab toolbox we built last year.
• We added in the Matlab toolbox a disconnected mode to allow closing the Matlab session while uncomplete Matlab jobs are still running on the scheduler side, and retrieving the job results at the next connection.
• We reorganized both Matlab and Scilab toolboxes with a cleaner and more intuitive API, a stronger and stabler implementation and an extensive documentation. We designed as well unit-tests to make the toolboxes fully usable for production standards.
• The Scilab toolbox is now deployed on PACAGrid cluster and used extensively by other partners of the OMD2 ANR.
6.3.4. Network Aware Cloud Computing

Participants: S. Malik, F. Huet.

We have proposed a cloud scheduler module named Network Awareness Module (NAM), which helps the scheduler to take the more efficient scheduling decisions on the basis of resource features, such as network latency, reliability, environment compatibility and monetary cost issues.

- Currently we are working on Reliability Assessment based Scheduling on Cloud Infrastructure. We are building a model, which enables a scheduler to schedule the tasks on cloud infrastructure, on the basis of adaptive reliability of nodes (virtual machine). The core of this model is a reliability assessment algorithm, which computes the reliability for individual resources and for the group of resources.

- We have proposed, designed and implemented an algorithm for the grouping of nodes on the basis of inter-node latencies. This algorithm can do the dynamic grouping and work with the incomplete latency information available. It groups the nodes on the basis of node latency instead of neighbor count. It produces mutually exclusive groups and can perform group reconfiguration.

- We have designed a model of the Virtual Cloud [27]. The concept of Virtual cloud revolves around the concept, “Rent Out the Rented Resources”. In this model, cloud vendors offer low cost cloud services by acquiring underutilized resources from some big third-party enterprise. The cloud vendor then further rents out those resources/services to the cloud users. The upfront and administrative costs for the Virtual cloud vendor are lower, and the cloud users access services at a cheaper rate.

- We have proposed a fault tolerance model for real time cloud computing [27]. In this model, the system tolerates the faults and makes the decision on the basis of reliability of the virtual machines. The reliability of the virtual machines is adaptive, which changes after every computing cycle. A metric model is given for the reliability assessment. The system provides both the forward and backward recovery mechanisms.
6. New Results

6.1. Mathematical analysis and control of macroscopic traffic flow models

6.1.1. Vehicular traffic

Participants: Maria Laura Delle Monache, Paola Goatin, Mauro Garavello [Piedmont University, Italy].

Concerning road traffic, the research activity during 2011 focused on the mathematical analysis of traffic flow models on road networks or subject to unilateral constraints. In particular, [34] is devoted to a hyperbolic 2nd order model for traffic flow with local flux constraint. We describe two admissible Riemann solvers and we construct ad hoc finite volume numerical schemes to compute these solutions. The paper [59] is devoted to the study of a traffic flow model on a network composed by an arbitrary number of incoming and outgoing arcs connected together by a node with a buffer. We define the solution to the Riemann problem at the node and we prove existence and well posedness of solutions to the Cauchy problem. Finally, a general traffic flow model with phase-transition is proposed and described in [28].

M.L. Delle Monache just started her doctoral thesis in the same topic. More precisely she will study hyperbolic models of traffic flow and associated optimization problems.

6.1.2. Crowd motion

Participants: Nora Aïssiouene, Régis Duvigneau, Nader El Khatib, Jihed Joobeur, Paola Goatin, Massimiliano D. Rosini [ICM, Warsaw University, Poland].

Concerning pedestrian motion modeling, we are interested in the optimization of facilities design, in order to maximize pedestrian flow and avoid or limit accidents due to panic situations. To this aim, we are now studying a macroscopic model for crowd movements consisting in a scalar conservation law accounting for mass conservation coupled with an Eikonal equation giving the flux direction depending on the density distribution. From the theoretical point of view, and as a first step, we are studying the problem in one space dimension (for applications, this case corresponds to a crowd moving in a corridor). In collaboration with M. Rosini (supported by the project CROM3, funded by the PHC Polonium 2011), we have established entropy conditions to select physically relevant solutions, and we have constructed explicit solutions for some simple initial data (these results are presented in [54]). We are now studying existence and uniqueness of solutions of the corresponding initial boundary value problem. From the numerical point of view, we are implementing the model in two space dimensions on triangular meshes on the Num3sis platform. This was partly done by N. El-Khatib (postdoc at INRIA from January to August 2011), and will be completed soon by Nora Aïssiouene. This will provide a performing numerical tool to solve the related optimization problems arising in the optimization of facilities design, such as the position and size of an obstacle in front of (before) a building exit in order to maximize the outflow through the door and avoid or limit over-compression. Moreover, jointly with the PULSAR team, we have supervised J. Joobeur’s internship, which was devoted to pedestrian data collection from real-word video recordings (Turin metro station). The density data will serve to validate the model.

The above researches were partially funded by the ERC Starting Grant “TRAM3 - Traffic management by macroscopic models”.

6.2. Optimum design in fluid dynamics and its couplings

In computational sciences for physics and engineering, Computational Fluid Dynamics (CFD) are playing one of the major roles in the scientific community to foster innovative developments of numerical methodologies. Very naturally, our expertise in compressible CFD has led us to give our research on numerical strategies for optimum design a particular, but not exclusive focus on fluids.
6.2.1. **Cooperation and competition in multidisciplinary optimization**

**Participants:** Étienne Baratchart [ENSEIBB MATMÉCA], Jean-Antoine Désidéri, Régis Duvigneau, Adrien Zerbinati.

The framework of our research aims to contribute to numerical strategies for PDE-constrained multiobjective optimization, with a particular emphasis on CPU-demanding computational applications in which the different criteria to be minimized (or reduced) originate from different physical disciplines that share the same set of design variables. These disciplines are often fluids, as a primary focus, coupled with some other discipline, such as structural mechanics.

Our approach to competitive optimization is based on a particular construction of Nash games, relying on a split of territory in the assignment of individual strategies. A methodology has been proposed for the treatment of two-discipline optimization problems in which one discipline, the primary discipline, is preponderant, or fragile. Then, it is recommended to identify, in a first step, the optimum of this discipline alone using the whole set of design variables. Then, an orthogonal basis is constructed based on the evaluation at convergence of the Hessian matrix of the primary criterion and constraint gradients. This basis is used to split the working design space into two supplementary subspaces to be assigned, in a second step, to two virtual players in competition in an adapted Nash game, devised to reduce a secondary criterion while causing the least degradation to the first. The formulation has been proved to potentially provide a set of Nash equilibrium solutions originating from the original single-discipline optimum point by smooth continuation, thus introducing competition gradually. This approach has been demonstrated over a testcase of aero-structural aircraft wing shape optimization, in which the eigen-split-based optimization reveals clearly superior [33].

While the two-discipline method is currently being applied to various complex physical multiobjective situations (see in particular 6.2.2, 6.2.6, 6.2.7, 6.2.8), the method has been extended to situations involving more than two objectives when the initial point is Pareto-optimal. Then, a particular convex combination of the criteria is locally stationary, and the two-discipline strategy can be applied using this combination as preponderant criterion, and a particular other criterion as secondary one. Whence, the proposed split of territory produces a continuum of Nash equilibrium points tangent to the Pareto set. This theoretical result has been illustrated in the context of a simpler numerical experiment by E. Baratchart during his internship [53], see Fig. 3.

![Figure 3. Combination of cooperative and competitive optimization algorithms: in red the Pareto set, in blue MGDA steps directed to the Pareto set, in green steps by Nash games with split of territory tangent to the Pareto set.](image_url)
Our approach to cooperative optimization is based on a result of convex analysis established for a general unconstrained multiobjective problem in which all the gradients are assumed to be known. The theorem [58] states that in the convex hull of the gradients, there exists a unique vector of minimal norm, $\omega$; if it is nonzero, the vector $\omega$ is a descent direction common to all criteria; otherwise, the current design point is Pareto-optimal. This result led us to generalize the classical steepest-descent algorithm by using the vector $\omega$ as search direction. We refer to the new algorithm as the multiple-gradient descent algorithm (MGDA). The MGDA yields to a point on the Pareto set, at which a competitive optimization phase can possibly be launched on the basis of the local eigenstructure of the different Hessian matrices. This general formulation fosters several connected studies detailed in 6.2.3.

6.2.2. Virtual games for coupling global to local shape optimization

Participant: Régis Duvigneau.

In several engineering problems, the system to optimize is characterized by some parameters that define global shape properties, while remaining parameters define local shape modifications. Of course, these two sets of parameters do not play the same role and have not the same impact on the cost functional value. Therefore, we are studying how to construct an efficient optimization strategy that takes benefit of this global / local splitting of parameters.

A typical aerodynamic shape optimization problem has been studied, that consists of a lift-constrained drag minimization for a transonic wing, whose sections are defined by two B-Spline curves whereas global shape characteristics are defined by five parameters (span, root tip length ratio, angle of attack, twist angle, sweep angle). It has been found that the naive simultaneous optimization of all parameters failed, due to the multimodality of the problem. Alternatively, the use of a virtual game strategy, based on a splitting between the local and global parameters, yields a satisfactory result for a moderate cost [47].

6.2.3. Multiple-Gradient Descent Algorithm (MGDA)

Participants: Jean-Antoine Désidéri, Régis Duvigneau, Adrien Zerbinati.

6.2.3.1. Basic experiments and validation

In multi-objective optimization, the knowledge of the Pareto set provides valuable information on the reachable optimal performance. A number of evolutionary strategies (PAES, NSGA-II, etc), have been proposed in the literature and proved to be successful to identify the Pareto set. However, these derivative-free algorithms are very demanding in terms of computational time. Today, in many areas of computational sciences, codes are developed that include the calculation of the gradient, cautiously validated and calibrated.

In [50], MGDA has been tested over a number of classical multiobjective-optimization testcases, and found successful to converge to Pareto-optimal solutions in situations of either convex or concave Pareto sets. Additionally, MGDA and PAES [61] were found to have complementary merits, making a hybrid method promising.

6.2.3.2. Metamodel-supported CFD optimization by MGDA

Using MGDA in a multi objective optimization problem requires the evaluation of a large number of points with regard to criteria, and their gradients. In the particular case of a CFD problems, each point evaluation is very costly since it involves a flow computation, possibly the solution of an adjoint-equation. To alleviate this difficulty, we have proposed to construct metamodels of the functionals of interest (lift, drag, etc) and to calculate approximate gradients by local finite differences. These metamodels are updated throughout the convergence process to the evaluation of the new design points by the high-fidelity model, here the 3D compressible Euler equations.

This variant of MGDA has been tested successfully over a problem of external aerodynamic optimum-shape design of an aircraft wing consisting of reducing wave-drag, and augmenting lift. After only a few cycles of database updates, the Pareto front visibly forms, and this result is achieved at a very moderate computational cost. This variant is currently being tested and extended to an internal flow optimization problem related to an automobile air-conditioning system and governed by the Navier-Stokes equations. This more difficult problem has been proposed by Renault within the OMD2 ANR project.
6.2.3.3. MGDA in functional setting

One aspect of the theoretical result concerning the minimal-norm element $\omega$ is that, regardless the possibly-functional setting of the problem in case of a distributed system, the descent-direction $\omega$ is identified in the standard $n$-dimensional vector space $\mathbb{R}^n$ ($n$: the number of objective functions).

This observation has led to examine the application of MGDA in the functional setting of domain-decomposition methods (DDM) in which a functional criterion and a functional control can be defined at each interface independently permitting to formulate the DDM problem as a multi-objective optimization. On-going research in this area is related to the necessary preconditioning, or normalization procedure, of the gradients.

6.2.4. Flow control

Participants: Régis Duvigneau, Jérémie Labroquère.

Shape optimization methods are not efficient to improve the performance of fluid systems, when the flow is characterized by a strong unsteadiness related to a massive flow separation. This is typically the case for the flow around an automotive body or a wing in stall condition. To overcome this difficulty, flow control strategies are developed, that aim at manipulating vortex dynamics by introducing some active actuators, such as periodic blowing/suction jets. In this context, the choice of the control parameters (location, amplitude, frequency) is critical and not straightforward. Therefore, a numerical study is conducted to i) improve the understanding of controlled flows ii) develop a methodology to determine optimal control parameters by coupling the controlled flow simulation with optimization algorithms. Two research axes have been considered:

- the solution of the unsteady sensitivity equations derived from the state equations, to exhibit the dependency of the flow dynamics with respect to the control;
- the optimization of control parameters using a statistical metamodel-based strategy. First results show the efficiency of such an approach for laminar flow problems [31], [44].

6.2.5. Optimum shape design in aerodynamics by the adjoint method

Participants: Manuel Bompard, Sébastien Bourasseau, Jean-Antoine Désideri, Jacques Peter [Research Engineer, ONERA/DSNA].

At ONERA, compressible flow simulations governed by the Euler or Navier Stokes (RANS) equations are conducted with the software elsA [57] that admits both structured and unstructured-grid formulations. Local aerodynamic optimizations are made with a version that includes the calculation of the shape gradient via the solution of an adjoint equation. The discrete adjoint is calculated formally step-by-step to include the various derivative terms involved, and is being enhanced gradually to account for more complex models. In particular, for RANS computations, this gradient today includes the differentiation of the turbulence model.

6.2.5.1. Metamodels including derivative information

In this context, to alleviate the cost of an optimum-shape design in aerodynamics, M. Bompard in his thesis [26], has examined how metamodels, firstly based on functional values only, could be used to determine shortcuts in the convergence process. Second, when the gradient w.r.t. the design parameters is known, the gradients of functionals of interest, that is, most commonly, aerodynamic coefficients, are calculated. Thus, these derivative informations can also used to construct more elaborate metamodels. Such constructions have also been studied systematically and used efficiently in global optimizations [37]; in particular co-Kriging and Support-Vector Regression, for which a technique to adjust automatically the free parameters has been proposed based on a simplification of the leave-one-out test.

6.2.5.2. Parameterization-free local optimization

When the derivatives of the functionals w.r.t. the volume geometry, $dJ/dX$, have been calculated, it is also possible to calculate the gradient w.r.t. surface coordinates, $dJ/DS$. Since the surface deformation steers the entire mesh movement, often through analytical dependencies, M. Bompard [26] has also examined how could $dJ/DS$ be used directly in a local aerodynamic optimization. However, it is well-known that the distribution of $dJ/DS$ is very irregular, and its usage in the optimization loop necessitates that adequate smoothing procedures be elaborated. Partial success was achieved in this area, still subject to research.
6.2.6. Aero-structural optimization

**Participants:** Gérald Carrier [Research Engineer, ONERA/DAAP], Jean-Antoine Désideri, Imane Ghazlane.

In industry, aircraft wings are designed by accounting for several multidisciplinary couplings. Certainly of greatest importance is the coupling, or concurrency, between aerodynamic optimization and structural design. At ONERA, in the former thesis of M. Marcelet, the aerodynamic gradient has been extended to account for (the main terms of) static fluid-structure interaction, commonly referred to as the “aeroelastic gradient”.

In her thesis, I. Ghazlane has extended M. Marcelet’s work to take into account, in the aeroelastic gradient, the terms originating from the differentiation of the wing-structural model. In this development, the wing structure is treated as an equivalent Euler-Bernoulli beam. These formal extensions have been validated by an extensive experimentation. Additionally, special post-processing procedures are applied to evaluate accurately the various physical contributions to drag. As a result, the numerical tools necessary to conduct a very realistic aircraft wing optimization are now set up and are being exploited [38]. It is also envisaged to conduct a two-objective optimization (drag and mass reduction) via a Nash game using our optimization platform FAMOSA.

6.2.7. Sonic boom reduction

**Participants:** Gérald Carrier [Research Engineer, ONERA/DAAP], Jean-Antoine Désideri, Andrea Minelli, Itham Salah El Din [Research Engineer, ONERA/DAAP].

When an aircraft flies at supersonic speed, it generates at ground level an N-shaped shock structure which can cause serious environmental damage (“sonic boom”). Thus a problem of interest in aerodynamic optimization is to design such an aircraft to reduce the intensity of the sonic boom while maintaining the aerodynamic performance (drag minimization under lift constraint). Andrea Minelli’s aimed at contributing to this two-discipline optimization problem. In the first part of his work, an inverse problem has been formulated and solved for “shaped sonic boom” and found in excellent agreement with the George-Seebs-Barden theory [60] for the calculation of the Whitham function corresponding to the lowest-boom (axisymmetric) shape. The method is currently being extended to account for more general geometries. Besides, aero-acoustic optimizations have been realized successfully by coupling the aerodynamic optimizer (based on Euler calculations by the elsA software) with the sonic-boom computation in a Nash game formulation. These experiments, conducted with our optimization platform FAMOSA, have demonstrated that starting from the shape optimized aerodynamically, one could retrieve smoothly a shape corresponding to nearly-optimal sonic-boom reduction.

6.2.8. Helicopter rotor blade optimization in both situations of hovering and forward flight

**Participants:** Michel Costes [Research Engineer, ONERA/DAAP], Jean-Antoine Désideri, Arnaud Le Pape [Research Engineer, ONERA/DAAP], Enric Roca Leon.

E. Roca Leon has recently started at ONERA a CIFRE thesis supported by EUROCOPTER, Marignane. This thesis follows the doctoral thesis of A. Dumont in which the adjoint-equation approach was used to optimize a rotor blade in hovering flight. The goal of this new thesis is to solve a two-objective optimization problem in which the hovering-flight criterion is considered preponderant, but a new criterion that takes into account the forward-flight situation is also introduced, concurrently. The thesis work includes the set up of a hierarchy of models from low to high fidelity, in order to calibrate appropriate functional criteria. Secondly, our Nash game approach to competitive optimization will be implemented, using our optimization platform FAMOSA, and comparisons with the results by A. Dumont will be made.

6.2.9. Optimum design in naval hydrodynamics

**Participants:** Régis Duvigneau, Louis Blanchard.

Naval hydrodynamics field has recently shown a growing interest for optimum design methods. The computational context is especially complex because it implies unsteady two-phase turbulent flows, with possibly very high Reynolds number (up to $10^9$). The use of automated design optimization methods for such problems requires new developments to take into account the large CPU time necessary for each simulation and the specificity of the geometries considered.
In collaboration with GALAAD Project-Team, some developments have been initiated on the geometrical modeling of hull shapes by parametric surfaces. The objective is to be able to modify existing hull shapes by controlling a small number of parameters, that are meaningful for naval architects. Two testcases are considered: the bow shape for trawler ships (see Fig. 4) and the whole hull shape for canoes, in collaboration with the Fédération francaise de Canoe-Kayak.

Figure 4. Initial shape (left) and deformed shape to generate a bow (right) for the trawler ship, to reach two line targets (in red).

6.3. Optimum design in structural mechanics

6.3.1. Shape Optimization in Multidisciplinary Non-Linear Mechanics

Participants: Aalae Benki, Jean-Antoine Désidéri, Abderrahmane Habbal.

In collaboration with the ArcelorMittal’s Center for Research in Automotive and Applications, we study the multidisciplinary shape and parameter design of highly non-linear mechanical 2D and 3D structures. We have developed methods adapted to the approximation of Pareto Fronts such as Normal Boundary Intersection NBI and Normalized Normal Constraint Method NNCM. Due to the time consuming cost evaluation, the use of cheap to evaluate surrogate models is mandatory. We have studied the consistency of the approach NBI or NNCM plus surrogates, which turned out to be successful for a broad panel of standard mathematical benchmarks. The application of this approach for the case of beverage cans which undergo elastoplastic deformation under high pressure is ongoing.

6.3.2. Optimization of Addendum Surfaces in Stamping

Participants: Fatima Zahra Oujebbour, Jean-Antoine Désidéri, Abderrahmane Habbal.

Within the OASIS Consortium (ArcelorMittal, ErDF, INRIA, UTC, EURODECISION, ESILV, NECS, DeltaCAD, SCILAB-DIGITEO), Opale Project leads the Optimization task. Our aim is to develop decentralized decision-making algorithms dedicated to find efficient solutions (Pareto optimal) in a complex multidisciplinary framework (forming, stamping, welding non-linear processes, spring-back, vibration, in-function linear processes, crash and fatigue non linear and non differentiable processes) for several (between three and five) criteria. An important difficulty when trying to identify the Pareto Front, even when using adapted methods such the Normal Boundary Intersection, is that the criteria involved (thanks to the high nonlinearity in the mechanical models) exhibit many local optima. So one must use global optimization methods. We have studied the hybrid approach Simulated Annealing with Simultaneous Perturbation SASP for a suite of mathematical test-cases. To envisage the application of our method to the complex CPU time consuming stamping process, we lead an intermediate phase dedicated to the validation of the SASP method for the minimization of the spring-back that follows the stamping of a metal sheet, the design variable being the thickness distribution.
6.4. Application of shape and topology design to biology and medicine

6.4.1. Mathematical modeling of dorsal closure DC

Participants: Abderrahmane Habbal, Luis Almeida [University of Nice-Sophia Antipolis], Patrizia Bagnerini [Genova University], Fanny Serman [University of Nice-Sophia Antipolis], Stéphane Noselli [University of Nice-Sophia Antipolis], Glenn Edwards [Duke University].

A mathematical model for simulation of actin cable contraction, during wound closure for Drosophila embryo, which contains an extra term in addition to the curvature flow is developed. The basic mathematical model introduced and validated in [27] is extended in order to include the non-homogeneous wound healing or non-homogeneous dorsal closure [52].

6.5. Particular applications of simulation methods

6.5.1. Analysis of a two-level parameterization optimization for antenna design

Participants: Benoît Chaigne [Doctoral student, 2007-2010], Jean-Antoine Désideri.

Similar to the discretization of ordinary or partial differential equations, the numerical approximation of the solution of an optimization problem is possibly subject to numerical stiffness. In the framework of parametric shape optimization, hierarchical representations of the shape can be used for preconditioning, following the idea of Multigrid (MG) methods. By analogy with the Poisson equation, which is the typical example for linear MG methods, we have addressed a parametric shape inverse problem. The ideal cycle of a two-level algorithm can be defined and adapted to shape optimization problems that require appropriate transfer operators. With the help of a symbolic calculus software we have shown that the efficiency of an optimization MG-like strategy is ensured by a small dimension-independent convergence rate. Numerical examples are worked out and corroborate the theoretical results. Applications to antenna design have been realized. Finally, some connections with the direct and inverse Broyden-Fletcher-Goldfarb-Shanno preconditioning methods have been shown [29].

6.5.2. Mesh qualification

Participants: Jean-Antoine Désideri, Maxime Nguyen, Jacques Peter [Research Engineer, ONERA/DSNA].

M. Nguyen Dinh is conducting a CIFRE thesis at ONERA supported by AIRBUS France. The thesis topic is the qualification of CFD simulations by anisotropic mesh adaption. Methods for refining the 2D or 3D structured mesh by node movement have been examined closely. Secondly, it is investigated how could the local information on the functional gradient $\|dJ/dX\|$ be exploited in a multi-block mesh context. This raises particular questions related to conservation at the interfaces.

6.5.3. Hybrid meshes

Participants: Sébastien Bourasseau, Jean-Antoine Désideri, Jacques Peter [Research Engineer, ONERA/DSNA], Pierre Trontin [Research Engineer, ONERA/DSNA].

S. Bourasseau has started a CIFRE thesis at ONERA supported by SNECMA. The thesis is on mesh adaption in the context of hybrid meshes, that is, made of both structured and unstructured regions. Again, the aim is to exploit at best the function gradient provided by the adjoint-equation approach. Preliminary experiments have been conducted on geometries of stator blade yielding the sensitivities to global shape parameters.

6.5.4. Nash game approach to image processing

Participants: Abderrahmane Habbal, Rajae Aboulaich [Mohamed V University of Rabat], Maher Moakher [University of Tunis], Moez Kallel [University of Tunis], Anis Theljani [University of Tunis].
We have started in 2011 to study the application of game modeling to image processing problems. We propose an original game theory approach to simultaneously restore and segment noisy images [56]. We define two players: one is restoration, with the image intensity as strategy, and the other is segmentation with contours as strategy. Cost functions are the classical relevant ones for restoration and segmentation, respectively. The two players play a static game with complete information, and we consider as solution to the game the so-called Nash Equilibrium. For the computation of this equilibrium we present an iterative method with relaxation. The results of numerical experiments performed on some real images show the relevance and efficiency of the proposed algorithm. Based on a similar idea, we formulated well known data completion (Cauchy) problems for Laplace equation as Nash games [55] and obtained results of existence, uniqueness and stability of a Nash equilibrium which turns out to be the Cauchy solution when the Cauchy data are compatible. With A. Theljani, we study the extension of the Nash data completion approach to nonlinear parabolic equations with application to image inpainting.

6.6. Isogeometric analysis and design
Participants: Louis Blanchard, Régis Duvigneau, Bernard Mourrain [Galaad Project-Team], Gang Xu [Galaad Project-Team].

Design optimization stands at the crossroad of different scientific fields (and related software): Computer-Aided Design (CAD), Computational Fluid Dynamics (CFD) or Computational Structural Dynamics (CSM), parametric optimization. However, these different fields are usually not based on the same geometrical representations. CAD software relies on Splines or NURBS representations, CFD and CSM software uses grid-based geometric descriptions (structured or unstructured), optimization algorithms handle specific shape parameters. Therefore, in conventional approaches, several information transfers occur during the design phase, yielding approximations that can significantly deteriorate the overall efficiency of the design optimization procedure. Moreover, software coupling is often cumbersome in this context.

The isogeometric approach proposes to definitely overcome this difficulty by using CAD standards as a unique representation for all disciplines. The isogeometric analysis consists in developing methods that use NURBS representations for all design tasks:

- the geometry is defined by NURBS surfaces;
- the computation domain is defined by NURBS volumes instead of meshes;
- the solution fields are obtained by using a finite-element approach that uses NURBS basis functions;
- the optimizer controls directly NURBS control points.

Using such a unique data structure allows to compute the solution on the exact geometry (not a discretized geometry), obtain a more accurate solution (high-order approximation), reduce spurious numerical sources of noise that deteriorate convergence, avoid data transfers between the software. Moreover, NURBS representations are naturally hierarchical and allows to define multi-level algorithms for solvers as well as optimizers. In this context, some research axes have been developed in collaboration with GALAAD Project-Team:

- Methods for adaptive parameterization including a posteriori error estimate for elliptic problems [36], [35], [42];
- Numerical schemes based on Spline functions for 2D inviscid compressible flow simulations;
- Optimization methods for structural elasticity, based on shape-gradient concept, and fluid-structure interactions [48] (in collaboration with Technical University of Munich).

6.7. Resilient workflows for distributed multidiscipline optimization
Participants: Toan Nguyen, Laurentiu Trifan.
A distributed platform based on the YAWL workflow management system has been designed and implemented to deploy HPC applications on the Grid5000 network infrastructure. The goal is to provide a generic environment for the design of complex applications that require HPC resources for large-scale fault-tolerant applications, see Fig. 2 and [39].

The platform provides application-level fault-tolerance, i.e., resilience, in order to restart the workflow execution whenever abnormal behavior or system-level errors occur. This allows a variety of errors to be taken into account, ranging from execution time-outs to out-of-bounds parameter values to be managed, with the help of user intervention when necessary [40].

The error management procedure uses exception handlers in YAWL to trigger the appropriate corrective actions, which are defined by rules invoking the adequate compensating workflows. Once defined, this can be made transparent to the users [41].

An original scheme based on asymmetric checkpoints has been designed in order to reduce overhead in both checkpointing and application restarts. It minimizes the number of required checkpoints created based on default rules and user-specific needs.

The platform is currently developed in Java on Linux workstations and should be portable on Windows and MacOS, although this has not been tested yet.

Examples are deployed on the Grid5000 national network infrastructure using the OMD2 test-cases (e.g., vehicle air-conditioner pipe optimization). The goal is here to provide a demonstrator platform that deploys large-scale optimization applications involving several (typically over five) HPC clusters distributed on the Grid5000 network. The coarse-grain definition of the application is defined by a workflow that monitors the distributed execution of the parallel component codes on the various clusters, providing resilience capabilities in case of system and application errors, see Fig. 5.

![Figure 5. Application definition using YAWL.](image)
6. New Results

6.1. The Mining of Complex Data

Formal concept analysis, together with itemset search and association rule extraction, are suitable symbolic methods for KDDK, that may be used for real-sized applications. Global improvements may be carried on the scope of applicability, the ease of use, the efficiency of the methods, and on the ability to fit evolving situations. Accordingly, the team is working on extensions of such symbolic data mining methods to be applied on complex data such as biological or chemical data or textual documents, involving objects with multi-valued attributes (e.g. domains or intervals), n-ary relations, sequences, trees and graphs.

6.1.1. FCA, RCA, and Pattern Structures

Recent advances in data and knowledge engineering have emphasized the need for Formal Concept Analysis (FCA) tools taking into account structured data. There are a few extensions of FCA for handling contexts involving complex data formats, e.g. graphs or relational data. Among them, Relational Concept Analysis (RCA) is a process for analyzing objects described both by binary and relational attributes [116]. The RCA process takes as input a collection of contexts and of inter-context relations, and yields a set of lattices, one per context, whose concepts are linked by relations. RCA has an important role in KDDK, especially in text mining [85], [84].

Another extension of FCA is based on Pattern Structures (PS) [90], which allows to build a concept lattice from complex data, e.g. nominal, numerical, and interval data. In (major [5]), pattern structures are used for building a concept lattice from intervals, in full compliance with FCA, thus benefiting of the efficiency of FCA algorithms. Actually, the notion of similarity between objects is closely related to these extensions of FCA: two objects are similar as soon as they share the same attributes (binary case) or attributes with similar values or the same description (at least in part). Various results were obtained in the study of the relations existing between FCA with an embedded explicit similarity measure and FCA with pattern structures [48]. Moreover, similarity is not a transitive relation and this lead us to the study of tolerance relations. In addition, a new research perspective is aimed at using frequent itemset search methods for mining interval-based data being guided by pattern structures and biclustering as well [50], [49].

Pattern structures in association with a similarity measure were applied in the field of decision support in agronomy. In this domain, a set of agro-ecological indicators is aimed at helping farmers to improve their agricultural practices by estimating the impact of cultivation practices on the “agrosystem”. The modeling and the assessment of environmental risk require a large number of parameters whose measure is imprecise. The propagation of the imprecision and the different types of imprecision have to be taken into account in the computation of the value of indicators for decision support. Actually, based on pattern structures with a associated similarity measure, this problem has been approached as an information fusion problems with substantial results [34], [35].

6.1.2. Miscellaneous in FCA and Pattern Mining

In the field of medicine, an approach based on a combination of FCA with sequential pattern mining was developed to explore patients care trajectories (PCT) [46]. When PCT are modeled as multidimensional and multilevel sequences [108], the results of a frequent sequential itemsets search feed an FCA step in order to compute interests measures such as concept stability. These measures help the experts to find the most interesting sequential patterns.
In the context of environmental sciences, research work is in concern with the mining of complex hydroecological data with concept lattices. FCA was compared and combined with statistical approaches to deal with multi-valued contexts in hydroecology [31], [27], [39]. Regarding the preparation of agronomical data, we have developed an episode-based analysis about the design of information systems (actually, this work was carried out during the ANR-ADD COPT project between 2005 and 2008). We focused on the experience of persons in charge of building observatoires, i.e. information systems, for the monitoring and the management of rural territories [32]. Moreover, Florence Le Ber –as a member of UMR 7517 Lhyges, Strasbourg– is the scientific head of an ANR project named “FRESQUEAU” (2011–2014) dealing with FCA and data mining and hydroecological data (see http://fresqueau.engees.eu/).

For completing the work on itemset search, there is still on-going work on frequent and rare itemset search, for being able to build lattices from very large data and completing the algorithm collection of the Coron platform. This year, results were obtained on the design of an integrated and modular algorithm for searching for closed and generators itemsets, and equivalence classes of itemsets, thus enabling the construction of the associated lattice [56]. This research aspect is also linked to the research carried on within a the PICS CaDoE research project (see Section 8.1.3).

6.1.3. Skylines, sequences and privacy

Pattern discovery is at the core of numerous data mining tasks. Although many methods focus on efficiency in pattern mining, they still suffer from the problem of choosing a threshold that influences the final extraction result. The goal of a study done this current year (2011) is to make the results of pattern mining useful from a user-preference point of view. That is, take into account some domain knowledge to guide the pattern mining process. To this end, we integrate into the pattern discovery process the idea of skyline queries in order to mine skyline patterns in a threshold-free manner. This forms the basis for a novel approach to mining skyline patterns. The efficiency of our approach was illustrated over a use case from chemoinformatics and we showed that small sets of dominant patterns are produced under various measures that are interesting for chemical engineers and researchers [55].

Sequence data is widely used in many applications. Consequently, mining sequential patterns and other types of knowledge from sequence data has become an important data mining task. The main emphasis has been on developing efficient mining algorithms and effective pattern representation.

However, important fundamental problems still remained open: (i) given a sequence database, can we have an upper bound on the number of sequential patterns in the database? (ii) Is the efficiency of the sequence classifier only based on accuracy? (iii) Do the classifiers need the entire set of extracted patterns or a smaller set with the same expressiveness power?

In three different works on sequences, we study the problem of bounding sequential patterns with the combinatorial complexity of sequences and the problem of sequence classifiers with the constraints of optimizing both accuracy and earliness [53], [46].

Orpailleur is one of the few project-teams working on privacy challenges which are becoming a core issue with different scientific problems in computer science. Privacy-preserving data publication has been studied intensely in the past years. In our recent works, we introduce two different data anonymization methodologies based on different usability scenarios [57], [58].

6.1.4. KDDK in Text Mining

Ontologies help software and human agents to communicate by providing shared and common domain knowledge, and by supporting various tasks, e.g. problem-solving and information retrieval. In practice, building an ontology depends on a number of “ontological resources” having different types: thesaurus, dictionaries, texts, databases, and ontologies themselves. We are currently working on the design of a methodology and the implementation of a system for ontology engineering from heterogeneous ontological resources. This methodology is based on both FCA and RCA, and was previously successfully applied in contexts such as astronomy and biology. At present, an engineer is in charge of implementing a robust system
being guided by the previous research results and preparing the way for some new research directions involving trees and graphs.

In another work in text mining [19], we propose a method based on a syntactic parsing for extracting rich semantic relationships between pairs of entities co-occurring in a single sentence. The method was applied in pharmacogenomics (study of the impact of individual genomic variation on drug responses) and we obtained a resource encoded in RDF that summarizes pharmacogenomics relationships mentioned into roughly 17 million Medline abstracts. This resource appears to be of major interest since it is used to guide human curation of biomedical databases, and to derive new knowledge about drug-drug interactions [92].

6.2. KDDK in Life Sciences

One of the major challenges in the post genomic era consists in analyzing terabytes of biological data stored in hundreds of heterogeneous databases (DBs). The extraction of knowledge units from these large volumes of data would give sense to the present data production effort with respect to domains such as disease understanding, drug discovery, and pharmacogenomics or systems biology. Research reported here addresses these important issues and shows the spreading of KDDK over such domains.

6.2.1. Ontology-based Functional Classification of Genes

Functional classification involves grouping genes according to their molecular functions or the biological processes they participate in. This unsupervised classification task is essential for interpreting gene datasets produced by postgenomic experiments. As the functional annotation of genes is mostly based on the Gene Ontology (GO), many similarity measures using the GO have been described, but few of them have been used for clustering [107]. We have evaluated a functional classification of genes using our previously described IntelliGO semantic similarity measure with the help of reference sets [38]. The IntelliGO measure computes semantic similarity between genes for discovering biological functions shared by genes and takes into account domain knowledge represented in Gene Ontology [82]. The reference sets consist of genes taken from human and yeast KEGG (Kyoto Encyclopedia of Genes and Genomes) pathways and Pfam clans. Hierarchical clustering and heatmap visualization were used to illustrate the advantages of IntelliGO over several other measures. Because genes often belong to more than one reference set, the fuzzy C-means clustering algorithm was then applied to the datasets using IntelliGO. The F-score method was used to estimate the quality of clustering and the optimal number of clusters. The results were compared with those obtained from the state of the art DAVID (Database for Annotation Visualization and Integrated Discovery) functional classification method. Overlap analysis allows to study the matching between clusters and reference sets, and leads us to propose a set-difference method for discovering missing information [38]. The IntelliGO similarity measure, the clustering tool and the reference sets used for the evaluation are available at http://plateforme-mbi.loria.fr/intelligo.

6.2.2. Use of Domain Knowledge for Dimension Reduction

Data complexity is a major challenge for knowledge discovery approaches. High dimensionality of datasets can impair the execution of most data mining programs and/or lead to the production of numerous and complex patterns, improper for interpretation by the supervising expert. Thus, an important research orientation is dimension reduction as part of the data preparation step [93]. Domain knowledge is essential for achieving such dataset modification with minimal loss of information. The Life Sciences constitute a suitable domain for testing knowledge-guided approaches for dimension reduction because of the continuous increase in the number of both complex datasets and bio-ontologies. Most of these bio-ontologies are used for annotating biological objects leading to high-dimensional datasets. We propose a new approach for reducing dimensions
in a dataset by exploiting semantic relationships between terms of an ontology structured as a rooted directed acyclic graph [40]. Term clustering is performed thanks to the IntelliGO similarity measure and the term clusters are further used as descriptors for data representation. The technique was applied to a set of drugs associated with their side effects collected from the SIDER database. Terms describing side effects belong to the MedDRA terminology. The hierarchical clustering of about 1,200 MedDRA terms into an optimal collection of 112 term clusters led to a reduced data representation. Two data mining experiments were conducted to illustrate the advantage of using such reduced data representation.

Results obtained in the frame of the collaborative Grand Challenge project (see previous report 2009 and 2010) have been published this year. We have designed the HIV-PDI (Protein-Drug Interactions) resource as a decision making tool to propose alternative antiretroviral drugs (ARVs) for personalized antiretroviral treatment [22]. The HIV-PDI is an integrated database in which sequence mutations of viral proteins can be mapped onto three-dimensional structural interactions between these proteins and ARVs. Thus, critical loss of interactions leading to resistance can be detected and serve as indicators for proposing appropriate ARVs escaping the resistance. As a first step, the HIV-PDI was populated with data relating to HIV protease: clinical information on patients, resistance to ARVs treatments, HIV protease structures and mutations, ARV drugs and their 3D interactions with HIV protease models. Possible queries include protein, drug and treatment conditions, coupled with dedicated tools for visualization/analysis of 3D Protein-Drug interactions. Case-studies demonstrate the capabilities of the HIV-PDI resource for retrieving information associated with patients and for analyzing structural data relating proteins and ligands [23].

6.2.3. Mining Agronomical Data with stochastic models

In the framework of agricultural landscape data mining, we have developed an original approach combining two methods used separately so far: the identification of explicit farmer decision rules through on-farm surveys methods and the identification of landscape stochastic regularities through data-mining of the mosaic of agricultural parcels, following preceding work [96]. This approach was assessed in a study on the Niort plain (West of France) database. In this database, provided by the CEBC (UPR CNRS), the land use occupations of the fields covering a 400km² area are recorded during 12 years. It results a segmentation of the landscape, based on both its spatial and temporal organization and partly explained by generic farmer decision rules. This consistency between results points out that the two modelling methods interact and may be combined for land-use modelling at landscape scale and for understanding the driving forces of spatial organization. Based on farm surveys, we were able to retrieve and measure changes in land use occupation and link some farmer decision and spatiotemporal regularities that were observed in the landscapes.

6.3. Structural Systems Biology and Docking

Participants: Thomas Bourquard, Marie-Dominique Devignes, Anisah Ghoorah, Bernard Maigret, Lazaros Mavridis, Violeta Pérez-Nueno, Dave Ritchie, Malika Smaïl-Tabbone, Vishwesh Venkatraman.

Structural systems biology aims to describe and analyze the many components and interactions within living cells in terms of their three-dimensional (3D) molecular structures. Much of our work in this area has been funded by the ANR Chaîres d’Excellence project entitled “High Performance Algorithms for Structural Systems Biology” (HPASSB) which was awarded to Dave Ritchie (January 2009 – September 2011). A related follow-on ANR project entitled “Polynomial Expansions of Protein Structures and Interactions” (PEPSI) has recently started (November 2011). The HPASSB project complements existing competencies in the Orpailleur team represented by Marie-Dominique Devignes (CR CNRS) who is coordinating the MBI project (Modelling Biomolecules and their Interactions, http://bioinfo.loria.fr ), Malika Smaïl-Tabbone (MCU Nancy University) who is working on data integration and relational data-mining approaches, and Bernard Maigret (DR CNRS) who has an extensive experience of molecular dynamics and virtual screening. We are currently developing advanced computing techniques for molecular shape representation, protein-protein docking, protein-ligand docking, high-throughput virtual drug screening, and knowledge discovery in databases dedicated to protein-protein interactions. The PEPSI project is a collaboration with Sergei Grudinin at INRIA Grenoble (project Nano-D) and Valentin Gordeliy at the Institut de Biologie Structurale in Grenoble. This new project will
involve developing further the above techniques and using them to help solve the structures of large molecular systems experimentally.

6.3.1. Accelerating protein docking calculations using graphics processors

We have recently adapted the Hex protein docking software to use modern graphics processors (GPUs) to carry out the expensive FFT part of a docking calculation [115]. Compared to using a single conventional central processor (CPU), a high-end GPU gives a speed-up of 45 or more. This software is publicly available at http://hex.loria.fr. A public GPU-powered server has also been created (http://hexserver.loria.fr) [99]. These advances have facilitated further work on modeling the assembly of multi-component molecular structures using a particle swarm optimization technique [69].

6.3.2. Eigen-Hex: Modeling protein flexibility during docking

Although the Hex protein docking software can often make reasonably good predictions about how two proteins might fit together, a major limitation of many current algorithms, including Hex, is that that they assume that proteins are rigid objects. In fact, proteins can be highly flexible, and the internal conformations of their atoms often change on going from the unbound forms in the free proteins to the bound conformations in the complex. We have developed a novel approach to model such flexibility using a principal component analysis (PCA) technique to identify and predict the main atomic motions during a docking calculation. Our approach gives better results than rigid body docking, although the flexible docking problem is still by no means solved. A journal article describing this work has been submitted.

6.3.3. 3D-Blast: A new approach for protein structure alignment and clustering

We recently developed a new sequence-independent protein structure alignment approach called 3D-Blast [102], which exploits the spherical polar Fourier (SPF) correlation technique used in the Hex protein docking software [114]. This approach recently performed very well in a blind shape comparison experiment organized by Orpailleur as part of Eurographics Workshop on 3D Object Retrieval [103]. The utility of this approach has been demonstrated by clustering subsets of the CATH protein structure classification database [106] for each of the four main CATH fold types, and by searching the entire CATH database of some 12,000 structures using several protein structures as queries. Overall, the automatic SPF clustering approach agrees very well with the expert-curated CATH classification, and ROC-plot analysis of database searches show that the approach has very high precision and recall. We recently proposed that the 3D-Blast approach could ultimately provide a novel way to enumerate and index protein fold space (major [7]).

6.3.4. KBDOCK: Protein docking using Knowledge-Based approaches

Protein docking is the difficult computational task of predicting how a pair of three-dimensional protein structures come together to form a complex. Historically, there has been considerable interest in developing ab initio docking algorithms such as the Hex docking program developed by Dave Ritchie. However, as structural genomics initiatives continue to populate the space of protein 3D structures, and as several on-line databases of protein interactions have recently become available, using structural database systems to perform docking by homology will become an increasingly powerful approach to predicting protein interactions. In order to explore such possibilities, Anisah Ghoorah has recently developed the KBDOCK system as part of her doctoral thesis project. KBDOCK combines residue contact information from the 3DID database [117] with the Pfam protein domain family classification [89] together with coordinate data from the Protein Data Bank [86] in order to describe and analyze all known protein-protein interactions for which the 3D structures are available. In a recent publication [24] we demonstrated the utility of this approach for template-based docking using 73 complexes from the Protein Docking Benchmark [94]. KBDOCK is available at http://kbdock.loria.fr.

6.3.5. V-Dock: scoring protein-protein interactions using Voronoi fingerprints
There is growing interest in using machine learning techniques to analyze and populate protein-protein interaction (PPI) networks \[104\]. The aim of this project is to investigate the use of Voronoi fingerprints \[16\] as a way to distinguish cognate and non-cognate pairs of protein-protein interfaces. In collaboration with colleagues in the INRIA AMIB and INRA Bios teams, we recently applied our Voronoi fingerprint representation (V-Dock) to re-score rigid body docking predictions from Hex \[60\], and we demonstrated that it could be used to improve the ranking of 7 out of 9 docking targets from the CAPRI protein docking experiment \[60\]. This approach was also used to predict the stability of engineered protein structures for another recent CAPRI target \[21\].

6.3.6. DOVSA: Developing new algorithms for virtual screening

In 2010, Violeta Pérez-Nueno joined the Orpailleur team thanks to a Marie Curie Intra-European Fellowship (IEF) award to develop new virtual screening algorithms (DOVSA). The aim of this project is to advance the state of the art in computational virtual drug screening by developing a novel consensus shape clustering approach based on spherical harmonic (SH) shape representations \[110\]. The main disease target in this project is the acquired immune deficiency syndrome (AIDS), caused by the human immuno-deficiency virus (HIV) \[109\]. However, the approach will be quite generic and will be broadly applicable to many other diseases. So far, good progress has been made on calculating and clustering spherical harmonic “consensus shapes” which represent rather well the essential features of groups of active molecules \[30\]. Recent progress on this project has been presented orally at the 5th Journée Nationale de Chémoinformatique in Cabourg, the 9th International Conference on Chemical Structures in Noordwijkerhout, and at 3rd International Conference on Drug Discovery and Therapy in Dubai. A review of the state of the art in drug promiscuity was also recently published \[29\].

6.4. Around the Kasimir research project

**Participants:** Nicolas Jay, Jean Lieber, Bart Lamiroy, Amedeo Napoli, Thomas Meilender.

This special research project involves researchers working around the Kasimir project and Bart Lamiroy who was attached to the Orpailleur Team during his “INRIA délégation” (2010-2011) and at the same time was a visiting scientist at Lehigh University, USA. The background of Bart Lamiroy is in document and image analysis. Recently he was interested in investigating the application of KDDK to numerical and structural data including document images. The objective is to extend mining tools towards complex and semi-structured multi-media data on the one hand, and to associate image analysis with KDDK techniques on the other hand.

The main research direction which is followed at the moment is in concern with the Kasimir project. Actually, oncology protocols are mainly documented and represented in diagram formats. The classification and CBR techniques used in the Kasimir project require that the ontologies and decision protocols have to be represented in OWL. Based on previous work, we started modeling the mapping of visual features in diagram charts with semantics of the medical domain ontology. The mapping between the visual ontology and the domain ontology should guide a more complete extraction of the protocols from the diagrams for completing the domain ontology of the Kasimir system.

Moreover, during his stay at Lehigh University, Bart Lamiroy developed a new approach for recovering useful information within image data. By recording a wide range of “provenance information” related to complex image analysis processes, the DAE platform (http://dae.cse.lehigh.edu) provides a large set of metadata that can be used by KDDK methods. For example, this allows the correlation and combination of numerical and symbolic aspects, e.g. relating image aspects and domain symbolic representations (within domain ontologies). This work bridges the gap between formal knowledge representation and signal-based pattern recognition and offers a robust experimental environment for further application of KDDK on image data.

6.5. Around the Taaable research project

**Participants:** Julien Cojan, Valmi Dufour-Lussier, Inaki Fernandez, Emmanuelle Gaillard, Laura Infante-Blanco, Florence Le Ber, Jean Lieber, Amedeo Napoli, Emmanuel Nauer, Yannick Toussaint.
The Taaable project (http://taaable.fr) has been originally created as a challenger of the Computer Cooking Contest (CCC, organized during the ICCBR Conference). A candidate to this contest is a system whose goal is to solve cooking problems on the basis of a recipe book (common to all candidates), where each recipe is a shallow XML document with an important plain text part. The size of the recipe book (about 1500 recipes) prevents from a manual indexing of recipes: this indexing is performed using semi-automatic techniques.

After being ranked twice second, in the 2008 and 2009 CCCs organized during the ICCBR conference, Taaable won the first price and the adaptation challenge, in 2010 (note that no contest was organized in 2011). Beyond its participation to the CCCs, the Taaable project aims at federating various research themes: case-based reasoning, information retrieval, knowledge acquisition and extraction, knowledge representation, minimal change theory, ontology engineering, semantic wikis, text-mining, etc.

The most important original features of this version are:

A module for refining the domain ontology for improving the case retrieval. In Taaable, the retrieval of similar cases is based on a query generalization using an ontology of the cooking domain. In order to make the case retrieval more progressive and more precise, an enrichment of the domain ontology, and especially the ingredient hierarchy, has been studied and implemented [42]. The refinement process consists in inserting intermediate classes into the initial hierarchy of the system for better distinguishing classes that were initially not distinguishable. In order to introduce new classes into the initial hierarchy, the initial classes of ingredients have been characterized with additional properties. These additional properties are cooking actions that can be applied to ingredients and that have been extracted from the texts of recipes. FCA has been used on these new properties for restructuring the initial hierarchy.

A module for computing adaptation knowledge. Adaptation knowledge discovery has been performed for better adapting cooking recipes to user constraints. This paper extends the approach proposed in 2009 [80] for extracting this kind of adaptation knowledge. The adaptation knowledge comes from the interpretation of closed itemsets whose items correspond to the ingredients that have to be removed, kept, or added. An original approach focusing on a restrictive binary context building and on a specific ranking based on the form of the closed itemsets has been proposed [47].

Several theoretical studies have been carried out that should be applied to some future versions of Taaable:

- The representation of preparations in temporal representation formalisms [63].
- An algorithm for adapting cases defined in the expressive description logic $\mathcal{ALC}$ [43], [11].
- The study of the relations between adaptation based on belief revision and other approaches to adaptation [61], [11].
- The study of the extension of the domain ontology to make the retrieval step of a case-based reasoning system more accurate [42].
- The study of adaptation knowledge discovery based on variation of ingredients between pairs of recipes [42].
6. New Results

6.1. Improvement of theoretical foundations

6.1.1. Algebraic rewriting

Participant: Yves Guiraud.

With P. Malbos (Institut Camille Jordan, Univ. Lyon 1), in [13], we have used rewriting to give a theoretical setting and concrete formal methods to formalise and give constructive proofs of coherence theorems. The first one is Mac Lane’s classical result on monoidal categories: the new proof we give is a direct application of [7]. Then, cases like symmetric monoidal categories are a first step towards a “rewriting modulo” version of the same work. Finally, we give a new understanding and a constructive proof of the result for cases like braided monoidal categories.

With P. Malbos, in [14], we have generalised the work of [7] to any dimension. We have introduced a notion of polygraphic resolution that generalises both usual algebraic resolutions, in combinatorial algebra, but also, more surprisingly, normalisation strategies, as used in rewriting theory and, in particular, in rule-based programming languages. Thus, a functional program can be mathematically defined as a complete cellular model of the functions it computes. This gives a strong mathematical background to the notion of program, together with a constructive way to build resolutions from convergent polygraphs. This work has been presented during an invited conference at the International Congress on Operads and Universal Algebra held in Tianjin, China, in July 2010. Those results will be further explored to give a mathematical description of the strategies used in Tom, in order to develop methods from algebraic topology to study their computational properties, like termination and complexity.

With S. Gaussent (Institut Élie Cartan, Univ. Nancy 1) and P. Malbos, in [26], we have applied higher-dimensional rewriting methods to actions of monoids on categories. The objective was to compute, starting from a presentation of a monoid by generators and relations, a “homotopy basis” that generates all the relations between the relations: this is exactly the piece of data one needs to use a presentation to give a practical definition of action of the monoid on categories. We show that methods from rewriting theory (Squier’s theorem, Knuth-Bendix completion procedure), adapted to Burroni’s polygraphs, can be used to compute that homotopy basis. In particular, we get a new, algebraic and constructive proof of a result by Deligne on actions of braid groups.

6.1.2. Certification of induction proofs

Participant: Sorin Stratulat.

We have defined a methodology for validating implicit induction proofs. In collaboration with Vincent Demange, we gave evidence of the possibility to perform implicit induction-based proofs inside certified reasoning environments, as that provided by the Coq proof assistant. This is the first step of a long term project focused on 1) mechanically certifying implicit induction proofs generated by automated provers like Spike, and 2) narrowing the gap between automated and interactive proof techniques by devising powerful proof strategies inside proof assistants that aim to perform automatically multiple induction steps and to deal with mutual induction more conveniently. Contrary to the current approaches of reconstructing implicit induction proofs into scripts based on explicit induction tactics that integrate the usual proof assistants, our checking methodology is simpler and fits better for automation. The underlying implicit induction principles are separated and validated independently from the proof scripts that consist in a bunch of one-to-one translations of implicit induction proof steps. The translated steps can be checked independently, too, so the validation process fits well for parallelisation and for the management of large proof scripts. Moreover, our approach is more general; any kind of implicit induction proof can be considered because the limitations imposed by the proof reconstruction techniques no longer exist. This result has been firstly presented at the Poster session of 2010 Grande Region Security and Reliability Day, Saarbrucken.
Based on the previous result, an implementation that integrates automatic translators for generating fully checkable Coq scripts from Spike proofs is reported in [55]. The induction ordering underlying the Spike induction principle was defined using COCCINELLE [34], a Coq library well suited for modelling mathematical notions needed for rewriting, such as term algebras and RPO. COCCINELLE formalises RPO in a generic way using a precedence and a status (multiset/lexicographic) for each function symbol. Spike automatically generates a term algebra starting from Coq function symbols which preserve the precedence of the original Spike symbols. Many useful properties about the RPO orderings have been already provided by COCCINELLE. On the other hand, the induction ordering was modelled as a multiset extension of RPO and only few properties about it were provided by COCCINELLE. We have proved useful lemmas about it and added them to COCCINELLE, for example, the multiset extensions of RPO is stable under substitutions. Finally, every single inference step derived with a restricted version of Spike can be automatically translated into equivalent Coq script. The restricted inference system was powerful enough to prove properties about specifications involving mutually defined functions and to validate a sorting algorithm. The scripts resulted from the translation of these proofs were successfully validated by Coq.

Another improvement of the COCCINELLE library was the redefinition of the RPO ordering in order to consider precedencies that take into account equivalent function symbols. The new release of CoLoR (http://color.inria.fr) that compiles with the new version 8.3 of Coq includes the updated version of COCCINELLE. This improvement allowed Rainbow, a program developed within the CoLoR project that uses COCCINELLE’s formalisation for RPO, to certify more than 30 additional proofs from the set of CPF files generated during the 2009 annual termination competition (http://termination-portal.org/wiki/Termination_Competition).

In [21], we reported new improvements in order to certify implicit induction proofs concerning industrial-size applications, in particular the validation proof of a conformance algorithm for the ABR protocol [51]. An interactive proof using PVS [54] was firstly presented in [52], then it has been shown in [53] that more than a third of the user interactions can be avoided using implicit induction techniques, Spike succeeding to prove 60% of the user-provided lemmas automatically. Now, a simpler but more restrictive version of the Spike inference system has been shown powerful enough to prove 2/3 out of these lemmas. Moreover, any generated proof has been automatically translated into a Coq script, then automatically certified by Coq. We stressed the importance of the automatic feature since the proof scripts are in many cases big and hard to manipulate by the users. The bottom-line is that these improvements allowed us to certify big proof scripts in a reasonable time, 20 times faster than in [55].

6.2. Integration of formal methods in programming languages

6.2.1. Formal islands and Tom

Participants: Jean-Christophe Bach, Horatiu Cirstea, Pierre-Etienne Moreau, Claudia Tavares.

In [1] we have proposed a framework which makes possible the integration of formally defined constructs into an existing language. The Tom system is an instance of this principle: terms, first-order signatures, rewrite rules, strategies and matching constructs are integrated into Java and C for instance. The high level programming features provided by this approach are presented in [48]. The Tom system is documented in [27]. A general overview of the research problem raised by this approach are presented in [47].

One interest of Tom is to make the compilation process independent of the considered data-structure. Given any existing data-structure, using a formal anchor definition, it becomes possible to match and to apply transformation rules on the considered data-structures.

During the internship of Maxime Gabut, we have developed a new approach for parsing island based languages. We have clearly separated the grammars of the two considered languages (host and island languages). At present, there is one scanner for each language, but this is not powerful enough to handle the general case. We are currently studying another approach based on a scanner able to recognized tokens from both languages.
During the internship of Alexandre Papin, we have developed a new backend for ADA 2005. The mid-term project is to use tom-ADA to develop new optimisation phases of the GNAT-ADA compiler.

We have defined a new type system for Tom which allows to declare first-order signatures with subtyping. This is particularly useful to encode inheritance relations into algebraic terms. Considering Java as the host language, in [ 25 ] we present this type system with subtyping for Tom, that is compatible with Java’s type system, and that performs both type checking and type inference. We propose an algorithm that checks if all patterns of a Tom program are well-typed. In addition, we propose an algorithm based on equality and subtyping constraints that infers types of variables occurring in a pattern. Both algorithms are exemplified and the proposed type system is showed to be sound and complete.

A first application consists in defining algebraic mappings for implementations of meta-models generated by the Eclipse Modeling Framework.

6.3. Practical applications

6.3.1. Security policies specification and analysis

Participants: Tony Bourdier, Horatiu Cirstea, Hélène Kirchner, Pierre-Etienne Moreau.

Access control policies, a particular case of security policies should guarantee that information can be accessed only by authorized users and thus prevent all information leakage. We proposed [ 18 ] a framework where the security policies and the systems they are applied on are specified separately but using a common formalism. This separation allows not only some analysis of the policy independently of the target system but also the application of a given policy on different systems. In this framework, we propose a method to check properties like confidentiality, integrity or confinement over secure systems based on different policy specifications.

We also propose an approach [ 12 ] where the specification of a security policy is split into two distinct elements: a security model and a configuration. The security model (expressed as an equational problem) describes how authorization requests must be evaluated depending on security information. The configuration (expressed as a rewriting system) assigns values to security information. We show that this separation eases the formal analysis of security policies and makes it possible to automatically convert a given policy with respect to an alternative security model.

6.3.2. Symbolic analysis of network security policies

Participants: Tony Bourdier, Horatiu Cirstea.

In computer networks, security policies are generally implemented by firewalls. We propose in [ 16 ] an original framework based on tree automata which can be used to specify firewalls and which takes into account the network address translation functionality. We show that this framework allows us to perform structural analysis as well as query analysis and comparisons over firewall policies.

We have extended the above formalism to take into account the composition of firewalls. In our approach [ 17 ] all the components of a firewall, i.e. filtering and translation rules, are specified as rewrite systems. The same formalism can be used to formally describe the composition of firewalls (including routing) in order to build a whole network security policy. The properties of the obtained rewrite systems are strongly related to the properties of the specified networks and thus, classical theoretical and practical tools can be used to obtain relevant properties of the security policies. We showed that the proposed specifications allow us to handle usual problems such as comparison, structural analysis, and query analysis over complete networks.

6.3.3. Model transformation using rewriting

Participants: Jean-Christophe Bach, Pierre-Etienne Moreau.

New development chains of critical systems rely on Domain Specific Modeling Languages (DSML) and on qualifiable transformations (insurance that a transformation preserves interesting properties). To specify and to make such transformations we have started to extend Tom.

Programs, Verification and Proofs - New Results - Project-Team PAREO
A first part of this extension is an EMF\(^1\) mapping generator which allows to use Tom with EMF. The idea of this tool is to generate Tom mappings (i.e. an algebraic view) by introspecting EMF generated Java code. These mappings can then be used to describe transformations of models that have been created in Eclipse. Tom-EMF is documented and available in the Tom source distribution.

The second part of this extension consists in the addition of new Tom language constructs to express transformations of models. Studying several use cases\(^2\), we have already handwritten the code that should be generated. We are currently considering abstraction of the code in order to make the generation of this one automatic in a near future.

6.3.4. A constraint language for algebraic terms

**Participants:** Horatiu Cirstea, Pierre-Etienne Moreau, François Prugniel.

With the development of model transformation formalisms and tools, a need for checking the result of transformations appears. For UML, the Object Management Group developed OCL\(^3\) but there are no equivalent formalisms for the algebraic views of models used in Tom-EMF. Starting from the OCL experiences, we have proposed an extension of Tom with a constraint language for algebraic signatures [ 23 ].

We show that the constructs of this new constraint language inspired from OCL and XPath can be naturally described using strategic rewriting and consequently, constraint checking can be performed by executing Tom programs. This kind of language is a major asset for debugging tools and a great step to obtain trustworthy compilers. Indeed, the first important application for this language will be the Tom compiler itself.

---

\(^3\)Object Constraint Language, http://www.omg.org/spec/OCL/2.2/
6. New Results

6.1. A supervised clustering approach for fMRI-based inference of brain states

We propose a method that combines signals from many brain regions observed in functional Magnetic Resonance Imaging (fMRI) to predict the subject’s behavior during a scanning session. Such predictions suffer from the huge number of brain regions sampled on the voxel grid of standard fMRI data sets: the curse of dimensionality. Dimensionality reduction is thus needed, but it is often performed using a univariate feature selection procedure, that handles neither the spatial structure of the images, nor the multivariate nature of the signal. By introducing a hierarchical clustering of the brain volume that incorporates connectivity constraints, we reduce the span of the possible spatial configurations to a single tree of nested regions tailored to the signal. We then prune the tree in a supervised setting, hence the name supervised clustering, in order to extract a parcellation (division of the volume) such that parcel-based signal averages best predict the target information. Dimensionality reduction is thus achieved by feature agglomeration, and the constructed features now provide a multi-scale representation of the signal. Comparisons with reference methods on both simulated and real data show that our approach yields higher prediction accuracy than standard voxel-based approaches. Moreover, the method infers an explicit weighting of the regions involved in the regression or classification task. See also [14] and Fig. 1.

Figure 1. Results for prediction of object size. Maps of weights found by supervised cut in the prediction of the size of an object. The proposed algorithm creates very interpretable clusters, compared to the reference methods that do not consider the spatial structure of the image.

6.2. Multiclass Sparse Bayesian Regression for fMRI-Based Prediction

Inverse inference has recently become a popular approach for analyzing neuroimaging data, by quantifying the amount of information contained in brain images on perceptual, cognitive, and behavioral parameters. As it outlines brain regions that convey information for an accurate prediction of the parameter of interest, it allows to understand how the corresponding information is encoded in the brain. However, it relies on a prediction function that is plagued by the curse of dimensionality, as there are far more features (voxels) than samples (images), and dimension reduction is thus a mandatory step. We introduce in this work a new model, called Multiclass Sparse Bayesian Regression (MCBR), that, unlike classical alternatives, automatically adapts the amount of regularization to the available data. MCBR consists in grouping features into several classes and then regularizing each class differently in order to apply an adaptive and efficient regularization. We detail these framework and validate our algorithm on simulated and real neuroimaging data sets, showing that it performs better than reference methods while yielding interpretable clusters of features. See also [13] and Fig. 2.
6.3. Total variation regularization for fMRI-based prediction of behaviour

While medical imaging typically provides massive amounts of data, the extraction of relevant information for predictive diagnosis remains a difficult challenge. Functional MRI (fMRI) data, that provide an indirect measure of task related or spontaneous neuronal activity, are classically analyzed in a mass-univariate procedure yielding statistical parametric maps. This analysis framework disregards some important principles of brain organization: population coding, distributed and overlapping representations. Multivariate pattern analysis, i.e., the prediction of behavioural variables from brain activation patterns better captures this structure. To cope with the high dimensionality of the data, the learning method has to be regularized. However, the spatial structure of the image is not taken into account in standard regularization methods, so that the extracted features are often hard to interpret. More informative and interpretable results can be obtained with the $\ell_1$ norm of the image gradient, a.k.a. its Total Variation (TV), as regularization. We apply for the first time this method to fMRI data, and show that TV regularization is well suited to the purpose of brain mapping while being a powerful tool for brain decoding. Moreover, this article presents the first use of TV regularization for classification. See also [15] and Fig. 3.

6.4. Quantitative evaluation of 10 tractography algorithms on a realistic diffusion MR phantom.

As it provides the only method for mapping white matter fibers in vivo, diffusion MRI tractography is gaining importance in clinical and neuroscience research. However, despite the increasing availability of different diffusion models and tractography algorithms, it remains unclear how to select the optimal fiber reconstruction method, given certain imaging parameters. Consequently, it is of utmost importance to have a quantitative comparison of these models and algorithms and a deeper understanding of the corresponding strengths and weaknesses. In this work, we use a common dataset with known ground truth and a reproducible methodology to quantitatively evaluate the performance of various diffusion models and tractography algorithms. To examine a wide range of methods, the dataset, but not the ground truth, was released to the public for evaluation in a contest, the "Fiber Cup". 10 fiber reconstruction methods were evaluated. The results provide evidence
Figure 3. Regression - Sizes prediction experiment - Inter-subject analysis. Maps of weights found by TV regression for various values of the regularization parameter $\lambda$. When $\lambda$ decreases, the TV regression algorithm creates different clusters of weights with constant values. These clusters are easily interpretable, compared to voxel-based map (see below). The TV regression algorithm is very stable for different values of $\lambda$. 
that: 1. For high SNR datasets, diffusion models such as (fiber) orientation distribution functions correctly model the underlying fiber distribution and can be used in conjunction with streamline tractography, and 2. For medium or low SNR datasets, a prior on the spatial smoothness of either the diffusion model or the fibers is recommended for correct modelling of the fiber distribution and proper tractography results. The phantom dataset, the ground truth fibers, the evaluation methodology and the results obtained so far will remain publicly available on http://www.lnao.fr See also [10].

6.5. Multi-subject dictionary learning (MSDL) to segment an atlas of brain spontaneous activity

Fluctuations in brain on-going activity can be used to reveal its intrinsic functional organization. To mine this information, we give a new hierarchical probabilistic model for brain activity patterns that does not require an experimental design to be specified. We estimate this model in the dictionary learning framework, learning simultaneously latent spatial maps and the corresponding brain activity time-series. Unlike previous dictionary learning frameworks, we introduce an explicit difference between subject-level spatial maps and their corresponding population-level maps, forming an atlas. We give a novel algorithm using convex optimization techniques to solve efficiently this problem with non-smooth penalties well-suited to image denoising. We show on simulated data that it can recover population-level maps as well as subject specificities. On resting-state fMRI data, we extract the first atlas of spontaneous brain activity and show how it defines a subject-specific functional parcellation of the brain in localized regions. See also [25] and Fif 4.

Figure 4. Outlines at 33% of all dictionary elements estimated by MSDL for 2 different set of cutting planes. The motor system is divided in (1) dorsal, (2) lateral, and (3) ventral regions. Similarly, the visual system is divided in (4) a primary region centered on the Calcarine sulcus, overlapping with (5) a region centered on the striate cortex, and (6) extrastriate regions. (7), (8): fine details of the vascular system segmented in several maps.

6.6. Functional brain imaging with M/EEG using structured sparsity in time-frequency dictionaries
Magnetoencephalography (MEG) and electroencephalography (EEG) allow functional brain imaging with high temporal resolution. While time-frequency analysis is often used in the field, it is not commonly employed in the context of the ill-posed inverse problem that maps the MEG and EEG measurements to the source space in the brain. In this work, we detail how convex structured sparsity can be exploited to achieve a principled and more accurate functional imaging approach. Importantly, time-frequency dictionaries can capture the non-stationary nature of brain signals and state-of-the-art convex optimization procedures based on proximal operators allow the derivation of a fast estimation algorithm. We compare the accuracy of our new method to recently proposed inverse solvers with help of simulations and analysis of real MEG data. See also [22].

6.7. A probabilistic framework to infer brain functional connectivity from anatomical connections

We present a novel probabilistic framework to learn across several subjects a mapping from brain anatomical connectivity to functional connectivity, i.e. the covariance structure of brain activity. This prediction problem must be formulated as a structured-output learning task, as the predicted parameters are strongly correlated. We introduce a model selection framework based on cross-validation with a parametrization-independent loss function suitable to the manifold of covariance matrices. Our model is based on constraining the conditional independence structure of functional activity by the anatomical connectivity. Subsequently, we learn a linear predictor of a stationary multivariate autoregressive model. This natural parameterization of functional connectivity also enforces the positive-definiteness of the predicted covariance and thus matches the structure of the output space. Our results show that functional connectivity can be explained by anatomical connectivity on a rigorous statistical basis, and that a proper model of functional connectivity is essential to assess this link. See also [20] and Fig. 5.

![Figure 5. Identifying structural connections associated with the default mode network. With yellow is represented the lateral parietal cortex, green areas represent the posterior cingulate gyrus (PCC), blue and light blue represent the medial prefrontal and orbito-frontal areas, respectively. The right model performs much better in terms of cross-validated data likelihood.](image)

6.8. M/EEG source reconstruction based on Gabor thresholding in the source space

Thanks to their high temporal resolution, source reconstruction based on Magnetoencephalography (MEG) and/or Electroencephalography (EEG) is an important tool for noninvasive functional brain imaging. Since the MEG/EEG inverse problem is ill-posed, inverse solvers employ priors on the sources. While priors are generally applied in the time domain, the time-frequency (TF) characteristics of brain signals are rarely employed as a spatio-temporal prior. In this work, we present an inverse solver which employs a structured sparse prior formed by the sum of $\ell_{21}$ and $\ell_1$ norms on the coefficients of the Gabor TF decomposition of the
source activations. The resulting convex optimization problem is solved using a first-order scheme based on proximal operators. We provide empirical evidence based on EEG simulations that the proposed method is able to recover neural activations that are spatially sparse, temporally smooth and non-stationary. We compare our approach to alternative solvers based also on convex sparse priors, and demonstrate the benefit of promoting sparse Gabor decompositions via a mathematically principled iterative thresholding procedure. See also [24].

6.9. Multifractal Analysis of Resting State Networks in Functional MRI

It has been know for at least one decade that functional MRI time series display long-memory properties, such as power-law scaling in the frequency spectrum. Concomitantly, multivariate model-free analysis of spatial patterns, such as spatial Independent Component Analysis (sICA), has been successfully used to segment from spontaneous activity Resting-State Networks (RSN) that correspond to known brain function. As recent neuroscientific studies suggest a link between spectral properties of brain activity and cognitive processes, a burning question emerges: can temporal scaling properties offer new markers of brain states encoded in these large scale networks? In this work, we combine two recent methodologies: group-level canonical ICA for multi-subject segmentation of brain network, and wavelet leader-based multifractal formalism for the analysis of RSN scaling properties. We identify the brain networks that elicit self-similarity or multifractality and explore which spectral properties correspond specifically to known functionally relevant processes in spontaneous activity. See also [19].

6.10. Multi-scale Mining of fMRI Data with Hierarchical Structured Sparsity

Inverse inference, or "brain reading", is a recent paradigm for analyzing functional magnetic resonance imaging (fMRI) data, based on pattern recognition tools. By predicting some cognitive variables related to brain activation maps, this approach aims at decoding brain activity. Inverse inference takes into account the multivariate information between voxels and is currently the only way to assess how precisely some cognitive information is encoded by the activity of neural populations within the whole brain. However, it relies on a prediction function that is plagued by the curse of dimensionality, as we have far more features than samples, i.e., more voxels than fMRI volumes. To address this problem, different methods have been proposed. Among them are univariate feature selection, feature agglomeration and regularization techniques. In this work, we consider a hierarchical structured regularization. Specifically, the penalization we use is constructed from a tree that is obtained by spatially constrained agglomerative clustering. This approach encodes the spatial prior information in the regularization process, which makes the overall prediction procedure more robust to inter-subject variability. We test our algorithm on a real data acquired for studying the mental representation of objects, and we show that the proposed algorithm yields better prediction accuracy than reference methods. See also [29] and Fig. 6.

6.11. Detecting Outlying Subjects in High-Dimensional Neuroimaging Datasets with Regularized Minimum Covariance Determinant

Medical imaging datasets used in clinical studies or basic research often comprise highly variable multi-subject data. Statistically-controlled inclusion of a subject in a group study, i.e. deciding whether its images should be considered as samples from a given population or whether they should be rejected as outlier data, is a challenging issue. While the informal approaches often used do not provide any statistical assessment that a given dataset is indeed an outlier, traditional statistical procedures are not well-suited to the noisy, high-dimensional, settings encountered in medical imaging, e.g. with functional brain images. In this work, we modify the classical Minimum Covariance Determinant approach by adding a regularization term, that ensures that the estimation is well-posed in high-dimensional settings and in the presence of many outliers. We show on simulated and real data that outliers can be detected satisfactorily, even in situations where the number of dimensions of the data exceeds the number of observations. See also [21] and Fig. 7.
Figure 6. Principle of structured sparsity: Example of a tree $\mathcal{T}$ when $p = 5$, with three voxels and two parcels. The parcel 2 is defined as the averaged intensity of the voxels $\{1, 2\}$, while the parcel 1 is obtained by averaging the parcel 2 and voxel 3. In red dashed lines are represented the five groups of variables that compose $\mathcal{G}$. If the group containing the parcel 2 is set to zero, the voxels $\{1, 2\}$ are also (and necessarily) zeroed out.

Figure 7. Regularized-MCD-based Mahalanobis distances of a small sample. The higher the Mahalanobis distance, the higher the probability for an observation to be tagged as outlying. Points in red are outliers subjects according to the whole population.
6.12. Connectivity-informed fMRI Activation Detection

A growing interest has emerged in studying the correlation structure of spontaneous and task-induced brain activity to elucidate the functional architecture of the brain. In particular, functional networks estimated from resting state (RS) data were shown to exhibit high resemblance to those evoked by stimuli. Motivated by these findings, we propose a novel generative model that integrates RS-connectivity and stimulus-evoked responses under a unified analytical framework. Our model permits exact closed-form solutions for both the posterior activation effect estimates and the model evidence. To learn RS networks, graphical LASSO and the oracle approximating shrinkage technique are deployed. On a cohort of 65 subjects, we demonstrate increased sensitivity in fMRI activation detection using our connectivity-informed model over the standard univariate approach. Our results thus provide further evidence for the presence of an intrinsic relationship between brain activity during rest and task, the exploitation of which enables higher detection power in task-driven studies. See also [23] and Fig 8.

6.13. Beyond brain reading: identify and predict with clustering and randomized sparsity

The prediction of behavioral covariates from functional MRI (fMRI) is known as brain reading. From a statistical standpoint, this challenge is a supervised learning task. The ability to predict cognitive states from new data gives a model selection criterion: prediction accuracy. While a good prediction score implies that some of the voxels used by the classifier are relevant, one cannot state that these voxels form the brain regions involved in the cognitive task. The best predictive model may have selected by chance non-informative regions, and neglected relevant regions providing duplicate information. In this contribution, we address the support identification problem. The proposed approach relies on randomization techniques which have been proved to be consistent for support recovery. To account for the spatial correlations between voxels, our approach makes use of a spatially constrained hierarchical clustering algorithm. Results are provided on simulations and a visual experiment. See Fig. 9.

6.14. Joint T1 and Brain Fiber Diffeomorphic Registration Using the Demons

Non-linear image registration is one of the most challenging tasks in medical image analysis. In this work, we propose an extension of the well-established diffeomorphic Demons registration algorithm to take into
Figure 9. Results on fMRI object recognition task (face vs. house). The selected voxels are in the Fusiform Face Area. **left.** Prediction Receiver-Operating Characteristic. **right.** Scores with Ward Randomized Logistic regression.

account geometric constraints. Combining the deformation field induced by the image and the geometry, we define a mathematically sound framework to jointly register images and geometric descriptors such as fibers or sulcal lines. We demonstrate this framework by registering simultaneously T1 images and 50 fiber bundles consistently extracted in 12 subjects. Results show the improvement of fibers alignment while maintaining, and sometimes improving image registration. Further comparisons with non-linear T1 and tensor registration demonstrate the superiority of the Geometric Demons over their purely iconic counterparts. See also [28] and Fig. 10.

Figure 10. **Influence of the fiber weighting term on the registration accuracy.** Fibers of 11 subjects were overlapped after registration with the Geometric Demons for three values of the fiber weighting parameter. Corresponding fibers in different subjects share colors.
6. New Results

6.1. Compilation techniques for synchronous languages

- The paper *Modular Static Scheduling of Synchronous Data-flow Programs* by M. Pouzet and P. Raymond (VERIMAG Grenoble) has been selected among the two best papers at EMSOFT 2009. An extended version is published in a special issue of the *Journal of Design Automation for Embedded Systems*, in 2010. This work solves a 20 years problem raised by P. Raymond in 88 [59].

- Significant extensions have been provided to the Heptagon language. C. Pasteur contributed a memory optimization pass, combining a static analysis with user-given annotations (a paper on this subject is submitted to LCTES’2012), and the integration of discrete controller synthesis, developed and used by the SARDES team at INRIA Rhones-Alpes. Other work-in-progress extensions and experiments conducted inside the PARKAS team include the generation of VHDL code, parallel code generation, and n-synchronous code generation from Lucy-n.

6.2. Semantics and Implementation of Hybrid System Modelers

Hybrid systems modelers have become the corner stone of embedded system development, with Simulink a de facto standard and Modelica a new player. They allow both discrete controllers and their continuous environments to be expressed in a single language. Despite the availability of such tools, there remain a number of issues related to the lack of reproducibility of simulations and to the separation of the continuous part, which has to be exercised by a numerical solver, from the discrete part, which must be guaranteed not to evolve during a step. Such tools still raise a number of issues that, we believe, require more fundamental understanding.

In collaboration with Albert Benveniste and Benoit Caillaud (INRIA Rennes) we have proposed using non standard analysis as a semantic domain for hybrid systems. Non standard analysis is an extension of classical analysis in which infinitesimals can be manipulated as first class citizens. This allows us to provide a denotational semantics and a constructive semantics for hybrid systems, thus establishing simulation engines on a firm mathematical basis. In passing, we cleanly separate the job of the numerical analyst (solving differential equations) from that of the computer scientist (generating execution schemes).

- In late 2010, we presented in 49th Conference on Design and Control in 2010 [11] the use of non standard semantics as a semantical ground for a hybrid synchronous language.

- Since the, we have extended this work in the following directions: 1/ a synchronous Kahn semantics for hybrid programs. Programs are viewed as synchronous ones running on an infinitely fast discrete base clock of the form $BaseClock(\partial) = \{n\partial \mid n \in \mathbb{N}\}$, with infinitesimal step $\partial$ and $\mathbb{N}$ the non-standard extension of $\mathbb{N}$. 2/ the definition of a standardization principle that gives sufficient conditions for a hybrid program to be standardizable. Under these conditions, the semantics corresponds to the semantics using super-dense time [44], [40], [42] for hybrid systems defined in [10]. 3/ a large amount of experimentations with Simulink to illustrate some of its pitfalls concerning in particular the treatment of zero-crossing cascades. This work is detailed in a long paper appearing in the *Journal of Computer Science and Systems* [1], in 2011.

---

12 https://modelica.org/
Starting from a minimal, yet full-featured, Lustre-like synchronous language, we have proposed a conservative extension where data-flow equations can be mixed with ordinary differential equations (ODEs) with possible reset. A type system is proposed to statically distinguish discrete computations from continuous ones and to ensure that signals are used in their proper domains. The extended data-flow language is realized through a source-to-source transformation into a synchronous subset, which can then be compiled using existing tools into routines that are both efficient and bounded in their use of memory. These routines are orchestrated with a single off-the-shelf numerical solver using a simple but precise algorithm which treats causally-related cascades of zero-crossings. We have validated the viability of the approach through experiments with the SUNDIALS library.

The basis of this work has been presented at the ACM International Conference on Languages, Compilers, Theory of Embedded Systems, 2011 [3].

This work shows that it is possible to define a language which combines both the expressiveness of synchronous a synchronous language and that of ODEs where continuous solvers are approximated by a black-box solver. The most noticeable result was to recycle several techniques developed for synchronous languages: Kahn semantics, compilation techniques, static analysis. During year 2011, we extended the basic language with with hierarchical automata. This work has been presented at the ACM International Conference on Embedded Software, 2011 [2].

In parallel with these theoretical works, M. Pouzet and T. Bourke have developed during year 2011 a new synchronous language and its compiler. The language, called ZELUS, extends a synchronous language with ODEs. It is first-order, functional and which mixes continuous-time and discrete-time signals. The expressiveness is that of (the first-order subset of) Lucid Synchrone (e.g., type inference and polymorphism, mix of data-flow and hierarchical automata) and ODEs with possible reset. Continuous trajectories are computed by a black-box numerical solver and we made our experiments with SUNDIALS.

6.3. N-Synchronous Languages

The n-synchronous model introduced a way to compose streams which have almost the same clock and can be synchronized through the use of a finite buffer.

We have designed the language Lucy-n to program in this model of computation [4], [48]. This language is similar to the first order synchronous data-flow language Lustre in which a buffer operator is added. A dedicated type system allows to check that programs can be executed in bounded memory and to compute the buffers sizes needed. Technically it is done through the introduction of a subtyping constraint at each bufferization point.

To solve the subtyping constraints we have defined an algorithm that uses an improved version of the state-of-the-art abstraction. We have proved the correctness properties of this new abstraction in Coq.

We also worked on new typing algorithms that do not use clock abstraction and thus allows to model Latency Insensitive Design [5] in Lucy-n [48].

A. Guatto, together with L. Mandel and M. Pouzet, worked on the code generation for Lucy-n. They investigated two approaches. The first one was to use the schedules and buffer sizes computed by the compiler to generate a classical Lustre program. The second approach was to define a dynamic scheduling protocol similar to the ones used in latency insensitive designs.

L. Mandel, in collaboration with F. Plateau (Prove&Run), developed a new resolution constraint algorithm for the clocking of Lucy-n programs [4]. Even if the new algorithm is less efficient that the one using abstraction, it has the advantage to be more precise and thus to accept more programs.

L. Mandel, F. Plateau and M. Pouzet have extended the Lucy-n language with a new operator to be able to model Latency Insensitive Designs. Thanks to the new resolution constraint algorithm, the Lucy-n compiler is able to compute static schedules for such designs [5].

[https://computation.llnl.gov/casc/sundials/main.html]
6.4. Synchronous Circuits

- Followed up on J. Vuillemin’s result that the XOR variant of non-deterministic automata can be efficiently minimized [65], we explore this newly opened branch of computational automata theory. One contribution is a Decision Diagram for Boolean functions which has minimal dimension: this is appealing for both the verification and synthesis of memory-less circuits. Parts of this recent work were presented at the Boole ANR cooperation [8] and Synchron 2011.

- An extension of Boolean Decision Diagrams to integer representation and operations is given in [66]: we pursue software experimentations with arithmetics on such gigantic (yet sparse) numbers.

- The paper [32] was translated to English from the 1974 original and published in honor of Gilles Kahn.

6.5. Reactive Programming

ReactiveML is an extension of OCaml with synchronous concurrency, based on synchronous parallel composition and broadcast of signals. The goal is to provide a general model of deterministic concurrency inside a general purpose functional language to program reactive systems. It is particularly suited to program discrete simulations, for instance of sensor networks. The current focus of the research is being able to simulate huge systems, composed of millions of agents, by extending the current purely sequential implementation in order to be able to take advantage of multi-core and distributed architectures.

A first experiment consisted in creating a parallel runtime without any modification to the language. As the OCaml language on which ReactiveML is based (the ReactiveML compiler generates OCaml code) does not allow to create parallel programs communicating via shared memory, the new runtime was written in the F# language, part of Microsoft .Net environment. As the language is almost source to source compatible with OCaml, the ReactiveML compiler was left untouched. Several parallel runtimes were written, using traditional task scheduling techniques like work stealing or directly using light task mechanisms available in F#. This experiment demonstrated many speedup opportunities by parallelizing the runtime but also highlighted several problems and limitations of the language. Although this experiment was very useful in understanding the stakes of parallelizing ReactiveML, the performance gap between OCaml and F# (OCaml generates sequential code that is about 10 times slower) makes this version of the runtime of little practical use. We then proposed an extension of ReactiveML called clock domains. It consists in creating local notions of instants that are invisible from the outside. This extension should solve most of the problems raised by the previous experiment and help the parallelization of the language. The sequential runtime was adapted to this extension and a distributed version, using processes communicating via message passing, is currently being developed.

In collaboration with P. Attar (INRIA), F. Boussinot (INRIA) and J.-F. Susini (CNAM), L. Mandel worked on the design of DSL [9], a script language for the orchestration of concurrent programs. L. Mandel developed in ReactiveML and JoCaml an interpreter for the DSL language.

6.6. Polyhedral Compilation

L.-N. Pouchet presented fundamental advances in the construction and linear optimization of multidimensional affine transformation spaces at the POPL 2011 conference, in collaboration with A. Cohen and colleagues from Paris Sud University, Louisiana State University and Ohio State University.

Our team is actively integrating the polyhedral optimization framework in two production compilers: the Graphite framework in GCC and the Polly framework in LLVM. We are also working towards using the polyhedral framework to target GPGPU and manycore architectures, and to generate aggressively optimized code starting from high level languages. New isl-based version of Graphite and Polly have been contributed, enabling state-of-the-art affine transformations in GCC and LLVM, respectively. Dramatic performance improvements are expected in 2012, impacting the upcoming GCC 4.8 and LLVM 3.1, respectively.

K. Trifunovic, F. Li and A. Cohen, in collaboration with R. Ladelsky from IBM Research Haifa, presented a paper about some of these progresses at the GROW 2011 workshop [7].
Among the challenges that arise when adapting the polyhedral framework to production compilers, Riyadh Baghdadi has been working on memory-based dependences. Part of it is a practical compiler construction issue, where upstream passes such as the transformation to three-address code and PRE/CSE introduce new scalar variables leading to additional memory-based dependences. The other difficulty is to identify a profitable tradeoff between memory expansion (privatization, renaming) and parallelism. Memory-based dependences not only increase the complexity of the optimization but most importantly, they reduce the degree of freedom available to express effective loop nest transformations, limiting the overall effectiveness of the polyhedral framework. We designed and implemented a technique that solves this problem by allowing a compiler to relax the constraint of memory-based dependences on loop nest transformations and that does not incur the memory footprint overhead of scalar and array expansion. The proposed technique is based on the concept of polyhedral live range interval interference. While previous polyhedral optimization techniques could not achieve any speedups in benchmarks with scalar variables. This technique enabled a speedup of up to $16 \times$ on numerical kernels from the Polybench benchmark suite (on a 24-core machine).

6.7. Parallel Data-Flow Programming

A. Pop defended his PhD thesis in September at MINES ParisTech, on a data-flow, streaming extension of OpenMP. Semantical, compilation and runtime system aspects have been covered in depth. Early results were published at HiPEAC 2011 and presented by A. Pop, in collaboration with A. Cohen. Follow-up work include the maturation of the proposed semantics and language extensions, with a thorough implementation and experimentation.

In parallel, F. Li, in collaboration with A. Pop and A. Cohen, explores the automatic compilation of SSA programs into dynamic data-flow parallelism, and the integration of streaming dependences to extend the method to non-scalar data flow. A paper has been published at WIR 2011 (workshop associated to CGO 2011), and a comprehensive, modular compilation method for arbitrary control flow, will be presented at MULTIPROG 2012 (associated with HiPEAC 2012).

Classical compilation techniques, found in Lustre, Scade, Lucid Synchrone, and all the dataflow synchronous languages, generate very efficient sequential code. Thus our main goal is to allow parallel code generation without changing the generation of the sequential code. To this matter, we introduced in the dataflow synchronous setting the famous asynchronous calls bundled with futures, which date back to MultiLisp designed by R. Halstead in the early 1980. It allows to separate the request of a computation from the actual use of its result. This approach has two main advantages. First, the compilation of these asynchronous calls is implemented by a simple wrapper encapsulating the called sequential code. It permits full compatibility with existing generated code. The futures are treated like usual values, so except for the asynchronous calls, we use the known sequential code generation. Second, this asynchronous calls and futures are only annotations and may be fully erased without changing the semantics of the program.

L. Gérard implements this proposition in our Heptagon compiler. The first backend was done in Java, as a proof of concept, using the threads and futures of the Java language. More efficient back-ends are being explored, using OpenMP stream-computing extensions and the TStar data-flow primitives.
6. New Results

6.1. Speech Analysis and Synthesis

Participants: Anne Bonneau, Vincent Colotte, Dominique Fohr, Yves Laprie, Joseph di Martino, Slim Ouni, Asterios Toutios, Sébastien Demange, Fadoua Bahja, Agnès Piquard-Kipffer, Utpala Musti.

6.1.1. Acoustic-to-articulatory inversion

6.1.1.1. Building new articulatory models

The possibility of generating the same sounds as those uttered by the speaker (or at least vocal tract transfer functions not too far from those observed) via the articulatory model and the acoustic simulation constitutes the underlying hypothesis of an analysis by synthesis method of acoustic-to-articulatory inversion. The articulatory model, and consequently its construction, thus plays a crucial role in inversion. An geometrical adaptation procedure has been developed in order to account for new speakers [28], [29]. It uses two scaling factors, one for the mouth cavity and the second for the pharyngeal cavity. In addition the model can be rotated globally and a second rotation controls the relative position of the pharynx with respect to the mouth cavity. In order to ensure a smooth transition from the mouth cavity to the pharynx cavity the angle of the rotation is a function of the distance with respect to the mouth axis.

The adaptation and model have been tested by using the X-ray data used by Maeda to construct his model. It should be noted that there are very few X-ray data with articulatory contour information available. These data correspond to a female speaker. The RMS reconstruction error reached by the adapted articulatory model is 0.550 mm what is very good for this particular speaker. Other data will be used in the future to validate the model and the adaptation procedure as soon as the contours will be delineated. An anatomical adaption procedure will also be developed in the future.

6.1.1.2. Determination of the vocal tract centerline

The connection of the articulatory model with the acoustic simulation requires the area function to be decomposed into elementary uniform tubes. The decomposition should respect the plane wave propagation. For that purpose the central line of the vocal tract has to be determined. The quality of the centerline strongly influences the closeness between natural and artificial formant frequencies.

We designed two complementary algorithms. The first exploits a dynamic programming approach to select points on interior and exterior walls of the vocal tract which minimize a global criterion combining the length of the centerline and the angle between the normal to the segments linking the points selected on both walls and the centerline [29]. It turned out that this first algorithm provides an insufficient smoothness of the centerline. A second algorithm has been designed by using an active curve which maximizes the smoothness of the centerline and the distance from any point of the centerline with exterior and interior walls. This second algorithm provides very good results.

6.1.1.3. Adaptation of cepstral coefficients for inversion

The inversion of speech requires spectra of natural speech to be compared with spectra synthesized via the articulatory synthesizer. This comparison cannot be carried out directly because the source is not taken into account in the synthetic spectra. Last year we thus investigated an affine adaptation of all the cepstral coefficients. This adaptation brings the spectral peaks of natural and synthetic spectra closer but at the same time tends to flatten the spectra. Moreover, it also appears that adaptation of only the very first cepstral coefficients (the first two except $C_0$ which represents energy) were sufficient to capture the spectral tilt. Since it is important to keep clear spectral peaks to explore the articulatory space, we used the bilinear transform in order to bring the two spectra closer [15]. The results are now better and the bilinear transform will be used to recover inverse solutions.
6.1.1.4. Acoustic-to-articulatory inversion using a generative episodic memory

We have developed an episodic based inversion method. Episodic modeling is interesting for two reasons. First, it does not rely on any assumption about the mapping relationship between acoustic and articulatory, but rather it relies on real synchronized acoustic and articulatory data streams. Second, the memory structurally embeds the naturalness of the articulatory dynamics as speech segments (called episodes) instead of single observations as for the codebook based methods. Estimating the unknown articulatory trajectories from a particular acoustic signal, with an episodic memory, consists in finding the sequence of episodes, which acoustically best explains the input acoustic signal. We refer to such a memory as a concatenative memory (C-Mem) as the result is always expressed as a concatenation of episodes. Actually a C-Mem lacks from generalization capabilities as it contains only several examples of a given phoneme and fails to invert an acoustic signal, which is not similar to the ones it contains. However, if we look within each episode we can find local similarities between them. We proposed to take advantage of these local similarities to build a generative episodic memory (G-Mem) by creating inter-episodes transitions. The proposed G-Mem allows switching between episodes during the inversion according to their local similarities. Care is taken when building the G-Mem and specifically when defining the inter-episodes transitions in order to preserve the naturalness of the generated trajectories. Thus, contrary to a C-Mem the G-Mem is able to produce totally unseen trajectories according to the input acoustic signal and thus offers generalization capabilities. The method was implemented and evaluated on the MOCHA corpus, and on a corpus that we recorded using an AG500 articulograph. The results showed the effectiveness of the proposed G-Mem which significantly outperformed standard codebook and C-Mem based approaches. Moreover similar performances to those reported in the literature with recently proposed methods (mainly parametric) were reached. [18]

The paradigm of episodic memories was also used for speech recognition. We do not extend the acoustic feature with any explicit articulatory measurements but instead we used the articulatory-acoustic generative episodic memories (G-mem). The proposed recognizer is made of different memories each specialized for a particular articulator. As all the articulators do not contribute equally to the realization of a particular phoneme, the specialized memories do not perform equally regarding each phoneme. We showed, through phone string recognition experiments that combining the recognition hypotheses resulting from the different articulatory specialized memories leads to significant recognition improvements. [19].

6.1.2. Using Articulography for Speech production

Since we have an articulograph (AG500, Carstens Medizinelektronik) available, we can easily acquire articulatory data required to study speech production. The articulograph is used to record the movement of the tongue (this technique is called electromagnetography - EMA). The AG500 has a very good time resolution (200Hz), which allows capturing all articulatory dynamics. The articulograph was used in a study about inversion (see the previous section) and to investigate pharyngealization.

Pharyngealized phonemes are commonly described as having the same place of articulation (dental) as their non-pharyngealized counterparts, but differ by the presence of a secondary articulation involving mainly the back of the tongue.

To study pharyngealized phonemes in Arabic from an articulatory point of view, our articulograph was used to record the movement of the tongue. Although EMA is not known as an optimal technique to cover the back of the tongue, good placement of the sensors and good interpretation of their positions can help to define pharyngealization relevantly. In fact, it is important to set one sensor as far as possible on the tongue (in our case, at 7cm from the tongue tip).

A corpus of several CVCVCVs was recorded using this articulograph, then phonetically labeled, and analyzed. The main finding of this work is that the coarticulation effect of the pharyngealized phonemes extends the immediate surrounding phonemes to influence the phonemes up to four-phoneme distance from the pharyngealized phoneme. The pharyngealization affects indifferently the previous and the following vowels and consonants.
We also investigated the effect of pharyngealization in Modern Standard Arabic (MSA) and Dialectal Arabic (DA). The acoustic material was more important than EMA. Although, we studied one speaker for EMA, the obtained results are encouraging to record more arabic speakers. [42]

6.1.3. Labial coarticulation

Results show that protrusion is a fragile cue to the rounding feature. Although we observe for each speaker a clear (but not large) separation between vowels /i/ and /y/ produced in isolation, many realizations of /i/ and /y/ come very close together and even overlap in few cases for vowels in contexts. The efficiency of the parameter depends on speakers and contexts. The distance between the corners is probably the most fragile cue to vowel roundedness. Many overlapping areas are observed for vowels in context. This is not good news for speech specialists since this parameter is easy to measure (with cameras and markers painted on the speaker’s face) and its evaluation can be fully automatic. Each of the three lip opening parameters constitutes a very efficient cue to the rounding feature. For vertical opening, the opposition between /i/ and /y/ in initial position appears to be endangered in bilabial context, due to the anticipation of lip closing during /i/. Nevertheless, the temporal variations of lip opening during the initial /i/ are very important, and more analyses, taking into account these variations, will be necessary to analyse /i/ vs. /y/ phonetic distinction more thoroughly.

6.1.4. Speech synthesis

Visual data acquisition was performed simultaneously with acoustic data recording, using an improved version of a low-cost 3D facial data acquisition infrastructure. The system uses two fast monochrome cameras, a PC, and painted markers, and provides a sufficiently fast acquisition rate to enable an efficient temporal tracking of 3D points. The recorded corpus consisted of the 3D positions of 252 markers covering the whole face. The lower part of the face was covered by 70% of all the markers (178 markers), where 52 markers were covering only the lips so as to enable a fine lip modeling. The corpus was made of 319 medium-sized French sentences uttered by a native male speaker and corresponding to about 25 minutes of speech.

We designed a first version of the text to acoustic-visual speech synthesis based on this corpus. The system uses bimodal diphones (an acoustic component and a visual one) and unit selection techniques (see 3.2.4). We have introduced visual features in the selection step of the TTS process. The result of the selection is the path in the lattice of candidates found in the Viterbi algorithm, which minimizes a weighted linear combination of three costs: the target cost, the acoustic joined cost, and the visual joined cost.

Finding the best set of weights is a difficult problem by itself mainly because of their highly different nature (linguistic, acoustic, and visual considerations). This year, we added the first derivative of the visual trajectories in the visual join cost and we developed a method to determine automatically the weights applied to each cost, using a series of metrics that assess quantitatively the performance of synthesis [37].

This year, more progress have been made regarding the definition of the target cost. Now, The target cost includes both acoustic target cost and visual target cost.

The visual target cost includes visual and articulatory information. We implemented and evaluated two techniques [32]: (1) Phonetic category modification, where the purpose was to change the current characteristics of some phonemes which were based on phonetic knowledge. The changes modified the target and candidate description for the target cost to better take into account their main characteristics as observed in the audio-visual corpus. The expectation was that their synthesized visual speech component would be more similar to the real visual speech after the changes. (2) Continuous visual target cost, where the visual target cost component is now considered as real value, and thus continuous, based on the articulatory feature statistics.

6.1.5. Phonemic discrimination evaluation in language acquisition and in dyslexia and dysphasia

6.1.5.1. Phonemic segmentation in reading and reading-related skills acquisition in dyslexic children and adolescents

Our computerized tool EVALEC was published [67] after the study of reading level and reading related skills of 400 hundred children from grade 1 to grade 4 (from age 6 to age 10) [69]. This research was supported by a grant from the French Ministry of Health (Contrat 17-02-001, 2002-2005). This first computerized battery
of tests in French language assessing reading and related skills (phonemic segmentation, phonological short term memory) comparing results both to chronological age controls and reading level age control in order to diagnostic Dyslexia. Both processing speed and accuracy scores are taken into account. This battery of tests is used by speech and language therapists. We keep on examining the reliability (group study) and the prevalence (multiple case study) of 15 dyslexics’ phonological deficits in reading and reading related skills in comparison with a hundred reading level children \[68\], and by the mean of longitudinal studies of children from age 5 to age 17 \[66\]. This year, we started the development of a project which examined multimodal speech both with SLI, dyslexics and control children (30 children). Our goal is to examine visual contribution to speech perception across different experiments with a natural face (syllables with several conditions). Our goal is to search what can improve intelligibility in children who have severe language acquisition difficulties.

6.1.5.2. Language acquisition and language disabilities (deaf children, dysphasic children)

Providing help for improving French language acquisition for hard of hearing (HOH) children or for children with language disabilities was one of our goal: ADT (Action of Technological Development) Handicom \[pquardkipffer:2010:inria-00545856:2\]. The originality of this project was to combine psycholinguistic and speech analyses researches. New ways to learn to speak/read were developed. A collection of three digital books has been written by Agnès Piquard-Kipffer for both 2-6, 5-9, 8-12 year old children (kindergarten, 1-4th grade) to train speaking and reading acquisition regarding their relationship with speech perception and audio-visual speech perception. A web interface has been created (using Symfony and AJAX technologies) in order to create others books for language impaired children. A Workflow which transforms a text and an audio source in a video of digital head has been developed. This workflow includes an automatic speech alignment, a phonetic transcription, a speech synthesizer, a French cued speech coding and speaking digital head. A series of studies (simple cases studies, 5 deaf children and 5 SLI children and group studies with 2 kindergarten classes) were proposed to investigate the linguistical, audio-visual processing in deaf children. Publication are submitted.

6.1.6. Enhancement of esophageal voice

6.1.6.1. Detection of F0 in real-time for audio: application to pathological voices

The work first rested on the CATE algorithm developed by Joseph Di Martino and Yves Laprie, in Nancy, 1999. The CATE (Circular Autocorrelation of the Temporal Excitation) algorithm is based on the computation of the autocorrelation of the temporal excitation signal which is extracted from the speech log-spectrum. We tested the performance of the parameters using the Bagshaw database, which is constituted of fifty sentences, pronounced by a male and a female speaker. The reference signal is recorded simultaneously with a microphone and a laryngograph in an acoustically isolated room. These data are used for the calculation of the contour of the pitch reference. When the new optimal parameters from the CATE algorithm were calculated, we carried out statistical tests with the C functions provided by Paul Bagshaw. The results obtained were very satisfactory and a first publication relative to this work was accepted and presented at the ISIVC 2010 conference \[46\]. At the same time, we improved the voiced/ unvoiced decision by using a clever majority vote algorithm electing the actual F0 index candidate. A second publication describing this new result was published at the ISCT 2010 conference \[45\].

6.1.6.2. Voice conversion techniques applied to pathological voice repair

Voice conversion is a technique that modifies a source speaker’s speech to be perceived as if a target speaker had spoken it. One of the most commonly used techniques is the conversion by GMM (Gaussian Mixture Model). This model, proposed by Stylianou, allows for efficient statistical modeling of the acoustic space of a speaker. Let “x” be a sequence of vectors characterizing a spectral sentence pronounced by the source speaker and “y” be a sequence of vectors describing the same sentence pronounced by the target speaker. The goal is to estimate a function F that can transform each source vector as nearest as possible of the corresponding target vector. In the literature, two methods using GMM models have been developed: In the first method (Stylianou), the GMM parameters are determined by minimizing a mean squared distance between the transformed vectors and target vectors. In the second method (Kain), source and target vectors are combined in a single vector “z”. Then, the joint distribution parameters of source and target speakers is estimated using
the EM optimization technique. Contrary to these two well known techniques, the transform function $F$, in our laboratory, is statistically computed directly from the data: no needs of EM or LSM techniques are necessary. On the other hand, $F$ is refined by an iterative process. The consequence of this strategy is that the estimation of $F$ is robust and is obtained in a reasonable lapse of time. This interesting result was published and presented at the ISIVC 2010 conference [70].

6.1.7. Perception and production of prosodic contours in L1 and L2

6.1.7.1. Language learning (feedback on prosody)

Feedback on L2 prosody based upon visual displays, speech modifications and automatic diagnosis has been elaborated and a pilot experiment undertaken to test its immediate impact on listeners. Results show that the various kinds of feedback provided by the system enable French learners with a low production level to improve their realisations of English lexical accents more than (simple) auditory feedback. These results should be confirmed with a large number of speakers but based upon the important differences between results obtained for speakers in test and control conditions, we are confident in the interest of the system presented here [41]. In particular, the system analyses learners’ realisations and provide indications on what they should correct, a guidance which is considered as necessary by specialists in the oral aspects of language learning.

6.1.7.2. Production of prosody contour

We report here relevant observations for the study continuation in French. These observations were obtained in an ongoing project about non-conclusive prosodic patterns in French and English (“Intonale” project 7.2.2). We specifically discuss slope variations, estimated in semitones, concerning two kinds of non-conclusive configurations, which are inside a clause, or at the end of a clause, respectively: (i) the final segment of a subject NP in an assertive sentence, followed or not by another syntagm ended by a continuation contour (ii) the final segment of a A clause, in a two clause utterance AB, where A and B are assertive clauses connected by an discourse relation, marked or not with a conjunction.

Intonation slopes are computed as regression slopes using F0 values in semitones estimated every 10 ms. Slopes are calculated on the two last syllables of the target segments of every sentence. Results show that slopes for segments which are not at the end of a clause, and segments at the end of a clause followed by a conjunction are typically rising, and not significantly different the ones from the others. On the contrary, slopes for ends of clauses not followed by a conjunction are significantly different from the previous ones. More than 50%

We are presently studying English sentences, in particular continuation contours, produced by French speakers, in order to determine the impact of their native language (French) on their English pronounciations.

6.1.8. Pitch detection

Over the last two years, we have proposed two new real time pitch detection algorithms (PDAs) based on the circular autocorrelation of the glottal excitation, weighted by temporal functions, derived from the CATE [64] original algorithm (Circular Autocorrelation of the Temporal Excitation), proposed initially by J. Di Martino and Y. Laprie. In fact, this latter algorithm is not constructively real time because it uses a post-processing technique for the Voiced/Unvoiced (V/UV) decision. The first algorithm we developed is the eCATE algorithm (enhanced CATE) that uses a simple V/UV decision less robust than the one proposed later in the eCATE+ algorithm.

We propose a recent modified version called the eCATE++ algorithm which focuses especially on the detection of the F0, the tracking of the pitch and the voicing decision in real time. The objective of the eCATE++ algorithm consists in providing low classification errors in order to obtain a perfect alignment with the pitch contours extracted from the Bagshaw database by using robust voicing decision methods. The main improvement obtained in this study concerns the voicing decision, and we show that we reach good results for the two corpora of the Bagshaw database.

6.2. Automatic Speech Recognition

Participants: Christophe Cerisara, Sébastien Demange, Dominique Fohr, Christian Gillot, Jean-Paul Haton, Irina Illina, Denis Jouvet, Odile Mella, Luiza Orosanu, Othman Lachhab, Larbi Mesbah.
6.2.1. Core recognition

6.2.1.1. Broadcast News Transcription

In the framework of the Technolangue project ESTER, we have developed a complete system, named ANTS, for French broadcast news transcription (see section 5.4).

Extensions of the ANTS system have been studied, including the possibility to use the sphinx recognizers. Training scripts for building acoustic models for the Sphinx recognizers are now available and take benefit of the computer cluster for a rapid optimization of the model parameters. The Sphinx models are also used for speech/text alignment on both French and English speech data. A new speech decoding program has been developed for efficient decoding on the computer cluster, and easy modification of the decoding steps (speaker segmentation and clustering, data classification, speech decoding in one or several passes, ...). It handles both the Julius and Sphinx (versions 3 and 4) decoders.

This year, we have proposed an approach to grapheme-to-phoneme conversion based on a probabilistic method: Conditional Random Fields (CRF). CRF gives a long term prediction, and assume a relaxed state independence condition. Moreover, we proposed an algorithm to the one-to-one letter to phoneme alignment needed for CRF training. This alignment is based on discrete HMMs. The proposed system was validated on two pronunciation dictionaries. Different set of input features were studied: POS-tag, context size, unigram versus bigram. Our approach compared favorably with the performance of the state-of-the-art Joint-Multigram Models (JMM) for the quality of the pronunciations, but provided better recall and precision measures for multiple pronunciation variants generation [22][21].

As the pronunciation lexicon is one the key-points of a speech recognition system, we have investigated to which extent wiktionary data can be used to build such a lexicon. Collecting the pronunciations available for many entries of the wiktionary make possible the creation of an initial pronunciation lexicon. Such initial lexicon is then used for training grapheme-to-phoneme conversion systems (either CRF-based of JMM-based), in order to obtain pronunciation variants for words that are not in the initial pronunciation lexicon extracted from the web wiktionary data. Combining the pronunciation variants generated by the 2 grapheme-to-phoneme systems provides the best results. Although the achieved results are not as good as those obtained with a hand-made pronunciation lexicon, this automatic approach makes possible an easy creation of a pronunciation lexicon for a new language [26].

Confidence measures aim at estimating the confidence of a hypothesis result provided by the speech recognition engine. Two word confidence measures were proposed, which can be computed without waiting for the end of the audio stream; one frame-synchronous and one local. Our local measures achieved performance very close to a state-of-the-art measure which requires the recognition of the whole sentence. A preliminary experiment to assess the contribution of our confidence measure in improving the comprehension of automatic transcription results by hearing impaired was also conducted [10].

6.2.1.2. Speech recognition for interaction in virtual worlds

Automatic speech recognition is investigated for vocal interaction in virtual worlds, in the context of serious games in the EMOSPEECH project. This year, a wizard-of-oz experiment was carried out to collect speech data corresponding to the dialogs from 5 players interacting with a serious game. The players were invited to speak freely to any character of the game with whom it is possible to interact, while the wizard of Oz (a game expert localized in the same room) answered them. Hence, the recorded interactions between the player and the characters of the game are natural dialogs. The audio sessions have been manually transcribed. Each session comprises roughly 30 speech turns (one player’s sentence plus one wizard’s sentence).

For training the language models, the text dialogs recorded by the TALARIS team (Midiki corpus) on the same serious game (but in a text-based interaction), have been used on addition of available broadcast news corpus. For this purpose we have also manually corrected the Midiki sentences, in order to handle the numerous typos and misspellings as well as chat specific "words" such as smileys ("mdr" or "lol"), emphasized punctuations ("!!!!!") or over-segmentations such as "é-lec-tro-nique". This normalization step is a strong requirement for speech recognition models. Different language models have then been created using different vocabulary sizes.
The acoustic models are adapted from the radio broadcast news models, using state-of-the-art Maximum A Posteriori adaptation algorithm. This reduces the mismatch in recording conditions between the game devices and the original models trained on radio streams. We are currently investigating solutions to integrate this adaptation within the speech recognition component and perform it online. At runtime, the targeted strategy is to ask the player to utter some few predefined sentences and to use these sentences to adapt the generic acoustic models to the player’s voice.

6.2.2. Speech recognition modeling

Robustness of speech recognition to multiple sources of speech variability is one of the most difficult challenge that limits the development of speech recognition technologies. We are actively contributing to this area via the development of the following advanced modeling approaches.

6.2.2.1. Detection of Out-Of-Vocabulary words

One of the key problems for large vocabulary continuous speech recognition is the occurrence of speech segments that are not modeled by the knowledge sources of the system. An important type of such segments are so-called Out-Of-Vocabulary (OOV) words (words are not included in the lexicon of the recognizer). Mostly OOV words yield more than one error in the transcription result because the error can propagate due to the language model.

We have investigated, with Frederik Stouten (postdoctoral), to what extent OOV words can be detected. For this we used a classifier that makes a decision about each speech frame whether it belongs to an OOV word or not. Acoustic features for this classifier are derived from three recognition systems. On top of the acoustic features we also used four language model features: the ngram probability, the order of the gram that was used to calculate the language model probability, the unigram probability for the current word and a binary indicator that takes the value one if the word is preceded by a first name.

We propose to exploit the fact that 38% of the OOV word observations in the broadcast news data are pronounced more than one time in a time period of less than 1 minute. To improve the detection of repeated OOV words, we design a clustering module working on the detected OOV word segments. This algorithm is based on the estimation of the entropy. The proposed incremental clustering algorithm has been evaluated on the broadcast news corpus ESTER and gave better performance than a classical baseline incremental clustering algorithm based on a distance threshold [36].

6.2.2.2. Detailed modeling exploiting uncertainty

Modeling pronunciation variation is an important topic for automatic speech recognition. It has been widely observed that speech recognition performance degrades notably on spontaneous speech, and more precisely, that the word error rate increases when the degree of spontaneity increases. The rate of speech is also an important variability source which impacts notably on the acoustic realization of the sounds as well as on the pronunciation of the words, and consequently affects recognition performance. Large increases in word error rates are observed when speaking rate increases. And, it should be noted that rate of speech and spontaneous speech are not completely independent as the rate of speech is an important cue for detecting spontaneous speech.

This year, we have investigated further the detailed modeling of the probabilities of pronunciation variants for large vocabulary continuous speech recognition, and evaluated it on broadcast news transcriptions. In particular we have refined the modeling of the probabilities of the pronunciation variants dependent on the speaking rate. This was achieved by taking into account the uncertainty in the estimation of the speaking rate that results from the word and phoneme boundary uncertainty (speech signal - phoneme alignment errors). Such uncertainty was handled both in the training process and in the decoding step, leading to speech recognition performance improvements [25].

Detailed acoustic modeling was also investigated using automatic classification of speaker data. With such an approach it is possible to go beyond the traditional four class models (male vs female, studio quality vs telephone quality). However, as the amount of training data for each class gets smaller when the number of classes increases, this limits the amount of classes that can efficiently be trained. Hence, this year we have
investigated introducing a classification margin in the classification process. With such a margin, which handle boundary classification uncertainty, speech data at the class-boundary may belong to several classes. This increases the amount of training data in each class, which makes the class acoustic model parameters more reliable, and finally improved the overall recognition performance.

6.2.2.3. Speech recognition using distant recording

Speech recognition of distant recording of speech commands was investigated. A set of domotic commands were recorded from a few speakers using a far talking microphone. Acoustic models were adapted to this context using some training data played with a loud speaker, and recorded using a distant microphone. Among other results, preliminary experiments showed the benefit of adapting the models, as well as using a noise robust acoustic analysis when dealing with noisy data.

6.2.2.4. Training HMM acoustic models

At the beginning of his second internship at INRIA Nancy research laboratory, Othman Lachhab focused on the finalization of a speech recognition system based on context-independent HMMs models, using bigram probabilities for the phonotactic constraints and a model of duration following a normal distribution $\mathcal{N}(\mu, \sigma^2)$ incorporated directly in the Viterbi search process. Currently, he built a reference system for speaker-independent continuous phone recognition using Context- Independent Continuous Density HMM (CI-CDHMM) modeled by Gaussian Mixture Models (GMMs). In this system he developed his own training technique, based on a statistical algorithm estimating the classical optimal parameters. This new training process compares favorably with already published HMM technology on the same test corpus (TIMIT).

6.2.3. Speech/text alignment

6.2.3.1. Alignment with native speech

Speech to text alignment is a research objective that is derived from speech recognition. While it seems easier to solve at first sight, expectations are also higher and new problems appear, such as how to handle very large audio documents, or how to handle out-of-vocabulary words. Another important challenge that motivated our work in this area concerns how to improve our results and meet the user expectation by exploiting as much as possible the interactions and feedback loop between the end-user and the system. This year, we kept on improving the open-source JTrans software platform for this task as described in Section (see section 5.6 ). We further submitted an ANR Corpus proposal in collaboration with University Paris 3. We also sent a new version of the software to the "Timecode" company to help them investigating the usefulness of this approach in the application context of foreign film dubbing (see section 7.4.1 ).

6.2.3.2. Alignment with non-native speech

Non-native speech alignment with text is one critical step in computer assisted foreign language learning. The alignment is necessary to analyze the learner’s utterance, in view of providing some prosody feedback (as for example bad duration of some syllables - too short or too long -). However, non-native speech alignment with text is much more complicated than native speech alignment. This is due to the pronunciation deviations observed on non-native speech, as for example the replacement of some target language phonemes by phonemes of the mother tongue, as well as errors in the pronunciations. Moreover, these pronunciation deviations are strongly speaker dependent (i.e. they depend on the mother tongue of the speaker, and on its fluency in the target foreign language) which makes their prediction difficult.

In this application context, the precision of phoneme boundaries is critical. Hence, speech-text alignment was investigated on non-native speech. A large non-native speech corpus has been manually segmented for building a reference corpus. Then automatic phonetic segmentation (resulting from the speech-text alignment) has been analyzed. The results shows that rather reliable boundaries are obtained for some phonetic classes [31] and that better results are obtained when only frequent pronunciation deviations are kept as variants in the pronunciation lexicon [27]. Further work is on-going to determine automatically a confidence value on the proposed alignments.
6.2.4. Computing and merging linguistic information on speech transcripts

The raw output of speech recognition is difficult to read for humans, and difficult to exploit for further automatic processing. We thus investigated solutions to enrich speech recognition outputs with non-lexical information, such as dialog acts, punctuation marks and syntactic dependencies. Computing such a linguistic information requires a corpus to train stochastic models, and we also worked out new semi-supervised training algorithms for building a French corpus dedicated to syntactic parsing of oral speech. The creation of this corpus is realized in collaboration with the TALARIS team. Finally, we designed a new solution to improve our core language models by integrating into them lexical semantic distances.

An important information for post-processing speech transcripts concerns dialog acts and punctuation marks. We initiated some work in this area several years ago with the Ph.D. thesis of Pavel Kral. Since then, we continued our collaboration in this domain by successively investigating specific challenges, such as finding the most relevant features, models and testing the adaptation of our approaches in two languages, Czech and French [59]. We further proposed this year an approach to improve commas generation with the help of syntactic features [17].

Inferring syntactic dependencies is an extremely important step towards structuring the text and an absolute prerequisite for working with relations between words and next interpreting the utterance. Yet, no state-of-the-art solutions designed for parsing written texts can be reliably adapted to parsing speech, and even less transcribed speech. The lack of such methods and resources is especially blatant in French. We started, in collaboration with the TALARIS team, to address this issue by building a new French treebank dedicated to speech parsing [52], as well as a software platform dedicated to working with this corpus (see section 5.5). We exploited this year this corpus to study specific syntactic structures, such as negations (Master internship in 2011) and left dislocations in French [13].

While a large part of our work is dedicated to enriching the output of our speech recognition system, we also tried integrating within the speech decoding process itself new information coming from the higher-levels. We thus extended the new approach proposed in 2010 about language model smoothing with a new probabilistic smoothing that takes into account much longer words history thanks to a Levenshtein-based clustering of the training sentences [20].

6.3. Speech-to-Speech Translation and Language Modeling

Participants: Kamel Smaïli, David Langlois, Sylvain Raybaud.

Our work on Confidence Measures is now published in Machine Translation [9]. Now we are working on Speech-to-Text translation. We have proposed a method to segment audio input stream for machine translation. First, audio stream is split into overlapping segments useful for speech recognition; then, these segments are transcribed and regrouped; last, the obtained text flow is segmented into machine translation-friendly segments and translated. We incorporated this work into our speech-to-text machine translation system, and we evaluated our system for French-English broadcast news translation [34]. The following step consists in integrating Confidence Measures into the system in order to improve the integration between the both recognition-translation processes.

Moreover, we pursued our collaboration with Chiraz Latiri from the URPAH Team, University of Tunis. Running on our previous works (based on word-based machine translation system) we compared our respective methods in the scope of phrase-based machine translation [30].
6. New Results

6.1. The Focused Calculus of Structures

Participants: Kaustuv Chaudhuri, Nicolas Guenot, Lutz Straßburger.

The sequent calculus is a proof system for logic that has many nice properties from a proof search perspective, the most famous being the subformula property that is essential to tame the search space. In recent years, the focusing property of sequent systems has become another useful property, both for shrinking the search space and to improve the representation of proofs. However, the sequent calculus does have some limitations. Primarily, not all logics have analytic (i.e., cut-free) proof systems, which are the sine qua non of proof search. A less obvious but equally bothersome limitation is that cut-free sequent proofs tend to contain large repeated sub-proofs.

To remedy these deficiencies, one can use the calculus of structures, a proof system that allows inferences anywhere inside a formula. This system can represent many more logics than the sequent calculus and can produce better (i.e., usually smaller) proofs because it can avoid sharing large subformulas. Nevertheless, because the rules of the calculus of structures have finer granularity than sequent rules, it has more non-determinism during search.

In this work, we show how to transplant the focusing result from the sequent calculus to the calculus of structures [19]. We thus improve the search capabilities of the calculus of structures, including the ability to go back and forth between focused sequent proofs and focused calculus of structures proofs, but we retain all the distinguishing features of the calculus of structures.

In particular, we preserve the ability to permute contractions below all other rules (first observed for the calculus of structures in [55], [31]). This permutation enables a two-stage normal form of proofs. The first stage contains only contractions, which increases the complexity of the formulas and is therefore a potential source of unbounded search; this phase needs to be recorded in order to reconstruct proofs by bounded search. The second stage that contains the remaining logical rules (except contraction) is strictly bounded and finite—hence decidable—and can be reconstructed if omitted from the proof object. Thus, we have the potential of obtaining very simple proof objects, recording only the first phase, for focused proofs; moreover, because of the bidirectional link, we can reconstruct focused sequent proofs from such proof objects.

Both the search and the representational aspects of focused calculus of structures proofs are being investigated in the Profound tool (see section 5.1).

6.2. Nested Sequents for Intuitionistic Modal Logics

Participant: Lutz Straßburger.

We show how the recent results for treating classical modal logics in the modal cube under S5 via nested sequents [32], [33] can be carried to intuitionistic modal logics. Thus, we present cut-free nested sequent systems for all intuitionistic modal logics in the modal cube up to IS5, and we show how this can be done in a modular way, i.e., to each of the axioms d, t, b, 4, and 5, we assign a set of inference rules, such that for each subset of d,t,b,4,5 the corresponding set of rules is sound and complete for the defined logic. This work has been presented in an invited talk at the IMLA workshop in Nancy [25].

6.3. The logic of nominal abstraction

Participant: Dale Miller.
In the paper [12], Gacek, Miller, and Nadathur have developed a strong logic that allows strong forms of induction and co-induction in the presence of the $\nabla$ quantifier. This quantifier was introduced in earlier work by Miller and Tiu [50] where it was shown to provide declarative and flexible operational semantic specifications for a number of systems such as the $\lambda$-calculus and the $\pi$-calculus. The paper introduces a generalization form of equality, called nominal abstraction, that permits natural specifications of predicates such as freshness. This paper provides the necessary meta theory (cut-elimination) for this new logic.

6.4. A framework for focusing and cut-elimination

Participant: Dale Miller.

Liang and Miller provide in [14] a general setting for specifying proofs in intuitionistic and classical logic. In this setting, it is possible to guarantee cut-elimination and initial elimination results simply by checking how certain simple side-conditions are used within a focused proof system. This setting treats both intuitionistic and classical logics as well allowing certain hybridizations of these two logics. This work helped lead the authors to finding a way to truly mix in one logic and one proof system both classical and intuitionistic logic, as described in [22].

6.5. Synthetic connectives and their proof system

Participant: Dale Miller.

In recent years, focused proof systems have being used to expand our understanding of how introduction rules and structural rule relate to each other. In these proof systems, inference rules and logical connectives are polarized as negative or positive in such a way that the invertible inference rules all belong to the negative polarity. Groups of negative connectives can then be grouped into one negative synthetic connective: similarly, positive connectives can be grouped into a positive synthetic connective. Such synthetic connectives admit cut-elimination. Remarkably, focused proof systems for classical and intuitionistic logics can be organized so that negative formulas are, in fact, treated linearly. That is, if weakening or contraction is applied to a formula, that formula is positive.

Focused proof systems can be used to design richly varying collections of synthetic connectives. These proof systems also provide for new means of describing parallelism within proofs and mixing computation and deduction. The ability to treat negative formulas linearly provides important information for the design of automated theorem provers. Synthetic connectives and their associated inference rules will also allow for the design of broad spectrum proof certificates that theorem provers will be able to print and simple proof checkers will be able to validate. Miller’s conference paper [20] develops this approach to proof certificates.

6.6. Automated reasoning and SMT solving

Participants: Mahfuza Farooque, Stéphane Lengrand.

Automated reasoning uses a broad range of techniques whose soundness and completeness relate to the existence of proofs. The research programme of the ANR PSI project at Parsifal is to build a finer-grained connection by specifying automated reasoning techniques as the step-by-step construction of proofs, as we know it from proof theory and logic programming. The goal is to do this in a unifying framework, namely proof-search in a classical polarized sequent calculus. One of the advantages of this is to combine those techniques more easily. Another one is to envisage extending those techniques.

For instance, the algorithm at the heart of SMT-solving (SAT-modulo-Theory) is DPLL(T), whose theory does not treat existential variables (although SMT-provers often implement incomplete ad hoc techniques for them). We have first encoded DPLL(T) as the step-by-step construction of a proof tree in a classical polarized sequent calculus extended with calls to a decision procedure for T (to be published). This proof-theoretic view now allows us to envisage how to extend the algorithm with existential variables.
Another range of techniques that we are addressing is the handling of equality (superposition / paramodulation calculi).

6.7. Towards a Stochastic Linear Logic for Biological Computation

Participants: Kaustuv Chaudhuri, Joëlle Despeyroux.

In previous work [35], Joëlle Despeyroux and Kaustuv Chaudhuri have given an encoding of the synchronous stochastic $\pi$-calculus in a hybrid extension of intuitionistic linear logic (called HyLL). Precisely, they have shown that focused partial sequent derivations in the encoding are in bijection with stochastic traces. The modal worlds are used to represent the rates of stochastic interactions, and the connectives of hybrid logic are used to represent the constraints in the stochastic transition rules.

One of the most successful applications of the stochastic $\pi$-calculus has been in representing signal transduction networks in cellular biology. An interesting application of this work would therefore be the direct representations of biological processes in HyLL, the original motivation for this line of investigation.

This year, we have worked on specifying some simple examples of regulatory gene networks, together with basic properties of them—such as stability or oscillation—in HyLL. This is ongoing work in collaboration with Gilles Bernot’s team at Nice-Sophia university.
6. New Results

6.1. Calibration of a mixed camera system

An approximately Euclidean representation of the visible scene can be obtained directly from a range, or
time-of-flight, camera. An uncalibrated binocular system, in contrast, gives only a projective reconstruction of
the scene. This paper analyzes the geometric mapping between the two representations, without requiring an
intermediate calibration of the binocular system. The mapping can be found by either of two new methods, one
of which requires point correspondences between the range and colour cameras, and one of which does not. It
is shown that these methods can be used to reproject the range data into the binocular images, which makes it
possible to associate high-resolution colour and texture with each point in the Euclidean representation.

6.2. Computation of scene flow

A simple seed growing algorithm for estimating scene flow in a stereo setup is presented. Two calibrated and
synchronized cameras observe a scene and output a sequence of image pairs. The algorithm simultaneously
computes a disparity map between the image pairs and optical flow maps between consecutive images. This,
together with calibration data, is an equivalent representation of the 3D scene flow, i.e. a 3D velocity vector
is associated with each reconstructed point. The proposed method starts from correspondence seeds and
propagates these correspondences to their neighborhood. It is accurate for complex scenes with large motions
and produces temporally-coherent stereo disparity and optical flow results. The algorithm is fast due to inherent
search space reduction. An explicit comparison with recent methods of spatiotemporal stereo and variational
optical and scene flow is provided.

6.3. 3D shape analysis and registration

We address the problem of 3D shape registration and we propose a novel technique based on spectral graph
theory and probabilistic matching. Recent advancement in shape acquisition technology has led to the capture
of large amounts of 3D data. Existing real-time multi-camera 3D acquisition methods provide a frame-
wise reliable visual-hull or mesh representations for real 3D animation sequences. The task of 3D shape
analysis involves tracking, recognition, registration, etc. Analyzing 3D data in a single framework is still a
challenging task considering the large variability of the data gathered with different acquisition devices. 3D
shape registration is one such challenging shape analysis task. The main contribution of this chapter is to
extend the spectral graph matching methods to very large graphs by combining spectral graph matching with
Laplacian embedding. Since the embedded representation of a graph is obtained by dimensionality reduction
we claim that the existing spectral-based methods are not easily applicable. We discuss solutions for the
exact and inexact graph isomorphism problems and recall the main spectral properties of the combinatorial
graph Laplacian; We provide a novel analysis of the commute-time embedding that allows us to interpret the
latter in terms of the PCA of a graph, and to select the appropriate dimension of the associated embedded
metric space; We derive a unit hyper-sphere normalization for the commute-time embedding that allows us to
register two shapes with different samplings; We propose a novel method to find the eigenvalue-eigenvector
ordering and the eigenvector sign using the eigensignature (histogram) which is invariant to the isometric
shape deformations and fits well in the spectral graph matching framework, and we present a probabilistic
shape matching formulation using an expectation maximization point registration algorithm which alternates
between aligning the eigenbases and finding a vertex-to-vertex assignment.
6.4. A differential model for the complex cell

The receptive fields of simple cells in the visual cortex can be understood as linear filters. These filters can be modelled by Gabor functions, or by Gaussian derivatives. Gabor functions can also be combined in an energy model of the complex cell response. This work proposes an alternative model of the complex cell, based on Gaussian derivatives. It is most important to account for the insensitivity of the complex response to small shifts of the image. The new model uses a linear combination of the first few derivative filters, at a single position, to approximate the first derivative filter, at a series of adjacent positions. The maximum response, over all positions, gives a signal that is insensitive to small shifts of the image. This model, unlike previous approaches, is based on the scale-space theory of visual processing. In particular, the complex cell is built from filters that respond to the 2-D differential structure of the image. The computational aspects of the new model are studied in one and two dimensions, using the steerability of the Gaussian derivatives. The response of the model to basic images, such as edges and gratings, is derived formally. The response to natural images is also evaluated, using statistical measures of shift insensitivity. The relevance of the new model to the cortical image-representation is discussed.

6.5. Audiovisual fusion based on a mixture model

The problem of multimodal clustering arises whenever the data are gathered with several physically different sensors. Observations from different modalities are not necessarily aligned in the sense there there is no obvious way to associate or to compare them in some common space. A solution may consist in considering multiple clustering tasks independently for each modality. The main difficulty with such an approach is to guarantee that the unimodal clusterings are mutually consistent. In this paper we show that multimodal clustering can be addressed within a novel framework, namely conjugate mixture models. These models exploit the explicit transformations that are often available between an unobserved parameter space (objects) and each one of the observation spaces (sensors). We formulate the problem as a likelihood maximization task and we derive the associated conjugate expectation-maximization algorithm. The convergence properties of the proposed algorithm are thoroughly investigated. Several local/global optimization techniques are proposed in order to increase its convergence speed. Two initialization strategies are proposed and compared. A consistent model-selection criterion is proposed. The algorithm and its variants are tested and evaluated within the task of 3D localization of several speakers using both auditory and visual data.
6. New Results

6.1. Leveraging Software Architectures to Guide and Verify the Development of Sense/Compute/Control Applications

A software architecture describes the structure of a computing system by specifying software components and their interactions. Mapping a software architecture to an implementation is a well-known challenge. A key element of this mapping is the architecture’s description of the data and control-flow interactions between components. The characterization of these interactions can be rather abstract or very concrete, providing more or less implementation guidance, programming support, and static verification.

In this work, we have introduced a notion of behavioral contract that expresses the set of allowed interactions between components, describing both data and control-flow constraints [15]. This declaration is part of the architecture description, allows generation of extensive programming support, and enables various verifications. We have instantiated our approach in an architecture description language for the domain of Sense/Compute/Control (SCC) applications, and described associated compilation and verification strategies.

The main contributions of this work are the following:

- We have introduced a language for behavioral contracts dedicated to SCC applications.
- We have shown that behavioral contracts can effectively guide the implementation of SCC applications by enabling the generation of highly customized programming frameworks using a dedicated compiler. This approach ensures the conformance between the architecture and the implementation, while facilitating software evolution.
- We have shown that such descriptions are precise enough to verify safety properties such as information flow reachability or behavioral invariants.
- Based on an implementation of behavioral contracts in a design language targeting SCC applications, we have assessed the benefit of behavioral contracts at a conceptual level and in terms of metrics on the resulting code.

6.2. A Step-wise Approach for Integrating QoS throughout Software Development

Non-functional requirements are used to express the quality to be expected from a system. For real-time systems such as avionics, it is critical to guarantee this quality, in particular time-related performance properties. In this domain, deterministic QoS is generally ensured at the execution platform level (e.g., operating systems, distributed systems technologies, hardware specificities), independently of a particular application. When addressing the QoS requirements of a given application, these platform-specific guarantees are not sufficient.

In this work, we have proposed a step-wise QoS approach integrated through all development phases and development artifacts [17]. This approach is dedicated to control-loop systems. Control-loop systems are systems that sense the external environment, compute data, and eventually control the environment accordingly. This kind of systems can be found in a range of domains, including avionics, robotics, and pervasive computing. For example, in the avionics domain, a flight management application is a control-loop system that (1) senses the environment for location and other navigation information, (2) computes the trajectory and (3) modifies the wings configuration accordingly.
The main contributions of this work are the following:

- We have developed a step-wise approach that systematically processes QoS requirements throughout software development. This integrated approach is dedicated to control-loop systems, allowing to rely on a particular architectural pattern and thus enhancing the design and programming support level for non-functional aspects. For now, we focus on time-related performance but the approach could be generalized to other non-functional properties (e.g., CPU or memory consumption).

- Our approach has been integrated into DIA SUITE, a tool-based development methodology dedicated to control-loop systems. DIA SUITE is based on a dedicated design language that we have enriched with time-related performance properties. This non-functional extension has been used to offer verification and programming support at each development stage.

- Our approach has been applied to the development of avionics applications such as a flight management system and a collision avoidance system. These experiments have demonstrated that our step-wise approach can effectively guide the avionics certification process.

### 6.3. Architecturing Conflict Handling of Pervasive Computing Resources

The rapid development of new devices (further resources) and development tools being opened to third-parties have paved the way to an increasing number of applications being deployed in pervasive computing environments. These applications anarchically access resources. In this situation, it is very common for a resource to be accessed by multiple applications, potentially leading to conflicts. For example, in a building management system, a security application that grants access inside the building, can conflict with an application dealing with emergency situations like fires, preventing the building to be evacuated.

Managing conflicts consists of three main parts, detection, resolution and prevention. These parts crosscut the development cycle of applications and pervasive computing systems. In this work, we have proposed a conflict management process that cleanly separates conflict management tasks by providing a design method and supporting tools [18]. This facilitates the work of developers, architects and administrators, who can follow clear guidelines to manage conflicts.

The main contributions of this work are the following:

- We have identified requirements at different stages during the development cycle that are necessary to detect, resolve, and prevent conflicts. We have assigned duties and responsibilities to existing roles, that are carried out during the conflict management process without interfering with the standard application development.

- We have extended a domain-specific design language to declare conflict resolution at an architectural level. During the conflict management process conditions are specified and prioritized. Afterwards conflicting applications (inter application) or modules (intra application) are linked to these conditions.

- The declared information is used to generate code dedicated to conflict handling. On the one hand, a compiler generates a dedicated framework that guides the implementation of the conflict handling logic at application and system level. On the other hand, it generates code that orchestrates resource accesses and prevents conflicts.
PI.R2 Project-Team

6. New Results

6.1. Proof-theoretical investigations

6.1.1. Sequent calculus and Computational duality

Thunks and duality. Guillaume Munch-Maccagnoni investigated a notion dual to the thunks of call-by-value lambda-calculus which allows to simulate call-by-value in call-by-name. He started to investigate how this structure arises in many models of call-by-name lambda-calculus, how it could explain various phenomena such as storage operators, and how it could relate to features of actual programming languages.

Categorical semantics. Guillaume Munch-Maccagnoni started a collaboration with Marcelo Fiore with the aim of understanding structures behind sequent calculus (of system L in particular) and polarisation (as found in Girard’s classical logic). The goal is to draw links with algebraic and/or computing structures in the unifying language of category theory. This work is also in collaboration with Pierre-Louis Curien.

Noam Zeilberger has continued to work with Paul-André Melliès (PPS) on developing a categorical framework for better understanding contexts and inference rules in proof theory and type theory, with the aim of achieving an integration with the theory of side-effects in programming languages. He presented some results from this work in March at the European Workshop on Computational Effects.

Polarised Peano arithmetic. Guillaume Munch-Maccagnoni extended polarised classical logic and polarised classical realisability to predicate calculus and to Peano arithmetic. This decomposes and simplifies technical artefacts found in call-by-name classical realisability, and sheds a new light on witness extraction from proofs of $\Sigma$ formulae.

(Con)Inductive Types in Sequent Calculus. Hugo Herbelin and Jeffrey Sarnat continued their work towards a sequent calculus presentation of a simply-typed fragment of CIC that has inductive and coinductive types, as formalized using recursion operators and a guard condition. Some progress was made on the formalization of the guard condition and normalization proof, but both remained unfinished as of the end of Sarnat’s postdoc in June.

Classical call-by-need and the duality of computation. In a collaboration with Zena Ariola (and especially after a 3-week visit by Alexis Saurin in Oregon early 2011), Zena Ariola, Hugo Herbelin and Alexis Saurin have presented the call-by-need strategy in the framework of the duality of computation, that is a sequent calculus approach to call-by-need, and they extended call-by-need from minimal logic to classical logic which allowed to integrate smoothly control operators, resulting in particular in a call-by-need $\lambda\mu$-calculus. Moreover, the duality principles involved in such a framework unveiled a new calculus, dual to the usual call-by-need but which is distinct from call-by-name, call-by-value as well as the usual call-by-need. These results were presented at TLCA 2011.

Pursuing the previous collaboration, the three previous authors, together with Paul Downen and Keiko Nakata, studied abstract machines for this classical call-by-need calculus.

6.1.2. Linear dependent types

Arnaud Spiwack started investigating dependent types variants of linear sequent calculus based on Curien & Herbelin’s $\mu\tilde{\mu}$. The goal is to study what kind of set theory arises from such a linear type theory when following the tradition of intuitionistic type theory of defining a set as a type equipped with a relation (this construction is also known as setoid). Sets defined in this manner in Coq gives rise to a quasitopos (as proved in Arnaud Spiwack’s PhD thesis) which makes for a reasonable approximation of usual mathematics, however
"linear sets" should be quite different and may support some unorthodox mathematics. To have an appropriate theory of linear sets seems to require a fairly rich linear type theory in particular one that supports so called strong elimination (the type theoretic equivalent to induction). So far, if extending $\mu\eta$ to dependently typed linear logic has been achieved, strong elimination proves to be harder to coin.

Pierre-Marie Pérot just started his PhD on this same general topic. While linear logic appeared as an operational decomposition of intuitionistic logic, dependent types are conversely an essential enrichment of the latter, as they permit to constructively formalize important parts of mathematics. Even though it is nowadays pervasively thought that we should mix them, actually it does seem that nobody seriously tried hitherto. This subject is quite vast, and both sides may mutually enhance the understanding of one another. From the linear side, linear logic is seriously lacking any satisfying syntax at all; and worse, it seems more prone to solely describe computational behavior instead of truly formalizing mathematics, for its very lack of richer types. From the dependent side, usual dependent type systems are based upon PTS, which, being a plain enrichment of basic lambda-calculus, are intrinsically call-by-name structures. Hence, a linear decomposition inspired from polarization techniques may permit a better analysis of the inner, yet-to-be discovered gears of PTS. One may even hope to include non-intuitionistic effects therein. Furthermore, practical systems used today (Coq, for example) come bundled with additional constructs, such as inductives, whose understanding with respect to models is still highly incomplete. One could expect linear logic to shed a new light upon these issues. This thesis stems from preliminary work of Pierre-Marie Pérot (during his M2 internship) inspired by models of GoI and other closely related results from Girard, which suggest a natural way to integrate dependency into them.

6.1.3. Proving with side-effects

Axiom of dependent choice. Hugo Herbelin showed that classical arithmetic in finite types extended with strong elimination of existential quantification proves the axiom of dependent choice. To get classical logic and choice together without being inconsistent is made possible first by constraining strong elimination of existential quantification to proofs that are essentially intuitionistic and second to turn countable universal quantification into an infinite conjunction of classical proofs evaluated along a call-by-need evaluation strategy so as to extract of them intuitionistic contents that complies to the intuitionistic constraint put on strong elimination of existential quantification. This work has been presented at the TYPES conference.

Memory assignment, forcing and delimited control. Hugo Herbelin investigated how to extend his work on intuitionistically proving Markov’s principle [35] and the work of Danko Ilik on intuitionistically proving the double negation shift (i.e. $\forall x \neg \neg A \rightarrow \neg \neg \forall x A$) [38] to other kind of effects. In particular, memory assignment is related to Cohen’s forcing as emphasized by Krivine [40] and as the observation that Cohen’s translation of formula $P$ into $\forall y \leq x \exists z \leq y P(z)$ is similar to a state-passing-style transformation of type $P$ into $S \rightarrow S \times P$.

Hugo Herbelin then designed a logical formalism with memory assignment that allows to prove in direct-style any statement provable using the forcing method, the same way as logic extended with control operators allows to support direct-style classical reasoning. Thanks to the use of delimiters over “small” formulas similar to the notation of $\Sigma^1_0$-formulas in arithmetic, the whole framework remains intuitionistic, in the sense that it satisfies the disjunction and existence property.

Two typical applications of proving with side-effects are global-memory proofs of the axiom of countable choice and an enumeration-free proof of Gödel’s completeness theorem.

The main ideas of this research program have been presented at the Geocal-Lac meeting of the GDR IM.

6.1.4. Delimited control

Delimited control and infinitary/stream calculi

During his summer internship, Paul Downen studied with Alexis Saurin some infinitary $\lambda$-calculi and infinitary rewriting and in particular a proposal by Ketema, Blom, Aoto and Simonsen which allows to consider transfinitely deep terms. The proposed calculus presented several defects on which Paul Downen studies focused. Some of these defects were corrected but the work is still on-going.
In a collaboration with Marco Gaboardi and Koji Nakazawa, Alexis Saurin has been studying how to turn the \( \Lambda \mu \)-calculus into a truly stream-based calculus. This involved enlarging the syntactical category for streams, defining a type system and comparing with other proposals for computing on streams.

Alexis Saurin also developed previous results on \( \Lambda \mu \)-calculus in a paper currently under final revision for publication in TCS.

**PTS and delimited control** Following Danvy-Filinski’ simply-typed system for a \( \lambda \)-calculus with delimited control, Hugo Herbelin and Pierre Boutillier have defined a set of rules for pure type systems with control operator. The work relies on the CPS used to encode them in standard Pure Type Systems and involves extra type annotations. Nevertheless, it seems to be more general than previous attempts to build classical PTS [20]. It has been presented at the workshop TPDC (Theory and Practice of Delimited Continuations) in Novi Sad and an article is under preparation.

### 6.1.5. Interactive Realizability

Thanks to the Curry-Howard correspondence for classical logic, it is possible to extract programs from classical proofs. These programs use control operators as a way to implement backtracking and processes of intelligent learning by trial and error. Unfortunately, such programs are often hard to write, difficult to understand and are very inefficient: every time a program backtracks, it forgets way too much information. This state of thing is due to a poor understanding and control of the backtracking mechanism that interprets classical proofs. In order to write down more efficient programs, it is necessary to describe exactly: a) what the programs learn, b) how the knowledge of programs varies during the execution.

A first step towards this goal is the theory of Interactive Realizability, a semantics for intuitionistic Arithmetic with excluded middle over semi-decidable predicates. It is based on a notion of state, which describes the knowledge of programs coming from a classical proof, and explains how the knowledge evolves during computation.

Federico Aschieri is working in two directions. First he is extending this realizability semantics to second-order intuitionistic Arithmetic with the same excluded middle over semi-decidable predicates. He has also discovered a new state passing style transformation, which allows to implement in System F efficient programs, which backtrack at the right point and do not forget anything when backtracking. He is also investigating an interesting relation with the forcing semantics: it seems that his transformation is a very direct, new constructive formulation of forcing.

Secondly, in collaboration with Berardi, he is also extending Interactive Realizability to first-order Arithmetic, with full excluded middle. This work promises to provide a significantly finer description of the learning mechanism that interprets classical proofs.

### 6.1.6. Substitutions and isomorphisms

Pierre-Louis Curien extended his collaboration with Martin Hofmann (Univ. of Munich) and Richard Garner (MacQuarie University, Sydney), started in 2010, to the point where the picture sought and announced in the report of last year turned out to be a bit less idyllic than expected. Let us recall the question addressed. We wanted to compare precisely two ways of giving a categorical interpretations of Martin-Löf type theory, both overcoming the following mismatch: syntax has exact substitutions, while their categorical interpretation, in terms of pullbacks or fibrations, “implements” substitutions only up to isomorphism. One can then either change the model (strictification) [36], or modify the syntax (by introducing explicit substitutions and more importantly explicit coercions between types that are now only isomorphic) [2]. These approaches turn out to be related through adjunctions in a suitable 2-categorical framework that has a conceptual interest of its own. But these adjunction do not fit entirely together, as we found out early 2011: One is base-dependent, and the other not. So we cannot put them directly aside to get the nice conceptual picture we hoped for. Still, our initial goal of expressing the interpretations in terms of on another can be attained, but this remains to be worked out in detail.
6.1.7. Miscellanea
During his three months visit in Beijing, Pierre-Louis Curien worked on the relations between Rewriting theory and the theory of Gröbner bases and other bases like Janet bases or involutive bases that have been introduced in computer algebra. These comparisons shed some light on the classification of various completion techniques for rewriting systems (a completion turns a rewriting system into an equivalent locally confluent one). This is work in progress.

6.2. Metatheory of Coq and beyond
Participants: Pierre Boutillier, Hugo Herbelin, Yann Régis-Gianas, Jeffrey Sarnat, Vincent Siles, Matthieu Sozeau, Noam Zeilberger.

From the work he has done last year on the Coq termination checker, Pierre Boutillier wrote an article to describe formally the exact new Coq implementation of a structural guard condition that handles commutative cuts.

6.2.1. Calculus of inductive constructions and typed equality
The work of Hugo Herbelin and Vincent Siles on the equivalence of Pure Type Systems with typed or untyped equality has been accepted for publication [11].

6.2.2. Proofs of higher-order programs
Jeffrey Sarnat and Noam Zeilberger continued to investigate the classical program transformations of continuation-passing-style translation and defunctionalisation [46], from the point-of-view of their effect on the termination proofs of higher-order programs. The practical aim of these investigations is to develop a more systematic understanding of termination proofs, which eventually could result in a compiler from proof assistants with higher-order reasoning (such as Coq) to ones with only first-order reasoning (such as Twelf).

6.2.3. Unification
Matthieu Sozeau and Hugo Herbelin worked on improving the unification algorithm of Coq, making it more predictable and resolving important soundness issues (e.g. type-checking, dealing with universes). In collaboration with Beta Ziliani at (PhD student at MPI Sarbrucken) and Aleksandar Nanevski (Resarcher at IMDEA Madrid), Matthieu Sozeau started a project to formalize (on paper) the improved unification algorithm, taking into account advanced features such as canonical structures and type classes. This will give a detailed view of the system to power users like [33] and improve the system to handle the delicate usage patterns developed in the Mathematical Components team at MSR to scale Coq to large formalizations.

6.3. Coq as a functional programming language
Participants: Stéphane Glondu, Pierre Letouzey, Matthias Puech, Matthieu Sozeau.

6.3.1. Type-classes and libraries
Matthieu Sozeau has worked with members of the Foundations team at Nijmegen on enhancing the implementation of type-classes to suit the needs of the development of the MathClasses formalization of abstract algebra (part of the ForMath EU project). This gave rise to an experimental implementation of forward reasoning for instance resolution. Concurrently, he started a collaboration with Jael Kriener (Univ. of Canterbury, who visited for a week in November) to adapt techniques from logic programming to the system, including a determinacy analysis that would give better control of the system when building large hierarchies of structures (as in the MathClasses library).

Pierre Castéran from INRIA Bordeaux and Matthieu Sozeau are developing a tutorial on the use of type-classes that will be the basis of an invited tutorial given by M. Sozeau at the JFLA conference in February 2012. It will be published as part of the new version of the Coq’Art book.
6.3.2. Equations

Matthieu Sozeau has continued the development of the Equations package to build and reason on dependently-typed programs. He reworked the internals of the tool for a more efficient implementation and extended it to handle recursion on arbitrary inductive families. He developed a sizable example of the use of the tool for proving the metatheory of the LF system. The plugin will be released with the upcoming 8.4 version of Coq. A journal article presenting the tool and its usage is in preparation.

6.3.3. Recursive definitions in proof assistants

Together with Ana Bove and Alexander Krauss, Matthieu Sozeau has written a survey article on tools and methods to build and reason on recursive functions in proof assistants based on type theory. The survey compares the relative strengths and weaknesses of various formalization methods available in constructive type theories like Agda or Coq and classical systems like HOL. The article is still under review.

6.3.4. Dependent pattern-matching

Hugo Herbelin and Pierre Boutillier worked on a new simulation of Agda’s style dependent pattern-matching [24] in the Calculus of Inductive Constructions which, on the contrary of Goguen et al.’s simulation [32], does not rely on any explicit notion of dependent equality. The simulation relies on a systematic re-generalization of a given matching over the next pattern to matching and over a notion of matching narrowed by type constraints formalized by Pierre Boutillier [14]. The former itself relies on Pierre Boutillier’s master thesis on making the guard condition traversing blocked commutative cuts. The simulation has been implemented in Coq 8.4 but without narrowing on subpatterns yet.

6.3.5. Modularized arithmetical libraries

Pierre Letouzey has integrated in Coq a deep reform of some parts of its Standard Library, mainly the Numbers library of generic / efficient arithmetic. This reform is part of the the version Coq 8.4. The idea is to take advantage of recent improvements of the Coq system in terms of modularity (Type Classes by Sozeau and better Modules by Soubiran) for providing more uniformity in the functions and properties about integers provided in the Standard Library. We now have a base of functions and lemmas which is statically guaranteed to be coherent from one numerical datatype representation to the other, allowing the user to choose more easily between these representations, according to the user’s need in term of simplicity or efficiency. These modernized libraries are also one of the first large-scale experimentations with many recent features of modules and type-classes, and have helped maturing them and established new usage guidelines. The transition from previous versions of these libraries should be relatively transparent thanks to a compatibility layer.

6.3.6. Certified extraction

Stéphane Glondu continued his work on extraction in the Coq-in-Coq formalisation. He proved that reductions in the source language can be simulated in the target language (the converse had been proven two years before). This proof highlighted a critical bug in the actual implementation of Coq that has been solved by Pierre Letouzey.

The formalised extraction is only a step of the actual implementation of Coq: replacing logical subterms by an inert constant. Stéphane Glondu considers this work done, even though some parts have been admitted. He worked on how the formalisation could be redesigned in order to avoid currently admitted lemmas and to allow a better integration with the existing Coq system.

6.3.7. Incrementality in proof languages

Matthias Puech and Yann Régis-Gianas worked on incremental type checking. This preliminary work will be presented during a contributed talk at TLDI 2012 [15]. It sets the grounds of an incremental proof development and checking system, by means of a representation language for repositories of proofs and proof changes.
The traditional interaction with a proof-checker is a batch process. Coq (among others) refines this model by providing a read-eval print loop with a global undo system, implemented in an ad-hoc way. A more general approach to incrementality is being developed by means of a finer-grained analysis of dependencies. The approach developed is adaptable to any typed formal language: the language is specified in a meta-language close to the Edinburgh Logical Framework, in which subsequent versions of a development can be type-checked incrementally. Applications of this framework are: proof language for proof assistants, integrated development environments for proof or programming languages, typed version control systems.

6.3.8. Proofs of programs in Coq

As part of the CerCo european project, in collaboration with Roberto Amadio (PPS, Paris Diderot University), Nicolas Ayache and Yann Régis-Gianas maintained a prototype compiler for a large subset of the C language whose specificity is to annotate input source programs with information about the worst-case execution cost of their machine code. Yann Régis-Gianas started a mechanized version of the proof technique used to prove the correctness of such an annotating compiler.

Yann Régis-Gianas developed another compiler for Core ML that uses a generalization of CerCo technique in order to obtain certified worst case execution time bounds on functional programs. This compiler produces proof obligations in Coq. The corresponding paper will be published in January 2012 in the proceedings of FOPARA 2011. It is available as a technical report [16].
6. New Results

6.1. Towards Data-Centric Networking

- **Disruption Tolerant Networking**
  
  We designed an efficient message delivery framework, called MeDeHa, which enables communication in an internet connecting heterogeneous networks that is prone to disruptions in connectivity[24]. MeDeHa is complementary to the IRTF’s Bundle Architecture: besides its ability to store messages for unavailable destinations, MeDeHa can bridge the connectivity gap between infrastructure-based and multi-hop infrastructure-less networks. It benefits from network heterogeneity (e.g., nodes supporting more than one network and nodes having diverse resources) to improve message delivery. For example, in IEEE 802.11 networks, participating nodes may use both infrastructure- and ad-hoc modes to deliver data to otherwise unavailable destinations. It also employs opportunistic routing to support nodes with episodic connectivity. One of MeDeHa’s key features is that any MeDeHa node can relay data to any destination and can act as a gateway to make two networks inter-operate or to connect to the backbone network. The network is able to store data destined to temporarily unavailable nodes till the time of their expiry. This time period depends upon current storage availability as well as quality-of-service needs (e.g., delivery delay bounds) imposed by the application. We showcase MeDeHa’s ability to operate in environments consisting of a diverse set of interconnected networks and evaluate its performance through extensive simulations using a variety of scenarios with realistic synthetic and real mobility traces. Our results show significant improvement in average delivery ratio and a significant decrease in average delivery delay in the face of episodic connectivity. We also demonstrate that MeDeHa supports different levels of quality-of-service through traffic differentiation and message prioritization.

Then, we have extended the MeDeHa framework to support multihop mobile ad-hoc networks (or MANETs). Integrating MANETs to infrastructure-based networks (wired or wireless) allows network coverage to be extended to regions where infrastructure deployment is sparse or nonexistent as well as a way to cope with intermittent connectivity. Indeed, to date there are no comprehensive solutions that integrate MANETs to infrastructure-based networks. We have proposed a message delivery framework that is able to bridge together infrastructure-based and infrastructure-less networks. Through extensive simulations, we have demonstrated the benefits of the extended MeDeHa architecture especially in terms of the extended coverage it provides as well as its ability to cope with arbitrarily long-lived connectivity disruptions. Another important contribution of this work is to deploy and evaluate our message delivery framework on a real network testbed as well as conduct experiments in “hybrid” scenarios running partly on simulation and partly on real nodes [32].

Finally, we have proposed a naming scheme for heterogeneous networks composed of infrastructure-based and infrastructure-less networks where nodes may be subject to intermittent connectivity. The proposed scheme, called Henna, aims at decoupling object identification from location and is designed to operate with status-quo Internet routing. We evaluated the proposed naming scheme using the ns-3 network simulator and demonstrated that nodes were able to receive messages in both infrastructure-based and infrastructure-less networks despite frequent disconnections and changing location identifiers (i.e., IP address), while visiting different networks [31].

Another important contribution of this work is to deploy and evaluate our message delivery framework on a real network testbed as well as conduct experiments in “hybrid” scenarios running partly on simulation and partly on real nodes. This was demonstrated at the ACM Sigcomm conference in Toronto on August 2011 [74].
These different works are the result of collaborations with Katia Obraczka and Marc Mendonca from University of California Santa Cruz (UCSC) in the context of the COMMUNITY Associated Team, see URL http://inrg.cse.ucsc.edu/community/.

Another activity in the same domain relates to efficient scheduling and drop policies in DTNs. We remind that Delay Tolerant Networks are wireless networks where disconnections may occur frequently. In order to achieve data delivery in such challenging environments, researchers have proposed the use of store-carry-and-forward protocols: there, a node may store a message in its buffer and carry it along for long periods of time, until an appropriate forwarding opportunity arises. Multiple message replicas are often propagated to increase delivery probability. This combination of long-term storage and replication imposes a high storage and bandwidth overhead. Thus, efficient scheduling and drop policies are necessary to:

(i) decide on the order by which messages should be replicated when contact durations are limited, and
(ii) which messages should be discarded when nodes’ buffers operate close to their capacity.

We worked on an optimal scheduling and drop policy that can optimize different performance metrics, such as the average delivery rate and the average delivery delay. First, we derived an optimal policy using global knowledge about the network, then we introduced a distributed algorithm that collects statistics about network history and uses appropriate estimators for the global knowledge required by the optimal policy, in practice. At the end, we are able to associate to each message inside the network a utility value that can be calculated locally, and that allows to compare it to other messages upon scheduling and buffer congestion. Our solution called HBSD (History Based Scheduling and Drop) integrates methods to reduce the overhead of the history-collection plane and to adapt to network conditions. The first version of HBSD and the theory behind have been published in 2008. A recent paper [27] provides an extension to a heterogenous mobility scenario in addition to refinements to the history collection algorithm. An implementation is proposed for the DTN2 architecture as an external router and experiments have been carried out by both real trace driven simulations and experiments over the SCORPION testbed at the University of California Santa Cruz. We refer to the web page of HBSD for more details http://planete.inria.fr/HBSD_DTN2/.

HBSD in its current version is for point-to-point communications. Another interesting schema is to consider one-to-many communications, where requesters for content express their interests to the network, which looks for the content on their behalf and delivers it back to them. We are working on this extension within a new framework called MobiTrade, which provides a utility driven trading system for efficient content dissemination on top of a disruption tolerant network. While simple tit-for-tat (TFT) mechanisms can force nodes to give one to get one, dealing with the inherent tendency of peers to take much but give back little, they can quickly lead to deadlocks when some (or most) of interesting content must be somehow fetched across the network. To resolve this, MobiTrade proposes a trading mechanism that allows a node (merchant) to buy, store, and carry content for other nodes (its clients) so that it can later trade it for content it is personally interested in. To exploit this extra degree of freedom, MobiTrade nodes continuously profile the type of content requested and the collaboration level of encountered devices. An appropriate utility function is then used to collect an optimal inventory that maximizes the expected value of stored content for future encounters, matched to the observed mobility patterns, interest patterns, and collaboration levels of encountered nodes. Using ns-3 simulations based on synthetic and real mobility traces, we show that MobiTrade achieves up to 2 times higher query success rates compared to other content dissemination schemes. Furthermore, we show that MobiTrade successfully isolates selfish devices. For further details on MobiTrade, we refer to [41] and to the web page of the project 1 where the code can be downloaded for both the ns-3 simulator and Android devices.

• Naming and Routing in Content Centric Networks

1 http://planete.inria.fr/MobiTrade/
Content distribution prevails in today's Internet and content-oriented networking proposes to access data directly by their content name instead of their location, changing the way routing must be conceived. We worked on a routing mechanism that faces the new challenge of interconnecting content-oriented networks. Our solution relies on a naming resolution infrastructure that provides the binding between the content name and the content networks that can provide it. Content-oriented messages are sent encapsulated in IP packets between the content-oriented networks. In order to allow scalability and policy management, as well as traffic popularity independence, binding requests are always transmitted to the content owner. The content owner can then dynamically learn the caches in the network and adapt its binding to leverage the cache use.

The work done so far is related to routing between content-oriented networks. We are starting an activity on how to provide routing inside a content network. To that aim, we are investigating on the one hand probabilistic routing and, on the other hand, deterministic routing and possible extension to Bellman-Ford techniques. In addition to routing, we are investigating the problem of congestion in content-oriented networks. Indeed, in this new paradigm, congestion must be controlled on a per-hop basis, as opposed to the end-to-end congestion control that prevails today. We think that we can combine routing and congestion control to optimize resource consumption. Finally, we are studying the implications of using CCN from an economical perspective. This activity was started in October 2011 by Damien Saucez.

- **Application-Level Forward Error Correction Codes (AL-FEC) and their Applications to Broadcast/Multicast Systems**

With the advent of broadcast/multicast systems (e.g., DVB-H/SH), large scale content broadcasting is becoming a key technology. This type of data distribution scheme largely relies on the use of Application Level Forward Error Correction codes (AL-FEC), not only to recover from erasures but also to improve the content broadcasting scheme itself (e.g., with FLUTE/ALC).

Our recent activities, in the context of the PhD of F. Mattoussi, included the design, analysis and improvement of GLDPC-Staircase codes, a "Generalized" extension to LDPC-Staircase codes. We have shown in particular that these codes: (1) offer small rate capabilities, i.e. can produce a large number of repair symbols 'on-the-fly', when needed; (2) feature high erasure recovery capabilities, close to that of ideal codes. Therefore they offer a nice opportunity to extend the field of application of existing LDPC-Staircase codes, while keeping backward compatibility (LDPC-Staircase "codewords" can be decoded with a GPLDPC-Staircase codec).

Our LDPC-Staircase codes, that offer a good balance in terms of performance, have been included as the primary AL-FEC solution for ISDB-Tmm (Integrated Services Digital Broadcasting, Terrestrial Mobile Multimedia), a Japanese standard for digital television (DTV) and digital radio. This is the first adoption of these codes in an international standard.

This success has been made possible, on the one hand, by major efforts in terms of standardization within IETF: the RFC 5170 (2008) defines the codes and their use in FLUTE/ALC, a protocol stack for massively scalable and reliable content delivery services, an active Internet-Draft published last year describes the use of these AL-FEC codes in FECFRAME, a framework for robust real-time streaming applications, and a recent Internet-Draft [66] defines the GOE (Generalized Object Encoding) extension of LDPC-Staircase codes for UEP (Unequal Erasure Protection) and file bundle protection services.

This success has also been made possible, on the other hand, by our efforts in terms of design and evaluation of two efficient software codecs of LDPC-Staircase codes. One of them is distributed in open-source, as part of our OpenFEC project (http://openfec.org), a unique initiative that aims at promoting open and free AL-FEC solutions. The second one, a highly optimized version with improved decoding speed and reduced memory requirements, will be commercialized in 2012.
through an industrial partner. This codec proves that LDPC-Staircase codes can offer erasure recovery performances close to ideal codes in many circumstances while keeping decoding speeds over 1Gbps.

The fact that LDPC-Staircase codes have been preferred to a major AL-FEC competitor for the ISDB-Tmm standard, is the recognition of their intrinsic qualities and of an appropriate balance between several technical and non technical criteria.

- Unequal Erasure Protection (UEP) and File bundle protection through the GOE (Generalized Object Encoding) scheme

This activity has been initiated with the PostDoc work of Rodrigue IMAD. It focuses on Unequal Erasure Protection capabilities (UEP) (when a subset of an object has more importance than the remaining) and file bundle protection capabilities (e.g. when one want to globally protect a large set of small objects).

After an in-depth understanding of the well-known PET (Priority Encoding Technique) scheme, and the UOD for RaptorQ (Universal Object Delivery) initiative of Qualcomm, which is a realization of the PET approach, we have designed the GOE FEC Scheme (Generalized Object Encoding) alternative. The idea, simple, is to decouple the FEC protection from the natural object boundaries, and to apply an independent FEC encoding to each "generalized object". The main difficulty is to find an appropriate signaling solution to synchronize the sender and receiver on the exact way FEC encoding is applied. In [65] we show this is feasible, while keeping a backward compatibility with receivers that do not support GOE FEC schemes. Two well-known AL-FEC schemes have also been extended to support this new approach, with very minimal modifications, namely Reed-Solomon and LDPC-Staircase codes [66], [65].

During this work, we compared the GOE and UOD/PET schemes, both from an analytical point of view (we use an N-truncated negative binomial distribution to that purpose) and from an experimental, simulation based, point of view [67]. We have shown that the GOE approach, by the flexibility it offers, its simplicity, its backward compatibility and its good recovery capabilities (under finite of infinite length conditions), outperforms UOD/PET for practical realizations of UEP/file bundle protection systems. See also http://www.ietf.org/proceedings/81/slides/rmt-2.pdf.

- Application-Level Forward Error Correction Codes (AL-FEC) and their Applications to Robust Streaming Systems

AL-FEC codes are known to be useful to protect time-constrained flows. The goal of the IETF FECFRAME working group is to design a generic framework to enable various kinds of AL-FEC schemes to be integrated within RTP/UDP (or similar) data flows. Our contributions in the IETF context are three fold. First of all, we have contributed to the design and standardization of the FECFRAME framework, now published as a Standards Track RFC [68].

Secondly, we have proposed the use of Reed-Solomon codes (with and without RTP encapsulation of repair packets) and LDPC-Staircase codes within the FECFRAME framework: [59] [60] [61].

Finally, in parallel, we have started an implementation of the FECFRAME framework in order to gain an in-depth understanding of the system. Previous results showed the benefits of LDPC-Staircase codes when dealing with high bit-rate real-time flows.

A second type of activity, in the context of robust streaming systems, consisted in the analysis of the Tetrys approach, in [29]. Tetrys is a promising technique that features high reliability while being independent from RTT, and performs better than traditional block FEC techniques in a wide range of operational conditions.
• A new File Delivery Application for Broadcast/Multicast Systems

FLUTE has long been the one and only official file delivery application on top of the ALC reliable multicast transport protocol. However FLUTE has several limitations (essentially because the object meta-data are transmitted independently of the objects themselves, in spite of their inter-dependency), features an intrinsic complexity, and is only available for ALC.

Therefore, we started the design of FCAST, a simple, lightweight file transfer application, that works both on top of both ALC and NORM. This work is carried out as part of the IETF RMT Working Group, in collaboration with B. Adamson (NRL). This document has passed WG Last Call and is currently considered by IESG[56], [57], [58].

• Security of the Broadcast/Multicast Systems

We believe that sooner or later, broadcasting systems will require security services. This is all the more true as heterogeneous broadcasting technologies will be used, for instance hybrid satellite-based and terrestrial networks, some of them being by nature open, as wireless networks (e.g., wimax, wifi). Therefore, one of the key security services is the authentication of the packet origin, and the packet integrity check. A key point is the ability for the terminal to perform these checks easily (the terminal often has limited processing and energy capabilities), while being tolerant to packet losses.

The TESLA (Timed Efficient Stream Loss-tolerant Authentication) scheme fulfills these requirements. We are therefore standardizing the use of TESLA in the context of the ALC and NORM reliable multicast transport protocols, within the IETF MSEC working group. This document has been published as RFC 5776.

In parallel, we have specified the use of simple authentication and integrity schemes (i.e., group MAC and digital signatures) in the context of the ALC and NORM protocols in [62], [63], [64]. This activity is also carried out within the IETF RMT working group.

• High Performance Security Gateways for High Assurance Environments

This work focuses on very high performance security gateways, compatible with 10Gbps or higher IPsec tunneling throughput, while offering a high assurance thanks in particular to a clear red/black flow separation. In this context we have studied last year the feasibility of high-bandwidth, secure communications on generic machines equipped with the latest CPUs and General-Purpose Graphical Processing Units (GPGPU).

The work carried out in 2011 has consisted in setting up and evaluating the high performance platform. This platform heavily relies on the Click modular TCP/IP protocol stack implementation, which turned out to be a key enabler both in terms of specialization of the stack and parallel processing. Our activities also consisted in analyzing the PMTU discovery aspect since it is a critical factor in achieving high bandwidths. To that goal we have designed a new approach for qualifying ICMP blackholes in the Internet, since PMTUD heavily relies on ICMP.

6.2. Network Security and Privacy

Participants: Sana Ben Hamida, Claude Castelluccia, Walid Dabbous, Mohamed Ali Kaafar, Arnaud Legout, Stevens Le Blond, Daniele Perito.

• Online users tracking and profiling techniques
Usernames are ubiquitously used for identification and authentication purposes on web services and the Internet at large, ranging from the local-part of email addresses to identifiers in social networks. Usernames are generally alphanumerical strings chosen by the users and, by design, are unique within the scope of a single organization or web service. In this work, we investigate the feasibility of using usernames to trace or link multiple profiles across services that belong to the same individual. The intuition is that the probability that two usernames refer to the same physical person strongly depends on the entropy of the username string itself. Our experiments, based on usernames gathered from real web services, show that a significant portion of the users’ profiles can be linked using their usernames. In collecting the data needed for our study, we also show that users tend to choose a small number of related usernames and use them across many services. This work is the the first to consider usernames as a source of information when profiling users on the Internet. It has been published in PETS 2011 [47], one of the most prestigious conference in the area of Computer Privacy, and has been awarded the Andreas Pfitzmann award for the best contribution.

- **Online Privacy measurements and threats identification in online social networks**

In this work, we show how these seemingly harmless interests (e.g., Music Interests) can leak privacy-sensitive information about users. In particular, we infer their undisclosed (private) attributes using the public attributes of other users sharing similar interests. In order to compare user-defined interest names, we extract their semantics using an ontologized version of Wikipedia and measure their similarity by applying a statistical learning method. Besides self-declared interests in Music, our technique does not rely on any further information about users such as friends relationship or group belongings. Our experiments, based on more than 104K public profiles collected from Facebook and more than 2000 private profiles provided by volunteers, show that our inference technique efficiently predicts attributes that are very often hidden by users. To the best of our knowledge, this is the first time that user interests are used for profiling, and more generally, semantics-driven inference of private data is addressed. This work has been published in the prestigious Network & Distributed System Security Symposium (NDSS) 2012 [37].

- **Privacy Enhancing Technologies**

The increasing amount of personal and sensitive information disseminated over the Internet prompts commensurately growing privacy concerns. Digital data often lingers indefinitely and users lose its control. This motivates the desire to restrict content availability to an expiration time set by the data owner. This work presents and formalizes the notion of Ephemeral Publishing (EphPub), to prevent the access to expired content. We propose an efficient and robust protocol that builds on the Domain Name System (DNS) and its caching mechanism. With EphPub, sensitive content is published encrypted and the key material is distributed, in a steganographic manner, to randomly selected and independent resolvers. The availability of content is then limited by the evanescence of DNS cache entries. The EphPub protocol is transparent to existing applications, and does not rely on trusted hardware, centralized servers, or user proactive actions. We analyze its robustness and show that it incurs a negligible overhead on the DNS infrastructure. We also perform a large-scale study of the caching behavior of 900K open DNS resolvers. Finally, we propose an Android application, Firefox and Thunderbird extensions that provide ephemeral publishing capabilities, as well as a command-line tool to create ephemeral files. This work has been published in ICNP 2011 [36].

- **Differentially private smart metering**
Several countries throughout the world are planning to deploy smart meters in households in the very near future. The main motivation, for governments and electricity suppliers, is to be able to match consumption with generation. Traditional electrical meters only measure total consumption on a given period of time (i.e., one month or one year). As such, they do not provide accurate information of when the energy was consumed. Smart meters, instead, monitor and report consumption in intervals of few minutes. They allow the utility provider to monitor, almost in realtime, consumption and possibly adjust generation and prices according to the demand. Although smart metering might help improving energy management, it creates many new privacy problems. Smart meters provide very accurate consumption data to electricity providers. As the interval of data collected by smart meters decreases, the ability to disaggregate low-resolution data increases.

We developed a new privacy-preserving smart metering system. Our scheme is private under the differential privacy model and therefore provides strong and provable guarantees. With our scheme, an (electricity) supplier can periodically collect data from smart meters and derive aggregated statistics while learning only limited information about the activities of individual households. For example, a supplier cannot tell from a user’s trace when he watched TV or turned on heating. Our scheme is simple, efficient and practical. Processing cost is very limited: smart meters only have to add noise to their data and encrypt the results with an efficient stream cipher.

This work was presented at IH’11 (the Information Hiding Conference, 2011) [34].

- **Protecting against Physical Resource Monitoring**

  This work considers the problem of resource monitoring. We consider the scenario where an adversary is physically monitoring on the resource access, such as the electricity line or gas pipeline, of a user in order to learn private information about his victim. Recent works, in the context of smart metering, have shown that a motivated adversary can basically profile a user or a family solely from his electricity traces. However, these works only consider the case of a semi-honest-but-non-intrusive adversary that is only trying to learn information from the consumption reports sent by the user. This work, instead, considers the much more challenging case of a intrusive semi-honest adversary, i.e. a semi-honest adversary that is in addition physically monitoring the resource by modifying the distribution network. We aim at answering to the following question: is it possible to design a resource distribution scheme that prevents resource monitoring and provides strong protection? We propose and analyze several possible solutions. The proposed solutions provide different privacy bounds and performance results. This work was presented at WPES’11 (ACM Workshop on Privacy in the Electronic Society) [35].

- **The Failure of Noise-Based Non-Continuous Audio Captchas**

  CAPTCHAs, which are automated tests intended to distinguish humans from programs, are used on many web sites to prevent bot-based account creation and spam. To avoid imposing undue user friction, CAPTCHAs must be easy for humans and difficult for machines. However, the scientific basis for successful CAPTCHA design is still emerging. This project examines the widely used class of audio CAPTCHAs based on distorting non-continuous speech with certain classes of noise and demonstrates that virtually all current schemes, including ones from Microsoft, Yahoo, and eBay, are easily broken. More generally, we describe a set of fundamental techniques, packaged together in our Decaptcha system, that effectively defeat a wide class of audio CAPTCHAs based on non-continuous speech. Decaptcha’s performance on actual observed and synthetic CAPTCHAs indicates that such speech CAPTCHAs are inherently weak and, because of the importance of audio for various classes of users, alternative audio CAPTCHAs must be developed.

  This work was presented at IEEE Security and Privacy 2011 [33].
- **BlueBear: Privacy in P2P systems**

  We have started a new project called bluebear on privacy threats in the Internet. Indeed, the Internet has never been designed with privacy in mind. For instance, the Internet is based on the IP protocol that exposes the IP address of a user to any other users it is communicating with. However, we believe that current users of the Internet do not realize how much they compromise their privacy by using the Internet. Indeed, the common wisdom is that there are so many users in the Internet that it is not feasible for an attacker, apart may be for national agencies, to globally compromise the privacy of a large fraction of users. Therefore, finding a specific user is like looking for a needle in a haystack. The goal of the bluebear project is to raise attention on privacy issues when using the Internet. In particular, we want to show that without any dedicated infrastructure, it is possible to globally compromise the privacy of Internet users. BitTorrent is arguably the most efficient peer-to-peer protocol for content replication. However, BitTorrent has not been designed with privacy in mind and its popularity could threaten the privacy of millions of users.

  In a first study we showed that it is possible to continuously monitor from a single machine most BitTorrent users and to identify the content providers (also called initial seeds). We performed a very large monitoring operation continuously “spying” on most BitTorrent users of the Internet from a single machine and for a long period of time. During a period of 103 days, we collected 148 million IP addresses downloading 2 billion copies of contents. We then identified the IP address of the content providers for 70% of the BitTorrent contents we spied on. We showed that a few content providers inject most contents into BitTorrent and that those content providers are located in foreign data centres. We also showed that an adversary could compromise the privacy of any peer in BitTorrent and identify the big downloaders that we define as the peers who subscribe to a large number of contents. This is a major privacy threat as it is possible for anybody in the Internet to reconstruct all the download and upload history of most BitTorrent users. This work was published in LEET 2010.

  To circumvent this kind of monitoring, BitTorrent users are increasingly using anonymizing networks such as TOR to hide their IP address from the tracker and, possibly, from other peers. We explored in a second study whose goal was to Exploit P2P Applications to Trace and Profile Tor Users, to which extent a P2P protocol such as BitTorrent, when not designed to protect users information, leak information that may compromise the identity of users. We quantified such an issue with BitTorrent on top of anonymizing networks. We also designed an attack that reveals the identity of Tor users (We showed that it is possible to retrieve the IP address for more than 70% of BitTorrent users on top of TOR). Moreover, once the IP address of a peer is retrieved, it is possible to link to the IP address other applications used by this peer on top of TOR [45].

  The fact that it is hard for a person to map an IP address to an identity mitigates the impact of the privacy attacks we described. However, we show that we can exploit a peer-to-peer VoIP system to associate a social identity (name, email address, etc.) to an IP address [46]. This means that anybody can now find this mapping that was only known by ISPs or big companies (like Google and Facebook), but never communicated unless in case of a legal action. The privacy threat is thus very high because this mapping enables blackmail, social attacks, targeted phishing attacks, etc.

  As a proof of concept, we show that it is possible to track VoIP users mobility and BitTorrent downloads [46] using Skype, one of the most popular VoIP system with more that 500 millions registered users.

  All these works received a very large media coverage (see http://www-sop.inria.fr/members/Arnaud.Legout/Projects/bluebear.html).
6.3. Network measurement, modeling and understanding

The main objective of our work in this domain is a better monitoring of the Internet and a better control of its resources. We work on new measurement techniques that scale with the fast increase in Internet traffic and growth of its size. We propose solutions for a fast and accurate identification of Internet traffic based on packet size statistics and host profiles. Within the ECODE FP7 project, we work on a network-wide monitoring architecture that, given a measurement task to perform, tune the monitors inside the network optimally so as to maximize the accuracy of the measurement results while limiting the overhead resulting from collected traffic. Within the ANR CMON project, we work on monitoring the quality of the Internet access by end-to-end probes, and on the detection and troubleshooting of network problems by collaboration among end users.

Next, is a sketch of our main contributions in this area.

- **Internet traffic classification by means of packet level statistics**
  One of the most important challenges for network administrators is the identification of applications behind the Internet traffic. This identification serves for many purposes as in network security, traffic engineering and monitoring. The classical methods based on standard port numbers or deep packet inspection are unfortunately becoming less and less efficient because of encryption and the utilization of non standard ports. In this activity, we come up with an online iterative probabilistic method that identifies applications quickly and accurately by only using the size of packets. Our method associates a configurable confidence level to the port number carried in the transport header and is able to consider a variable number of packets at the beginning of a flow. By verification on real traces we observe that even in the case of no confidence in the port number, a very high accuracy can be obtained for well known applications after few packets were examined. In another work [39], we make a complete study about the inter-packet time to prove that it is also a valuable information for the classification of Internet traffic. We discuss how to isolate the noise due to the network conditions and extract the time generated by the application. We present a model to preprocess the inter-packet time and use the result as input to the learning process. We discuss an iterative approach for the online identification of the applications and we evaluate our method on two different real traces. The results show that the inter-packet time is an important parameter to classify Internet traffic.

  We pursued this activity further by accounting for the communication profiles of hosts for the purpose of a better traffic classification [39], [38], [40]. We use the packet size and the inter-packet time as the main features for the classification and we benefit from the traffic profile of the host (i.e., which application and how much) to refine the classification and decide in favor of this or that application. The host profile is then updated online based on the result of the classification of previous flows originated by or addressed to the same host. We evaluate our method on real traces using several applications. The results show that leveraging the traffic pattern of the host ameliorates the performance of statistical methods. They also prove the capacity of our solution to derive profiles for the traffic of Internet hosts and to identify the services they provide.

  For a more thorough study of the traffic classification problem by means of packet statistics and host profiles, we refer to the PhD dissertation of Mohamad Jaber who was the main contributor to this activity inside the EPI Planete.

- **Adaptive network-wide traffic monitoring**

  The remarkable growth of the Internet infrastructure and the increasing heterogeneity of applications and users’ behavior make more complex the manageability and monitoring of ISP networks and raises the cost of any new deployment. The main consequence of this trend is an inherent disagreement between existing monitoring solutions and the increasing needs of management applications.
In this context, we work on the design of an adaptive centralized architecture that provides visibility over the entire network through a network-wide cognitive monitoring system. Given a measurement task, the proposed system drives its own configuration, typically the packet and flow sampling rates in routers, in order to address the tradeoff between monitoring constraints (processing and memory cost, collected data) and measurement task requirements (accuracy, flexibility, scalability). We motivate our architecture with an accounting application: estimating the number of packets per flow, where the flow can be defined in different ways to satisfy different objectives (e.g., Domain-to-Domain traffic, all traffic originated from a domain, destined to a domain). The architecture and the algorithms behind it are explained in paper published in 2010 for the case of a proactive control and in [44] for the case of a reactive control. In [44] the architecture and its algorithms are specified to a flow counting application. In all these works, the performances of our architecture are being validated in typical scenarios over an experimental platform we developed for the purpose of the study. Our platform is called MonLab (Monitoring Lab) and is described with more details in the Section on produced softwares. For now, MonLab presents a new approach for the emulation of Internet traffic and for its monitoring across the different routers. It puts at the disposal of users a real traffic emulation service coupled to a set of libraries and tools capable of Cisco NetFlow data export and collection, the overall destined to run advanced applications for network-wide traffic monitoring and optimization.

The activities in this direction are funded by the ECODE FP7 STREP project (Sep. 2008 - Dec. 2011). The dissertation of Imed Lassoued [21] provides an introduction to the field in addition to details on our contributions and the MonLab emulation platform.

• **Spectral analysis of packet sampled traffic**

In network measurement systems, packet sampling techniques are usually adopted to reduce the overall amount of data to collect and process. Being based on a subset of packets, they hence introduce estimation errors that have to be properly counteracted by a fine tuning of the sampling strategy and sophisticated inversion methods. This problem has been deeply investigated in the literature with particular attention to the statistical properties of packet sampling and the recovery of the original network measurements. Herein, we propose a novel approach to predict the energy of the sampling error on the real time traffic volume estimation, based on a spectral analysis in the frequency domain. We start by demonstrating that errors due to packet sampling can be modeled as an aliasing effect in the frequency domain. Then, we exploit this theoretical finding to derive closed-form expressions for the Signal-to-Noise Ratio (SNR), able to predict the distortion of traffic volume estimates over time. The accuracy of the proposed SNR metric is validated by means of real packet traces. The analysis and the expressions of the SNR that stemmed from are described in [26]. In [52], we adopt such a model to design a real-time algorithm, that sets the IPFIX counter export timers in order to grant, to each flow, a target estimation accuracy. The work within this direction has been partially supported by the FP7 ECODE project.

• **Monitoring the quality of the Internet access by end-to-end probes**

The detection of anomalous links and traffic is important to manage the state of the network. Existing techniques focus on detecting the anomalies but little attention has been devoted to quantify to which extent network anomaly affects the end user access link experience. We refer to this aspect as the *local seriousness* of the anomaly. In order to quantify the local seriousness of an anomaly, we consider the percentage of affected destinations, that we call the *impact factor*. In order to measure it, a host should monitor all possible routes to detect any variation in performance, but this is not practical in reality. In this activity, funded by the ANR CMON project, we work on finding estimates for the impact factor and the local seriousness of network anomalies through a limited set of measurements to random nodes we call landmarks.
We initially study the user access network to understand the typical features of its connectivity tree. Then, we define an unbiased estimator for the local seriousness of the anomaly and a framework to achieve three main results: (i) the computation of the minimum number of paths to monitor, so that the estimator can achieve a given significance level, (ii) the localization of the anomaly in terms of hop distance from the local user, and (iii) the optimal selection of landmarks. We are using real data to evaluate in practice the local seriousness of the anomaly and to determine the sufficient number of landmarks to select randomly without knowing anything on the Internet topology. The localization mechanism leverages the study on the connectivity tree and the relationship between the impact factor and the minimum hop distance of an anomaly. Our first results show that the impact factor is indeed a meaningful metric to evaluate the quality of Internet access. The current work focuses on extending this solution towards a collaborative setting where different end users collaborate together by exchanging the results of their observations. The objective will be a better estimation of the impact factor by each of them and a finer localization of the origin of any network problem.

On the experimental side, we have implemented the solution in a tool called ACQUA, which stands for Application for Collaborative Estimation of QUality of Internet Access. We design an anomaly detection mechanism based on the histogram of delay measurements and the likelihood of observations. Then, we give to ACQUA a pipeline based software architecture, and we go deeply into experimentation inside and outside Planetlab. We show what the properties and usage of the algorithm are, focusing also on how this tool can help us to get information about the network anomalies detected. Later we extend the idea of Impact Factor Estimation (IFE) by using what we call Inverse IFE from Planetlab, where the computer of the user whose connectivity is tested has a completely passive role in the measurements procedure. We study its strong and weak points, and we show conditions under which Inverse IFE from Planetlab gives similar results to traditional IFE.

- **Applied Internet Measurements**

  The performance of several Internet applications often relies on the measurability of path similarity between different participants. In particular, the performance of content distribution networks mainly relies on the awareness of content sources topology information. It is commonly admitted nowadays that, in order to ensure either path redundancy or efficient content replication, topological similarities between sources is evaluated by exchanging raw traceroute data, and by a hop by hop comparison of the IP topology observed from the sources to the several hundred or thousands of destinations. In this project, based on real data we collected, we advocate that path similarity comparisons between different Internet entities can be much simplified using lossy coding techniques, such as Bloom filters, to exchange compressed topology information. The technique we introduce to evaluate path similarity enforces both scalability and data confidentiality while maintaining a high level of accuracy. In addition, we demonstrate that our technique is scalable as it requires a small amount of active probing and is not targets dependent. This work has been published in [25].

- **Reliability of Geolocation Databases**

  In this project, we question the reliability of geolocation databases, the most widely used technique for IP geolocation. It consists in building a database to keep the mapping between IP blocks and a geographic location. Several databases are available and are frequently used by many services and web sites in the Internet. Contrary to widespread belief, geolocation databases are far from being as reliable as they claim. We conduct a comparison of several current geolocation databases -both commercial and free- to have an insight of the limitations in their usability. First, the vast majority of entries in the databases refer only to a few popular countries (e.g., U.S.). This creates an imbalance.

\[ \text{http://planete.inria.fr/acqua/} \]
in the representation of countries across the IP blocks of the databases. Second, these entries do not reflect the original allocation of IP blocks, nor BGP announcements. In addition, we quantify the accuracy of geolocation databases on a large European ISP based on ground truth information. This is the first study using a ground truth showing that the overly fine granularity of database entries makes their accuracy worse, not better. Geolocation databases can claim country-level accuracy, but certainly not city-level. This study has been published in CCR [28].

- Impact of Live Streaming Traffic

Video streaming is the most popular traffic in the Internet and a strong case for content centric networks. Therefore, it is fundamental to understand the network traffic characteristics of video streaming. In this work [49], we extensively studied the network traffic characteristics of YouTube and Netflix (the most popular video streaming traffic in the USA). We have shown that the traffic characteristics vastly depends on the type of browser, mobile application, and container (Flash, Silverlight, HTML5) used.

6.4. Experimental Environment for Future Internet Architecture

Participants: Walid Dabbous, Thierry Parmentelat, Baris Metin, Frédéric Urbani, Daniel Camara, Alina Quereilhac, Shafqat Ur-Rehman, Thierry Turletti, Julien Tribino.

- SFA Federation of experimental testbeds

The OneLab2 project has come to its end in spring 2010. We are now involved in the NOVI (E.U. STREP) project, the F-Lab (French A.N.R.) project, and have the lead of the “Federation” WorkPackage of OpenLab (E.U. IP) project. Within these frameworks, we are codevelopping with Princeton University a reference implementation for the Testbed-Federation architecture known as SFA for Slice-based Federation Architecture. As a sequel of former activities we also keep a low-noise maintenance activity of the PlanetLab software, which has been running in particular on the PlanetLab global testbed since 2004, with an ad-hoc federated model in place between PlanetLab Central (hosted by Princeton University) and PlanetLab Europe (hosted at INRIA) since 2007.

During 2011 we have focused on the maturation of the SFA codebase, with several objectives in mind. Firstly we have contributed to a major overhaul of the specification as defined essentially within the GENI (N.S.F.) Project, with participations from all over the world. These changes, that affected both the core API and the schema used to expose and manage resource specifications, aimed at reaching a mature level of interoperability between the PlanetLab world and the EmuLab a.k.a. ProtoGeni world that has its own implementation, and are now available in SFA-2.0 issued late 2011.

Secondly, the SFA codebase has been redesigned to provide a more generic shelter that other testbeds can easily leverage in order to come up with their own SFA-compliant wrapper. This is perceived as a powerful means to foster further adoption of the architecture, and the Planète team has been intrumental in bringing two entirely different testbeds to the federation, namely Senslab - developped in other INRIA Project-teams - and FEDERICA, the outcome of another E.U.-funded Project. Along the same lines we are working, although more remotely, with NICTA in Australia that publishes the O.M.F. testbed for running wireless testbeds, and who are interested in adopting this federation paradigm.

Finally, as part of the pure PlanetLab development, we have added a feature for running nodes in a 'reservable' mode, which breaks the usual best-effort PlanetLab model, but turned out very helpful both for making experiments possible, that needed a more reproducible behaviour of experiments, and also in a federation perspective, for closing the usage gap with, notably wireless testbeds, that typically have a reservable-only provisioning mechanisms.
• **Content Centric Networks Simulation**

We worked this year on the extension of the DCE framework for ns-3 in order to run CCN implementation under the ns-3 simulator. DCE stands for Direct Code Execution, its goal is to execute unmodified C/C++ binaries under ns-3 network simulator. With this tool researchers and developers can use the same code to do simulation and real experiments. DCE operation principle is to catch the standard systems calls done by the real application in the experiment and to emulate them within the ns-3 virtual network topology. Concerning CCN we use the PARC implementation named CCNx which is a well working open source software reference implementation of Content Centric Network protocol. As promised by DCE this integration of CCNx requires no modification of its code, it requires ‘only’ working on adding the system calls used by CCN that are not already supported by DCE. The advantage of this approach is that the integration work of CCN advanced DCE and will be useful in others completely different experiments. Another great advantage is that every evolution of the CCNx implementation is very easy to integrate, all what is needed is to compile the new source code. The next steps will be naturally to use DCE/ns-3 to evaluation CCN protocols in specific scenarii, to improve the coverage of systems calls supported by DCE, and to improve the DCE scheduler to be more realistic and to take into account CPU time spent in router queues. This work is done in the context of the ANR CONNECT project.

• **ns-3 Module store**

Bake is an integration tool which is used by software developers to automate the reproducible build of a number of projects which depend on each other and which might be developed, and hosted by unrelated parties. This software is being developed with the participation of the Planète group and is intended to be the automatic building tool adopted by the ns-3 project.

The client version of Bake is already working and the Planète group had a significant participation in its development. The contributions were in the context the addition of new functionalities, bug fixing and in the development of the regression tests. We are now starting the development of the ns-3 modules repository, which is a web portal to store the meta-information of the available modules.

In the present state we have already designed and implemented the portal data basis and the main interface. It is already possible to register new modules and browse among the already registered ones.

The web portal has to be finished, notably the part that will create the xml file that will be used to feed the bake’s client. We also need to add new functionalities to the client part, to enable incremental build over partially deployed environments. As it is today, bake does not enable the user to add just one new module to an already deployed version of the ns-3 simulator. This work is done in the context of the ADT MobSim in collaboration with Hipercom and Swing Inria project-teams.

• **The ns-3 consortium**

We have founded last year a consortium between INRIA and University of Washington. The goals of this consortium are to (1) provide a point of contact between industrial members and the ns-3 project, to enable them to provide suggestions and feedback about technical aspects, (2) guarantee maintenance of ns-3’s core, organize public events in relation to ns-3, such as users’ day and workshops and (3) provide a public face that is not directly a part of INRIA or NSF by managing the [http://www.nsnam.org](http://www.nsnam.org) web site. This web site is now finalized. However, activities related to developing the consortium have slowed down during 2011 due to the leave of Mathieu Lacage. We plan to put more resources on this aspect in 2012.
Using Independent Simulators, Emulators, and Testbeds for Easy Experimentation

Evaluating new network protocols, applications, and architectures uses many kinds of experimentation environments: simulators, emulators, testbeds, and sometimes, combinations of these. As the functionality and complexity of these tools increases, mastering and efficiently using each of them is becoming increasingly difficult.

We designed the preliminary prototype of the Network Experiment Programming Interface (NEPI) whose goal is to make easier the use of different experimentation environments, and switch among them easily. NEPI intends to make it possible to write a single script to control every aspect of a potentially mixed experiment, including a hierarchical network topology description, application-level setup, deployment, monitoring, trace setup, and trace collection. We showed how a single object model which encompasses every aspect of a typical experimentation workflow can be used to completely describe experiments to be run within very different experimentation environments. The development of NEPI started in 2009 with the implementation of the core API, an address allocator, a routing table configurator, but also a prototype ns-3 backend driven by a simple graphical user interface based on QT. Last year, we validated and evolved the core API with the addition of a new backend based on linux network namespace containers and stabilized the existing ns-3 backend. This year we have enhanced the design of NEPI and provided experiment validation, distributed experiment control, and failure recovery functionalities. In particular, we enforced separation between experiment design and execution stages, with off-line experiment validation. We also introduced a hierarchical distributed monitoring scheme to control experiment execution. We implemented a stateless message-based communication scheme, and added failure recovery mechanisms to improve robustness. The NEPI approach has been validated by implementing support for three complementary environments: a physical testbed, a network emulator, and a network simulator. Furthermore, we showed with a concrete experiment use case, available online for reproduction, how easy it is with NEPI to integrate these environments for hybrid-experimentation [48].

Guidelines for the accurate design of empirical studies in wireless networks

Traditionally, wireless protocol proposals have been often tested and validated using only analytical and simulation models [73]. However, as the wireless environment is very complex to model accurately, and since the cost of wireless cards has decreased in an exponential way, today more and more research papers include evaluation of new proposals using experimentation on real devices. Indeed, experimentation is a mandatory step before possible deployment of new network protocols with real users. However, wireless experimentation is much more complex to set up and run than simulation, and it is important to avoid many pitfalls that can occur during experimentation. The objectives of this work are twofold. First, we described typical problems currently encountered in wireless-based experimentation, and we present simple guidelines to avoid them [50]. Second, we proposed an experimental methodology where the detection of anomalies, calibration of the measurement setup, and clear definition of the scenario (among others) make easier the repeatability of results [55]. This work has been done in collaboration with Cristian Tala, Luciano Ahumada and Diego Dujovne from the Universidad Diego Portales of Chili, in the context of the WELCOME STIC AMSud 2011.

Multicast Video Streaming over WiFi Networks: Impact of Multipath Fading and Interference
We conducted an experimental study in order to analyse the impact of interference, multipath fading and path loss on multicast video streaming (i.e., goodput, packet loss and ultimately on the video quality) using off-the-shelf fixed WiFi equipment in a wireless (802.11 b/g) local area network (WLAN) environment. We used the ricean K-factor as a measure of multipath fading, spectrum analyzer to estimate channel interference and received signal strength indicator (RSSI) as indication of signal power and attenuation. In order to realistically measure aforementioned metrics, we conducted extensive wireless experiments against six test cases representing common real-world situations using off-the-shelf wireless equipment.

We showed that interference has more impact on performance than multipath fading. Multipath fading can result in considerable performance degradation in environments where moving objects cause perturbance. On the contrary, channel interference is more frequent and more prominent cause of performance degradation in wireless networks because ISM 2.4 GHz band is increasingly being utilized in homes and work places. Being able to quantify the impact of multipath fading and interference is crucial in planning, troubleshooting, managing as well as benchmarking and optimizing wireless networks. This study has been published in MediaWin 2011 [51].

**Making easier Experimentation**

Wireless experimentations are challenging to evaluate due to the high variability of the channel characteristics and its sensitivity to interferences.

Merging traces represents a complex problem especially in wireless experimentations, due to packet redundancy in multiple probes. Merging traces solutions need to be efficient in order to process the large amount of generated traces. These solutions should provide an output data structure that allows easy and fast analysis and must be scalable in order to be used in large and various experimental settings. We have designed an algorithm that performs trace synchronization and merging in a scalable way. The algorithm output is stored in a configured MYSQL database allowing for smart packet trace storage. This solution reduces processing time by 400% and storage space by 200% with regard to raw trace file solutions. It has been implemented in an open source software called CrunchXML, available under the GNU General Public License v2 at [http://twiki-sop.inria.fr/twiki/bin/view/Projets/Planete/CrunchXML](http://twiki-sop.inria.fr/twiki/bin/view/Projets/Planete/CrunchXML).

**An Integration Framework for Network Experimentation**

Many different experimentation environments address complementary aspects of network protocol evaluation, but because of their disparities and complexities it is often hard to use them to reproduce the same experiment scenario.

Simulation is often used for the evaluation of new network protocols and architectures. In order to perform more realistic simulations, modern simulators such as ns-3 integrate more detailed models and even support direct execution of real protocol code. However, such complex models require more computational and memory requirements. We have studied the feasibility of a hybrid approach based on distributing a complex simulation scenario on several nodes in a grid network. We showed that by exploiting the real time operation of the ns-3 simulator, it is possible to map such complex scenarios on grid nodes. We also proposed a basic mapping algorithm to distribute a simulation scenario in several nodes [42].
6. New Results

6.1. Numerical methods for time domain wave propagation

6.1.1. High Order Theta Scheme for the linear wave equation.

Participants: Juliette Chabassier, Sébastien Impériale.

We have pursued our work about a new class of high order implicit three time step schemes for semi-discretized wave equations of the form

\[
\frac{d^2}{dt^2} u_h + K_h u_h = 0, \quad u_h(0) = u_{0,h}, \quad \frac{du_h}{dt}(0) = u_{1,h},
\]

where \( K_h \) is a symmetric positive definite matrix. For such problems, explicit three time step schemes generally show good performances but present two major drawbacks, in some situations, that have not yet been completely overcome:

- If the mesh presents elements of quite different sizes, the time step must be adapted to the smallest one because of the CFL condition.
- If the mass matrix is non diagonal or non block-diagonal, its inversion (at least one time per iteration) can lead to a dramatic cost of the schemes, which is obviously not the case with implicit schemes for which a matrix has to be inverted in any case.

A natural way to avoid this restriction is to use local time stepping techniques which divides into two categories. First, the locally implicit technique, which is optimal in term of CFL restriction but "only" second order accurate in time, and requires the inversion of interface matrices. Second, the fully explicit local time stepping, as developed that enables to achieve high order time stepping but without (up to now) a full control over the CFL condition.

This is why we construct generalized implicit \( \theta \)-scheme using the modified equation approach to obtain 4th order approximation. These schemes introduce 2 degree of freedom \( \theta \) and \( \varphi \) and can be written under a general form as

\[
\frac{u_h^{n+1} - 2u_h^n + u_h^{n-1}}{\Delta t^2} + K_h \left( \theta u_h^{n+1} + (1 - 2 \theta) u_h^n + \theta u_h^{n-1} \right) + \left( 1 - \frac{\theta}{12} \right) K_h^2 \left( \varphi u_h^{n+1} + (1 - 2 \varphi) u_h^n + \varphi u_h^{n-1} \right) = 0.
\]

The parameters \( \theta \) and \( \varphi \) are chosen as functions of the time step through the resolution of an optimization problem: we consider that the time step is given and we try to obtain a scheme that minimizes the consistency errors still being stable. The limit problem when the time step tends is infinite gives an optimal unconditionally stable fourth order scheme. This work has been submitted for publication.

6.1.2. Discontinuous Galerkin Methods for wave equations

Participants: Patrick Joly, Antoine Tonnoir.
This has been the subject of the internship of A. Tonnoir and can be seen as a contribution to the mathematical analysis of coupled BEM / DG methods for time domain diffraction problems (see section 6.1.4). We did not pretend to make a real contribution to the field of the analysis of DG methods, but wanted to understand in sufficient detail the quite surprising observation that the non-centered (in space) schemes, provided by the use of non centered fluxes in the DG approach, leads to a better accuracy than the centered schemes issued for central fluxes! This has been done (for the simple 1D wave equation) from two points of view: the direct energy method and the Fourier analysis (or dispersion analysis) on regular grids.

### 6.1.3. Analysis of time domain boundary integral equations

**Participants:** Patrick Joly, Nicolas Le Guillarme.

This has been developed again as a part of the mathematical analysis of coupled BEM / DG methods for time domain diffraction problems (see section 6.1.4). With J. Rodríguez, we have revisited the analysis of the coercivity / continuity properties of space-time boundary integral associated to wave diffraction problem. Unlike the more traditional approach based on Laplace transform in time (cf the initial work by Bamberger-Ha Duong) we treat this question directly in the time domain by exploiting in a simple way the connection between integral equations and boundary value problems. This can be done in a very general setting but also particularized to the 1D case for which we got sharp estimates (internship of N. Le Guillarme). Furthermore, we can reinterpret the classical discretization by finite elements for retarded potentials as non conforming finite element methods. This allows to investigate in a new way the error analysis of time domain boundary element methods, which will be the subject of a future work.

### 6.1.4. Coupling Retarded Potentials and Discontinuous Galerkin Methods for time dependent wave propagation problems

**Participant:** Patrick Joly.

This topic is developed in collaboration with J. Rodriguez (Santiago de Compostela) in the framework of the contract ADNUMO with AIRBUS. Let us recall that our objective was to use time-domain integral equations (developed in particular at IMACS and EADS) as a tool for constructing transparent boundary conditions for wave problems in unbounded media. Our previous contribution of this topic concern the construction of an energy preserving method for the coupling space-time Galerkin approximation of the integral equations with discontinuous Galerkin finite elements and leap-frog time discretization for the numerical approximation of the equations inside the computational domain. For stability reasons, we had to use central fluxes. The drawback of central fluxes is that they do not lead to an optimal accuracy (see also the paragraph on the analysis of DG methods) which is traduced in practice by high frequency spurious oscillations.

Our objective this year was to look for another discretization approach that would overcome these problems. The approach we propose consists in playing on the time discretization procedure. For this we decompose the stiffness bilinear form as the sum of a conservative term corresponding to the use of central fluxes and a ("small") dissipative term due to off-centering and involving jumps across interfaces of the discrete solution. We propose a scheme which treats the conservative part of the equation in a centered way (leap-frog type) and the dissipative term in a non centered way (backward Euler type). Doing so, the overall accuracy in time of the scheme is preserved (with respect to the case of central fluxes) and the stability is maintained at the price of a (slightly) more constraining CFL conditions, which does not seem that much penalizing for the application. The stability is analyzed through the decay of an discrete energy. As a consequence, we can adapt the discretization of the coupling terms between integral and interior equations in order to preserve the stability of the fully coupled scheme under the same CFL condition. Numerical validations are in progress.

### 6.1.5. Solving the Homogeneous Isotropic Linear Elastodynamics Equations Using Potentials and Finite Elements.

**Participants:** Eliane Bécache, Aliénor Burel, Sébastien Impériale, Patrick Joly.
This topic is the subject of the first part of the PhD thesis of A. Burel and has been developed for a part in collaboration with Marc Duruflé. Decomposing the displacement field into potentials is a well-known tool in elastodynamics, and it expresses the decoupling of the pressure wave and the shear wave inside a homogeneous isotropic media. Although this tool is classically used when searching for analytic solutions, it does not seem to have been exploited for numerical computation using finite elements for instance. However, this is a priori attracting since, contrary to a displacement field approach for instance, it allows to decouple the approximation of P and S waves and to adapt the discretization process (mesh size, order of elements) to the dynamics of each type of wave, which is a priori particularly interesting when S-waves propagate much more slowly than P-waves (soft materials such as rubber). The main difficulty is to cope with the coupling of the different types of waves (the so-called conversion of modes) which occurs, due to wave reflections and transmissions, at interfaces between homogeneous media or at physical boundaries. The simplest situation where this phenomenon appears is the propagation of elastic waves in a homogeneous domain with clamped boundary. The main difficulty is to guarantee the stability of the treatment of the boundary condition. For this, we have proposed a variational formulation in which the stiffness bilinear form appears as a sum of a decoupled volumic bilinear form and a coupled surfacic bilinear form. This formulation is is compatible to an energy conservation result. After space discretization with finite elements spaces well adapted to each type of waves (using different meshes and/or polynomial degrees), we propose a discrete energy preserving numerical scheme, based on an explicit discretization of the volume terms and an implicit discretization of the surface terms. The resulting scheme is mainly explicit (only a sparse boundary linear system has to be solved at each time step) and stable under a CFL stability condition that is not affected by the presence of the boundary. An approach based on a modification of this scheme has been proposed for treating the free surface condition. This approach appears to give satisfactory results in the frequency domain (on the basis of numerical simulations) but fails in time domain due to (apparently unconditional) instabilities.

6.1.6. Mathematical and numerical modeling of piezoelectric sensors.

Participants: Sébastien Impériale, Patrick Joly.

This research, which constitutes the subject of the PhD thesis of S. Imperiale (which will be defended in January 2012) is developed in the framework of a collaboration with CEA-LIST about the numerical modeling of non-destructive testing experiments using ultrasonic waves. More precisely, we have concerned during the past three years by mathematical and numerical questions related to the simulation of non destructive testing experiments using piezoelectric devices. In particular, we have investigated the modeling of piezoelectric sensors that are used to generate and record ultrasonic waves in a solid material: such waves are typically used to investigate in a non invasive way the possible presence of defects in manufactured items. Such an issue has already been tackled in the engineering literature but not, to our knowledge, by way of rigorous applied mathematics. As we are arriving at the conclusion of this work, let us summarize our main contributions during these three years (these have been published in M2AN)

- The full equations of piezoelectricity couple Maxwell’s equations with linear elastodynamics equations which corresponds to a coupled hyperbolic system. This system presents quite different time scales due to the very large ratio between the speed of light and the sound speed, which makes it impossible to treat by a direct numerical approach. To overcome this problem, we have given a rigorous justification, via asymptotic analysis, of the so-called quasi-static approximation model in which the electric unknowns are reduced to a scalar electric potential: the reduced model appears as a coupled elliptic-hyperbolic system.

\[
\begin{align*}
\rho \partial_t u - \text{div} C \epsilon(u) - \text{div} e \nabla \varphi &= 0 \quad \text{in } \Omega_S \quad \text{(the solid domain)}, \\
\nabla \cdot \epsilon \nabla \varphi - \nabla \cdot e^T \epsilon(u) &= 0 \quad \text{in } \mathbb{R}^3.
\end{align*}
\]

- We have next justified the reduction of the computation of this electric potential to the piezoelectric parts of the computational domain, considering the large contrast of permittivity between piezoelectric materials and surrounding polymers. This relies again on a limit process: the ratio between permittivities is the small parameter.
- A particular attention has to be devoted to the modeling of the electric supply process: more precisely the nonlocal (in space) boundary conditions on the electrodes (used to model the emission and reception regimes), as well as the modeling of the coaxial cable connecting the sensor to the electric generator (see also section 6.4.1).

- Concerning the numerical approximation, an energy preserving finite element / finite differences numerical scheme is developed. A specific procedure is used for treating the nonlocal boundary conditions on the electrodes. Unbounded media have been treated via PML techniques that are dealt with using an original mortar element technique (see section 6.3.1 for more details). Various numerical results in academic or more realistic situations have been obtained. For instance, we have been able to model how one can exploit multi-component devices (see figure 1) to produce well focused waves (see figure 2).

- A computational code issued from our research, named Ondomatic (12 000 lines in C++), has been implemented. This code uses the finite element library FEMME (15 000 lines in C++) that essentially relies upon the use of spectral finite element on hexahedral meshes.

Figure 1.

Figure 2.
6.1.7. Maxwell’s equations in Lorentz materials

*Participants:* Patrick Ciarlet, Patrick Joly, Valentin Vinoles.

This is the time-domain counterpart of the research done at Poems about metamaterials (see also the section 6.2.7) and has been the subject of the internship of V. Vinoles. Lorentz materials are particular non dissipative dispersive materials which behave as metamaterials (with negative index of refraction) in some range of frequencies. Their constitutive laws (links between electric and magnetic fields and the related inductions) are described in terms of ordinary differential equations (harmonic oscillators). We have studied Maxwell’s equations in such materials and in particular proposed an energy preserving space-time discretization scheme based on an extension of classical methods (mixed finite elements in space, leap-frog type schemes in time). This has been implemented in a code including PMLs for the treatment of unbounded domains. Various numerical experiments have been performed. They illustrate the spectacular dispersive effects of Lorentz materials and allow us to recover the expected focalisation phenomena by an interface between a metamaterial and a standard dielectric one. This code will be an essential tool for the further investigation of more theoretical (and challenging) issues such as the limiting amplitude principle in this context.

6.1.8. Evolution problems in perturbed infinite periodic media

*Participants:* Julien Coatléven, Sonia Fliss.

First, as a part of the PhD of J. Coatléven, based on the former method to solve linear evolution problems in locally perturbed infinite periodic strips through the construction of transparent boundary conditions, a method has been developed to solve its natural geometric extension, i.e. the case of a locally perturbed line defect in an infinite periodic media. The method is again based on a semi-discretization in time of the problem on the whole infinite periodic media, and a generalization of the Lippmann-Schwinger equation approach we have developed for the treatment of this kind of geometries but for harmonic wave problems. At each time step, the solution is written as the sum of the solution of a time step in the unperturbed line defect and a contribution of the perturbation due not only to the current time step but also to all time steps involved in the numerical scheme. This intrication of time steps requires a careful treatment of the Lippmann-Schwinger equation, and in particular of the source term. Using the Floquet-Bloch transform, the computation of all the quantities involved can be reduced to the resolution of a few time steps of linear evolution problems in locally perturbed infinite periodic strips, where we can use the former method. As in the harmonic case, the discretization of the inverse Floquet-Bloch transform is done using appropriate quadrature rules, whereas the space discretization requires classical finite elements. The theoretical basis as well as the numerical analysis of this method are well understood, and the method has been successfully tested numerically. For instance, it can be shown, and checked numerically, that in the particular case of the wave equation, if one uses enough quadrature points (depending on the length of the time interval), then this quadrature creates no error of approximation.

For parabolic problems set in locally perturbed periodic media, we have developed another approach to determine the time-domain DtN operator. The principle is to apply the Laplace Transform in time to the equation and use the construction of the DtN operator for stationary equations. The main difficulty is the computation of the inverse of the Laplace Transform, more precisely to understand how to deal with the unbounded interval of integration and the choice of the discretization of the laplace variable. To deal with the first difficulty for waveguide problem, we have studied the asymptotic behavior of the DtN operator in the laplace domain when the laplace variable tends to \( p_0 \pm \infty \). To deal with the second difficulty, we have used the Z-Transformation and its properties. The numerical study is still in progress. This work enters in the framework of the ANR PRoject MicroWave (Sonia Fliss is an external collaborator), in collaboration with Karim Ramdani (Institut Elie Cartan de Nancy, UMR CNRS 7502), Christophe Besse and Ingrid Violet (Laboratoire Paul Painlevé, UMR CNRS 8524).

6.1.9. Modeling and numerical simulation of a piano.

*Participants:* Juliette Chabassier, Patrick Joly.
This work is developed in collaboration with Antoine Chaigne (UME, ENSTA). The purpose of this work the time domain modeling and numerical simulation of a piano. We aim at explaining the vibratory and acoustical behavior of the piano, by taking into account the main elements that contribute to sound production. The soundboard is modeled as a bidimensional thick, orthotropic, heterogeneous, frequency dependant damped plate, using Reissner Mindlin equations. The vibroacoustics equations allow the soundboard to radiate into the surrounding air, in which we wish to compute the complete acoustical field around the perfectly rigid rim. The soundboard is also coupled to the strings at the bridge, where they form a slight angle from horizontal. Each string is modeled by a one dimensional damped system of equations, taking into account not only the transversal waves excited by the hammer, but also the stiffness thanks to shear waves, as well as the longitudinal waves arising from geometric nonlinearities. The hammer is given an initial velocity that projects it towards a choir of strings, before being repelled. The interacting force is a nonlinear function of the hammer compression.

The final piano model that is discretized is a coupled system of partial differential equations, each of them exhibiting specific difficulties (nonlinear nature of the string system of equations, frequency dependant damping of the soundboard, great number of unknowns required for the acoustic propagation), in addition to couplings’ inherent difficulties. On the one hand, numerical stability of the discrete scheme can be compromised by nonlinear and coupling terms. A very efficient way to guarantee this stability is to construct a numerical scheme which ensures the conservation (or dissipation) of a discrete equivalent of the continuous energy, across time steps. A major contribution of this work has been to develop energy preserving schemes for a class of nonlinear systems of equations, in which enters the string model. On the other hand, numerical efficiency and computation time reduction require that the unknowns of each problem’s part, for which time discretization is specific, hence different, be updated separately. To achieve this artificial decoupling, adapted Schur complements are performed after Lagrange multipliers are introduced.

The potential of this time domain piano modeling is emphasized by realistic numerical simulations. Beyond greatly replicating the measurements, the program allows us to investigate the influence of physical phenomena (string stiffness or nonlinearity), geometry or materials on the general vibratory behavior of the piano, sound included. Spectral enrichment, << phantom partials >> and nonlinear precursors are clearly revealed when large playing amplitudes are involved, highlighting how this approach can help better understand how a piano works.

The main contributions of this year have been the following :

- to write the acoustic propagation as a first order system of equation, involving the physical sound pressure (as opposed to before, when its primitive had to be considered) and the acoustical velocity: this allowed us to artificially bound the computation domain with Perfectly Matched Layers.
- to decrease the numerical computation times via a massive parallelization of the code: parallel modal search for the soundboard, parallel dense matrix-vector product for the vibroacoustic equations in the modal basis, parallel resolution of the 3D acoustic propagation, multi-threaded computation of the strings’ problem.
- to perform realistic computations, which have provided physically relevant numerical simulations (see Figure 3).

Several measurements have also been conducted on a grand piano in order to provide realistic values of parameters and calibrated data to compare simulation with.

6.2. Time-harmonic diffraction problems

6.2.1. Numerical computation of variational integral equation methods

Participants: Marc Lenoir, Nicolas Salles.
The dramatic increase of the efficiency of the variational integral equation methods for the solution of scattering problems must not hide the difficulties remaining for an accurate numerical computation of some influence coefficients, especially when the panels are close and almost parallel.

The formulas have been extended to double layer potentials and, for self influence coefficients, to affine basis functions. Their efficiency for the solution of Maxwell equations has been proved in the framework of a collaboration with CERFACS. The redaction of a paper devoted to the case of parallel panels has been completed and submitted to SIAM J. Sci. Comp. Some preliminary work on the numerical integration of the regular part of the integrand has been undertaken in the context of an internship.

6.2.2. Fast Multipole Method for Viscoelastodynamics

Participants: Marc Bonnet, Stéphanie Chaillat.

This work is done in collaboration with Eva Grasso (LMS, Ecole Polytechnique) and Jean-François Semblat (IFSTTAR). We have extended the single- and multi-domain time-harmonic elastodynamic multi-level fast multipole BEM (Boundary Element Method) formulations to the case of weakly dissipative viscoelastic media [21]. The underlying boundary integral equation and fast multipole formulations are formally identical to that of elastodynamics, except that the wavenumbers are complex-valued due to attenuation. Attention was focused on evaluating the multipole decomposition of the visco-elasticodynamic fundamental solution, involving complex-valued wavenumbers. As a result, a damping-dependent modification of the selection rule for the multipole truncation parameter was proposed and assessed on 3D single-region and multi-region visco-elasticodynamic examples involving up to about $3 \times 10^5$ boundary nodal unknowns.

6.2.3. Formulation and Fast Evaluation of the Multipole Expansions of the Elastic Half-Space Fundamental Solutions

Participants: Marc Bonnet, Stéphanie Chaillat.
This ongoing work is concerned with a formulation and computation algorithm for the elastodynamic Green’s
tensor for the traction-free half-space allowing its use within a Fast Multipole Boundary Element Method
(FM-BEM). Due to the implicit satisfaction of the traction-free boundary condition achieved by the Green’s
tensor, discretization of (parts of) the free surface is no longer required. Unlike the full-space fundamental
solution, the elastodynamic half-space Green’s tensor cannot be expressed in terms of usual kernels such as
$e^{i k r}/r$ or $1/r$. Its multipole expansion thus cannot be deduced from known expansions, and is formulated
in this work using a spatial two-dimensional Fourier transform approach. The latter achieves the separation
of variables which is required by the FMM. A key numerical issue, upon which current work is focused, is
concerned with the definition of an efficient numerical quadrature for the evaluation of the inverse Fourier
transform, whose integrand is both singular and oscillatory, as classical Gaussian quadratures would perform
poorly, fail or require unacceptably large number of quadrature points.

6.2.4. Multiple scattering by small scatterers
Participants: Maxence Cassier, Christophe Hazard.

We consider the scattering of an acoustic time-harmonic wave by an arbitrary number of sound-soft obstacles
located in a homogeneous medium. When the size of the obstacles is small compared with the wavelength, the
numerical simulation of such a problem by classical methods (e.g., integral equation techniques or methods
based on a Dirichlet-to Neumann map) can become highly time-consuming, particularly when the number
of scatterers is large. In this case, the use of an asymptotic model may reduce considerably the numerical
cost. Such a model was introduced by Foldy and Lax in the middle of the last century to study multiple
isotropic scattering in a medium which contains randomly distributed small scatterers. Their asymptotic model
is based on the fact that the scattered wave can be approximated by a wave emitted by point sources placed
at the centers of the scatterers; the amplitudes of the sources are calculated by solving a linear system which
represents the interactions between the scatterers. Nowadays, the Foldy–Lax model is still used in numerous
physical and numerical applications to approximate the scattered wave in a deterministic media. But to the best
of our knowledge, there was no mathematical justification of this asymptotic model. We have proposed such
a justification which provides local error estimates for the two-dimensional problem in the case of circular
obstacles. An article on this subject has been recently submitted to Wave Motion.

6.2.5. Harmonic wave propagation in locally perturbed infinite periodic media
Participants: Julien Coatléven, Sonia Fliss, Patrick Joly.

A part of the PhD of J. Coatléven consists in developing a method for solving harmonic wave problems
with locally perturbed line defects in periodic media. For the treatment of these unbounded defects, which
are structured apart from a local perturbation, a new approach has been developed, based on a perturbation
principle. The solution is written as a the sum of a solution corresponding to the unperturbed line defect and a
contribution of the local perturbation. This decomposition leads to a generalization of the so-called Lippmann-
Schwinger equation, whose coefficients are computed through their Floquet-Bloch transform, which leads
to solve wave-guide problems, these last problems being solved using the transparent boundary condition
method developed during S. Fliss’s PhD. The discretization of the inverse Floquet-Bloch transform is done
using appropriate quadrature rules, whereas the space discretization requires classical finite elements. The
theoretical basis as well as the numerical analysis of this method are well understood, and the method has
been successfully tested numerically. In particular, the theoretical convergence estimates have been checked
in practice, and the method has a satisfying behavior in limit cases not fully covered by the theory, such as the
non-absorbing case.

Concerning the non absorbing case, the question of the limiting absorption principle has been treated for
locally perturbed periodic media with particular assumptions. In this case, we are studying the behavior of the
solution at large distance of the local perturbation.

6.2.6. Time harmonic aeroacoustics
Participants: Anne-Sophie Bonnet-Ben Dhia, Jean-François Mercier.
We are still working on the numerical simulation of the acoustic scattering and radiation in presence of a mean flow. This is the object of the ANR project AEROSON, in collaboration with Florence Millot and Sébastien Pernet at CERFACS, Nolwenn Balin at EADS and Vincent Pagneux at the Laboratoire d’Acoustique de l’Université du Maine. The main recent improvements concern: the consideration of ducts with treated boundaries and the development of an alternative model to Galbrun’s equation.

**Treated boundaries**

Our aim is to extend the time harmonic equation of Galbrun to take into account acoustically treated boundaries. Such boundaries are generally described by the Myers boundary condition. Since this condition is naturally expressed in terms of Galbrun’s unknown, the displacement $u$, Galbrun’s equation easily extends to treated boundaries. However we face a difficulty: the original equation of Galbrun leads to a non coercive problem. For rigid boundaries, considering an augmented variational formulation leads to well-posedness. But this approach does not work anymore for treated boundaries.

We have improved our understanding of this difficulty. We are now convinced that the Augmented Galbrun’s equation combined with Myers condition leads to an ill-posed problem. More precisely source terms for which the solution of Galbrun’s equation does not belong to standard functional spaces exist. Such source terms are very particular: located on the treated boundary and singular. This is why during the numerical validations performed at Cerfacs, for ”standard” source terms ($L^2$ functions compactly supported in the fluid) we did not get any problem.

To get a well-posed problem, Myers boundary condition, which just requires the normal displacement to belong to $L^2$, must be regularized. It can be achieved by requiring the tangential derivative of $u \cdot n$ to belong to $L^2$. We have also understood that less regularity is sufficient to get a well-posed problem, as it is the case if the fluid is in contact of an elastic medium (such interface cannot be described by a Myers condition since it is necessarily non-local). In particular in the case of a uniform flow well-posedness is proved for a sufficiently slow flow.

**Alternative to Galbrun’s model**

We have kept on considering the model of Goldstein’s equations, alternative to Galbrun’s equation. The Goldstein’s equations couples two unknowns: the velocity potential $\varphi$ and a vectorial unknown $\xi$. $\varphi$ satisfies a modified Helmholtz’s equation with variable coefficients linked to the flow, in which $\xi$ is added as a source term. $\xi$ satisfies a transport equation coupled to the velocity potential. This new model facilitate the treatment of 3D problems since Galbrun’s equation requires to introduce many unknowns. Moreover the vectorial unknown in Goldstein’s formulation vanishes in the areas where the flow is potential which is interesting since realistic flows are mainly potential, the non-potential areas being located near the boundaries or behind obstacles.

As it is the case to calculate the vorticity $\psi = \text{curl}u$, used to regularize Galbrun’s equation, a Discontinuous Galerkin (DG) discretization is used to determine $\xi$ and numerical simulations have been performed at Cerfacs. We have also developed an alternative method allowing to solve Goldstein’s equations with simple Lagrange Finite Element and this was the object of Jean-Emmanuel Lauzet’s internship. We have developed a method combining the Streamline Upwind Petrov Galerkin (SUPG) scheme to discretize the Goldstein’s model with the introduction of PML to bound the calculation domain. To test the efficiency of the method, a non-potential flow has been determined analytically. It consists of a lid-cavity flow connected to a uniform flow in a duct. The viscous cavity flow is solution of the Stoke’s equation and is determined in a rectangular domain by a modal method.

### 6.2.7. Modeling of meta-materials in electromagnetism

**Participants:** Anne-Sophie Bonnet-Ben Dhia, Patrick Ciarlet, Lucas Chesnel.

A collaboration with Eric Chung (Chinese Univ. of Hong Kong) and Xavier Claeys (ISAE).
Meta-materials can be seen as particular media whose dielectric and/or magnetic constant are negative, at least for a certain range of frequency. This type of behavior can be obtained, for instance, with particular periodic structures. Of special interest is the transmission of an electromagnetic wave between two media with opposite sign dielectric and/or magnetic constants. As a matter of fact, applied mathematicians have to address challenging issues, both from the theoretical and the discretization points of view.

The first topic we considered a few years ago was: when is the (simplified) scalar model well-posed in the classical $H^1$ framework? It turned out this issue could be solved with the help of the so-called $T$-coercivity framework. While numerically, we proved that the (simplified) scalar model could be solved efficiently by the most "naive" discretization, still using $T$-coercivity.

Recently, we have been able to provide sharp conditions for the $T$-coercivity to hold in general 2D and 3D geometries (with L. Chesnel), which involve explicit estimates in simplified geometries together with localization arguments. We then analyzed the discretization of the scalar problem with a classical, $H^1$ conforming, finite element method, and proved the convergence under the same sharp conditions (with L. Chesnel). We also showed that the problem can be solved with the help of a Discontinuous Galerkin discretization, which allows one to approximate both the field and its gradient (with E. Chung).

Last (with L. Chesnel and X. Claeys), we investigated the case of a 2D corner which can be ill-posed (in the classical $H^1$ framework). Using the Mellin transform, we showed that a radiation condition at the corner has to be imposed to restore well-posedness. Indeed there exists a wave which takes an infinite time to reach the corner: this "black hole" phenomenon is observed in other situations (elastic wedges for example).

As a second topic, we studied the transmission problem in a purely 3D electromagnetic setting from a theoretical point of view: to achieve well-posedness of this problem, we had to proceed in several steps, proving in particular that the space of electric fields is compactly embedded in $L^2$. For that, we had to assume that the interface is "sufficiently smooth", excluding in particular corners. With L. Chesnel, we have been able to remove this assumption, so that we can solve the problem around an interface with corners. It turns out the $T$-coercivity framework can be applied once more, under the same assumptions as for the scalar model. In the process, we recover more compact embedding results.

6.2.8. Numerical MicroLocal Analysis

Participants: Jean-David Benamou, Francis Collino, Simon Marmorat.

Numerical microlocal analysis of harmonic wavefields is based on a family of linear filters using Bessel functions and applied to wave data collected on a circle of fixed radius $r_0$ around the observation point $x_0$ where we want to estimate the Geometric Optics/High Frequency components. The data can easily be reconstructed from more conventional line array or grid geometry. The output is an angular function presenting picks of amplitudes in the direction angles of rays.

The original NMLA algorithm relied on a local plane wave assumption for the data. For arbitrary waves, it meant linearization errors and accuracy limitations. Also, only the directions of the (multiple) rays are recovered but the traveltime and amplitudes are not reliably computed. We recently introduced a new "impedant" observable which allows to prove a stability theorem. Numerical results confirm that the new NMLA filter is robust to random and correlated noise.

Using asymptotic expansion on NMLA filtered point sources data, we designed a correction method for the angle which also estimates the wavefront curvature. It can be used to correct the linearization errors mentioned above and provides a second order correction in the Taylor approximation of the traveltime.

The parameters of the method (size of observation circle, discretization) are automatically optimized and a posteriori quantitative error on angles and curvature are available. Numerical studies validate the stability result and confirm the superior accuracy of the curvature corrected NMLA version over image processing methods.
When some bandwidth is available we can also compute the traveltime. The amplitude remains polluted by phase errors. Its determination is still open.

6.3. Absorbing boundary conditions and absorbing layers

6.3.1. Perfectly matched transmission problem with absorbing layers: application to anisotropic acoustics

**Participant:** Sébastien Impériale.

This work has been carried out in collaboration with Edouard Demaldent from CEA-LIST. We have worked on an original approach to design perfectly matched layers (PML) for transient wave equations. This approach is based, first, on the introduction of a modified wave equation and, second, on the formulation of general "perfectly matched" transmission conditions for this equation. The stability of the transmission problem is discussed by way of the adaptation of a high frequency stability (necessary) condition, and we apply our approach to define PML suited for the anisotropic wave equation. A variational formulation of the problem is then developed. It includes a Lagrange multiplier at the interface between the physical and the absorbing domains to deal with the "perfectly matched" transmission conditions. We have carried out numerical results in 2D and 3D that first show the validity of our approach in term of stability and accuracy and the efficiency when using constant damping coefficients combined with high order elements. This work has been submitted for publication.

6.3.2. On the stability in PML corner domains

**Participant:** Eliane Bécache.

In collaboration with Andres Prieto, from the university of Santiago de Compostella. We have finalized our work on the stability of the discretization of PMLs in the corners and submitted a paper (see preprint [24]).

6.3.3. High-order Absorbing Boundary Conditions for anisotropic elastodynamics

**Participants:** Daniel Baffet, Eliane Bécache.

This work is done in collaboration with Daniel Baffet, PhD student of Dan Givoli, at the Technion University in Haifa (Israel) and has started during a visit of Daniel at Poems.

The aim is to design new efficient and stable absorbing boundary conditions for anistropic materials. It is known that the anisotropy introduces a specific difficulty, for ABC as well as for PMLs, in particular for models which involve inverse modes, i.e. waves for which the phase velocity and the group velocity propagate in opposite directions (with respect to the boundary). This has given rise to specific treatment for scalar models but for anisotropic elastodynamics, there are some materials for which no satisfactory solution exist. for these materials however, we can design a low order boundary condition, which is proved to be stable via an energy estimate. We have started to investigate several ways to design higher-order boundary conditions. The main difficulty is to show whether these boundary conditions are stable or not...

6.3.4. Dirichlet to Neumann map with overlap for waveguides

**Participants:** Anne-Sophie Bonnet-Ben Dhia, Sonia Fliss, Geoffrey Martinache, Antoine Tonnoir.

For scattering problems in acoustic waveguides, a usual approach consists in restricting the computation to a bounded domain containing the sources and the perturbations, using transparent boundary conditions on the artificial boundaries. These conditions are written by using the so-called Dirichlet-to-Neumann maps which can be expressed thanks to a modal decomposition.
An iterative solution of the related linear system can be seen as a domain decomposition formulation without overlapping, where one domain is the bounded region and the other one is infinite. This iterative method does not converge necessarily. A classical idea is to consider a domain decomposition method with overlapping. In this work, we find the equivalent of this method in terms of a new Dirichlet-to-Neumann operator which links the trace of the solution on a section of the waveguide to the normal trace on a different one. This operator can also be expressed analytically via a modal decomposition. Its main advantage is that, because of the overlapping, it becomes compact and this is exactly why we think an iterative resolution has more chance to converge. Other advantages will appear with the elasticity application. Indeed, in the formulation of the transparent boundary condition without overlapping, appears a Lagrange multiplier which makes the resolution more costly. This additional unknown will be avoided with an overlap.

For now, the theory is done for the scalar acoustic waveguide and the method has been implemented in the Melina code. The extension to the elastic case is in progress.

6.3.5. An alternative to DTN maps in waveguides

Participants: Anne-Sophie Bonnet-Ben Dhia, Guillaume Legendre.

We are interested by the treatment of the radiation condition at infinity for the numerical solution of a problem set in an unbounded waveguide. We have proposed an alternative to the classical approach involving a modal expression of Dirichlet-to-Neumann (DtN) operators. This new method is particularly simple to implement since it only requires to solve several times a boundary value problem with local boundary conditions. In the case of an acoustic waveguide, we have proved that the corresponding approximate solution is comparable in accuracy to the one obtained by truncating the infinite series in the DtN maps. The number of linear systems to invert, which has to be greater than the number of propagative guided modes, can be significantly reduced by combining the approach with the perfectly matched layer (PML) technique. It works even in elastic waveguides, despite existence of the so-called backward waves which are known to make the PMLs inefficient, when used alone.

6.4. Waveguides, resonances, and scattering theory

6.4.1. Modelling of non-homogeneous lossy coaxial cable for time domain simulation.

Participants: Sébastien Impériale, Patrick Joly.

In this work, we focus on the time-domain simulation of the propagation of electromagnetic waves in non-homogeneous lossy coaxial cables. This question has been motivated by our collaboration with CEA-LIST about the numerical modeling of non-destructive testing (for the detection of cracks in metallic bodies for instance) by ultra-sounds and more precisely the modeling of piezo-electric transducers (see section 6.1.6). The complete description of such devices often requires an accurate modeling of the supply process, which includes the propagation of the electric current along coaxial cables. This question appears as an independent sub-problem.

The main characteristic of such coaxial cables is that their transverse directions are very small with respect to their length as well as the wavelength. As a consequence, one would like to use a simplified 1D model as an effective (or homogenized) model for electromagnetic propagation. In this work, we construct and justify rigorously such a model by way of an asymptotic analysis of time harmonic 3D Maxwell’s equations in such a structure. The effective model appears as a generalized wave equation with additional time convolution terms that take into account electric and magnetic losses. By this way, we justify and extend some models proposed in the electrical engineering literature, in particular the well-known telegraphist’s equation. The properties of our limit model in time domain has been analyzed and a stable discretization process has been proposed. Numerical simulation in academic simulations exhibit some exotic phenomena of “dispersive dissipation”.

Our further investigations of the subject will be developed in the framework of the new ANR project SODDA in collaboration with the team Sysiphe (M. Sorine).
6.4.2. Study of lineic defect in periodic media

Participant: Sonia Fliss.

This work deals with one-dimensional infinite perturbation - namely line defects - in periodic media. In optics, such defects are created to construct an (open) waveguide that concentrates light. The existence and the computation of the eigenmodes is a crucial issue. This is related to a self-adjoint eigenvalue problem associated to a PDE in an unbounded domain (in the directions orthogonal to the line defect), which makes both the analysis and the computations more complex. Using a Dirichlet-to-Neumann (DtN) approach, we show that this problem is equivalent to one set on a small neighborhood of the defect. In opposition to existing methods, this method is exact but there is a price to be paid: the reduction of the problem leads to a nonlinear eigenvalue problem of a fixed point nature. An article presenting the method and its properties is being written, the numerical study is in progress in collaboration with Kersten Schmidt and Dirk Klindworth from the Technische Universität Berlin.

Our further investigations of the subject will be developed in the framework of a new DGA project.

6.4.3. A new approach for the numerical computation of non-linear modes of vibrating systems

Participants: Anne-Sophie Bonnet-Ben Dhia, Jean-François Mercier.

A collaboration with Cyril Touzé and François Blanc (Unité de Mécanique, ENSTA). The simulation of vibrations of large amplitude of thin plates or shells requires the expensive solution of a non-linear finite element model. The main objective of the proposed study is to develop a reliable numerical method which reduces drastically the number of degrees of freedom. The main idea is the use of the so-called non-linear modes to project the dynamics on invariant subspaces, in order to generate accurate reduced-order models. Cyril Touzé from the Unité de Mécanique of ENSTA has derived an asymptotic method of calculation of the non-linear modes for both conservative and damped systems. But the asymptotically computed solution remains accurate only for moderate amplitudes. This motivates the present study which consists in developing a numerical method for the computation of the non-linear modes, without any asymptotic assumption. This is the object of a collaboration with Cyril Touzé, and new results have been obtained during the post-doc of François Blanc in the Unité de Mécanique of ENSTA. The partial differential equations defining the invariant manifold of the non-linear mode are seen as a vectorial transport problem: the variables are the amplitude and the phase \( (a, \varphi) \) where the phase \( \varphi \) plays the role of the time. In the case of conservative systems, a finite difference scheme is used and an iterative algorithm is written, to take into account the \( 2\pi \)-periodicity in \( \varphi \) which is seen as a constraint. An adjoint state approach has been introduced to evaluate the gradient of the control function. The method has been validated in a simple example with two degrees of freedom. Good agreement with an alternative method, the continuation of periodic solutions method, has been found. Currently the method is extended to the case of damped systems. The main difficulty is that, due to a change of variables, the \( 2\pi \)-periodicity does not hold anymore and new constraints more complicated to implement must be considered. Numerical implementation is still under progress.

6.5. Asymptotic methods and approximate models

6.5.1. Effective boundary conditions for thin periodic coatings

Participants: Mathieu Chamaillard, Patrick Joly.

This topic is developed in collaboration with H. Haddar (DEFI, INRIA Saclay) can be seen as a continuation of the PhD thesis of B. Delourme (see the activity report of last year) on effective transmission conditions for thin rough interfaces. On this last subject, the mathematical analysis of such transmission conditions in the (difficult) case of 3D Maxwell’s equations has been completed and submitted for publication.
We are now coming back to the more traditional issue of effective or approximate boundary conditions for simulating thin periodic coatings at the surface of a diffractive obstacle. This subject has already been more widely investigated, in particular in France (see the works by Achdou, Ammari and their collaborators for instance). However, we attack, with the PhD thesis of M. Chamaillard, supported by a DGA/INRIA scholarship, various new aspects of the problem, namely:

- the treatment of surfaces of general geometry,
- the use of non standard materials, such as ferromagnetic materials, for the coating,
- the construction of higher order impedance conditions.

This is motivated by various recent progress in the domain of stealth technology and we hope to develop a collaboration in this domain with CEA-DAM (CESTA and Le Ripault).

6.5.2. Elastic wave propagation in strongly heterogeneous media

Participants: Patrick Joly, Simon Marmorat.

This subject enters our long term collaboration with CEA-LIST on the development on numerical methods for time-domain non destructive testing experiments using ultra-sounds. This is also the subject of the PhD thesis of Simon Marmorat. Our objective is to develop an efficient numerical approach for the propagation of elastic waves in a medium which is made of many small inclusions / heterogeneities embedded in a smooth (or piecewise smooth) background medium, without any particular assumption (such as periodicity) on the spatial distribution of these heterogeneities. Our idea is to exploit the smallness of the inclusions (with respect to the wavelength in the background medium) to derive a simplified approximate model in which each inclusion would be described by very few parameters (functions of time) coupled to the displacement field in background medium for which we could use a computational mesh that ignores the presence of the heterogeneities. For deriving such a model, we intend to use and adapt the asymptotic methods previously developed at Poems (such as matched asymptotic expansions).

6.5.3. Approximate models in aeroacoustics

Participants: Anne-Sophie Bonnet-Ben Dhia, Patrick Joly, Guillaume Legendre, Ricardo Weder.

This topic concerns the 2D acoustic propagation in presence of a mean flow, modeled for instance by the Galbrun equation. We had previously derived effective boundary conditions taking into account the boundary layers of the mean flow near a rigid or treated boundary. These boundary conditions are in general non local with respect to the normal coordinate inside the boundary layer. However when the Mach profile in the shear layer is piecewise linear, the condition can be replaced by a system of 1D advection equations, which are coupled with the Galbrun equation in the 2D domain. We have derived a variational formulation for this model, in time-harmonic regime and for the case of a rigid boundary. This formulation has been implemented in the Melina code: the first results are promising and the validation, by comparison to the solution obtained by a full discretization of the shear layer, is in progress.

6.6. Imaging and inverse problems

6.6.1. Sampling methods in waveguides

Participants: Laurent Bourgeois, Eric Lunéville, Alexandre Routier.

We have derived a modal formulation of sampling methods (both the Linear Sampling Method and the Factorization Method) in an acoustic waveguide when the obstacle to recover is a set of cracks. This was the subject of the Master internship of Alexandre Routier. For such particular obstacle, we have analyzed the importance of the test function we introduce in the sampling method if we a priori know the type of boundary condition we have on the lips of the crack, both from the theoretical and the numerical point of view. Besides we have proved that in our modal formulation, the Factorization Method is applicable by using the same data as those used in the Linear Sampling Method, which is a novelty as concerns sampling methods in waveguides. The Linear Sampling Method has been extended to the elastic case, for which the usual obstacle is a set of traction free cracks. This makes the choice of the test function crucial, and we have emphasized such fact on numerical examples.
6.6.2. Inverse scattering with generalized impedance boundary conditions
Participants: Laurent Bourgeois, Nicolas Chaulet.
This work is a collaboration between POEMS and DEFI projects (more precisely Housssem Haddar) and constitutes the subject of the PhD thesis of N. Chaulet. We are concerned with the identification of some obstacle and some Generalized Impedance Boundary Conditions (GIBC) on the boundary of such obstacle from far field measurements. The GIBCs are approximate models for thin coatings or corrugated surfaces. During this last year, we have completed the computation of the partial derivatives of the far field with respect to the unknowns, among which is the boundary of the obstacle, and we have implemented many numerical experiments. In particular, we have shown the efficiency of the method consisting in approximating a perfect conductor which is coated with a thin dielectric layer of variable width by a second order GIBC in order to retrieve the obstacle, as well as the refraction index and the width of the layer.

6.6.3. Detection of targets using time-reversal
Participants: Maxence Cassier, Patrick Joly, Christophe Hazard.
This topic concerns the studies started last year about time-reversal in the context of Maxence Cassier’s thesis. The main question is to generate a time-dependent wave that focuses on one given scatterer not only in space, but also in time. Our recent works concern two items. On one hand, we have proposed a way to construct such a focusing wave which does not require an a priori knowledge of the location of the obstacle. This wave is represented by a suitable superposition of the eigenvectors of the so-called time-reversal operator in the frequency domain. Numerical results show the focusing properties of such a wave. On the other hand, we try to understand how to translate the physical idea of “focusing” into mathematical terms. We have proposed an energy criterion which can be used in numerical experiments in order to evaluate the quality of the focus. The question is to relate such a criterion with the construction of the above mentioned focusing wave. Works on this topic are in progress.

6.6.4. Interior transmission problem
Participants: Anne-Sophie Bonnet-Ben Dhia, Lucas Chesnel.
This work is a collaboration with Housssem Haddar from the DEFI project. The interior transmission problem plays an important role in the inverse scattering theory for inhomogeneous media. In particular, it arises when one is interested in the reconstruction of an inclusion embedded in a background medium from multi-static measurements of diffracted fields at a given frequency. Physically, it is important to prove that, for a given frequency, there are no waves which do not scatter. Mathematically, this last property boils down to say that the frequency is not a transmission eigenvalue, that is, an eigenvalue of the interior transmission problem. An important issue is to prove that transmission eigenvalues form at most a discrete set with infinity as the only accumulation point. This is not trivial because the operator associated with this problem exhibits a sign changing in its principal part and its study is not standard. Using the T-coercivity approach, we proved the discreteness under relatively weak assumptions. In particular, the simple technique we proposed allows to treat cases, which were not covered by existing methods, where the difference between the inclusion index and the background index changes sign.

6.6.5. Flaw identification using elastodynamic topological derivative
Participant: Marc Bonnet.
In collaboration with Cédric Bellis (Columbia Univ. USA), Bojan Guzina (Univ. of Minnesota, USA). The concept of topological derivative (TD) quantifies the perturbation induced to a given cost functional by the nucleation of an infinitesimal flaw in a reference defect-free body, and may serve as a flaw indicator function. In this work, the TD is derived for three-dimensional crack identification exploiting over-determined transient elastodynamic boundary data. This entails in particular the derivation of the relevant polarization tensor, here given for infinitesimal trial cracks in homogeneous or bi-material elastic bodies. Simple and efficient adjoint-state based formulations are used for computational efficiency, allowing to compute the TD field for arbitrarily shaped elastic solids. The latter is then used as an indicator function for the spatial location of the sought
crack(s). This approach, which allows a qualitative reconstruction of cracks in terms of their location but also their orientation (utilizing the fact that the polarization tensor depends on the normal to the trial small crack), has been implemented within a conventional FEM platform. A standard Newmark unconditionally-stable time-marching scheme is used for simulating data, and for computing the free and adjoint solutions used in the evaluation of the TD field. Extensive 3D time-domain numerical experiments for the detection of cracks buried either in a homogeneous pipe-like structure or on the interface between two sandwiched plates highlight its usefulness and performance. The application of TD to flaw identification has thus far rested upon a heuristic basis. Its justification in limiting situations such as the Born approximation is currently being investigated.

6.6.6. Topological derivative in anisotropic elasticity

Participant: Marc Bonnet.

In collaboration with Gabriel Delgado (CMAP, Ecole Polytechnique). This work addresses the current lack of a comprehensive treatment of the topological derivative for anisotropic elasticity, by addressing the case where both the background material and the trial small inhomogeneity have arbitrary anisotropic elastic properties. Accordingly, a formula for the topological derivative of any cost functional defined in terms of regular volume or surface densities depending on the displacement is established, by combining small-inhomogeneity asymptotics and the adjoint solution approach. The latter feature makes the proposed result simple to implement and computationally efficient. Both three-dimensional and plane-strain settings are covered; they differ mostly on details pertaining to the elastic moment tensor. This result achieves a direct generalization to the fully anisotropic case of previously-known formulations for isotropic elasticity. Moreover, the main properties of the EMT, a critical feature of any elastic topological derivative formula, are studied for the fully anisotropic case, generalizing available results on the isotropic case. Finally, further generality is achieved by also deriving the topological derivative of strain energy-based cost functionals, which depend on the displacement gradient. This case, seldom addressed so far, requires a specific, and separate, treatment. Applications of these results include topology optimization of composite structures (a topic currently pursued by G. Delgado) or flaw identification using experimental data from nondestructive testing.

6.6.7. Energy functionals for elastic medium reconstruction using transient data

Participant: Marc Bonnet.

In collaboration with Wilkins Aquino (Cornell Univ., USA). Energy-based misfit cost functionals, known in mechanics as error in constitutive relation (ECR) functionals, are known since a long time to be well suited to (electrostatic, elastic,...) medium reconstruction. In this ongoing work, a transient elastodynamic version of this methodology is developed, with emphasis on its applicability to large time-domain finite element modeling of the forward problem. The formulation involves coupled transient forward and adjoint solutions, a fact which greatly hinders large-scale computations. A computational approach combining an iterative treatment of the coupled problem and the adjoint to the discrete Newmark time-stepping scheme is found to perform well on large FE models, making the time-domain ECR functional a worthwhile tool for medium identification.

6.6.8. Accelerated boundary element method for diffuse optical imaging

Participant: Marc Bonnet.

In collaboration with Simon Arridge and Josias Elisee (University College London, UK). Numerical methods for calculating forward models of light propagation in tissue are extensively used in diffuse optical imaging (DOI). DOI involves a Helmholtz-type PDE with a complex-valued wavenumber. It requires modelling large optical regions whose parameters are known and piecewise constant. The boundary element method (BEM) answers this need and avoids the detailed interior meshing of these regions. The single-level Fast Multipole Method has been applied for solving the DOI governing equation, allowing substantial reduction of computational costs. The enhanced practicability of the BEM in DOI was demonstrated through test examples on single-layer problems, where two-digit reduction factors on solution time are achieved, and on a high-resolution version of a three-layered neonate’s head.
6.6.9. **High-Velocity Estimates and Inverse Scattering for Quantum N-Body Systems with Stark Effect**

**Participants:** Ricardo Weder, Gerardo Daniel Valencia.

In an \(N\)-body quantum system with a constant electric field, by inverse scattering, we uniquely reconstruct pair potentials, belonging to the optimal class of short-range potentials and long-range potentials, from the high-velocity limit of the Dollard scattering operator. We give a reconstruction formula with an error term.

6.6.10. **Small-Energy Analysis for the Matrix Schrödinger Operator on the Half-Line**

**Participant:** Ricardo Weder.

In collaboration with Tuncay Aktosun (University of Texas Arlington) and Martin Klaus (Virginia Tech). The matrix Schrödinger equation with a selfadjoint matrix potential is considered on the half line with the most general selfadjoint boundary condition at the origin. When the matrix potential is integrable and has a first moment, it is shown that the corresponding scattering matrix is continuous at zero energy. An explicit formula is provided for the scattering matrix at zero energy. The small-energy asymptotics are established also for the related Jost matrix, its inverse, and various other quantities relevant to the corresponding direct and inverse scattering problems.

6.7. **Other topics**

6.7.1. **Fast non-overlapping Schwarz domain decomposition methods for the neutron diffusion equation**

**Participant:** Patrick Ciarlet.

A collaboration with Erell Jamelot (CEA Saclay/DEN). Investigating numerically the steady state of a nuclear core reactor can be very expensive, in terms of memory storage and computational time. In order to address both requirements, one can use a domain decomposition method, which is then implemented on a parallel computer.

We model the problem using a mixed approach, which involves a scalar flux and a vector current. The equivalent variational formulation is then discretized with the help of Raviart-Thomas-Nédélec finite elements.

The domain decomposition method is based on the Schwarz iterative algorithm with Robin interface conditions to handle communications. This method is analyzed from the continuous to the discrete point of views: well-posedness, convergence of the finite element method, optimality of the parameter appearing in the Robin interface condition and algorithms. Numerical experiments carried out on realistic 3D configurations using the APOLLO3© code (of CEA/DEN) show the parallel efficiency of the algorithm.

6.7.2. **Equivalent local boundary conditions for the Monge Kantorovitch Mass Transport problem**

**Participant:** Jean-David Benamou.

This work is done in collaboration with Adam Oberman Brittany Froese from Simon Fraser University, Vancouver. In the last 20 years, the Monge Kantorovich Optimal Transport problem (OTP) and its relationship with Partial Differential Equations (PDE) experienced a spectacular research revival (the Fields medal was awarded to Cédric Villani in 2010 partly for his contributions to OTP). Applications appeared in fields as diverse as meteorology, medical image processing, astronomy and economy. This new area offers numerical challenges which go beyond current knowledge in the field. Novel computational tools are needed. The OTP can also be reformulated as a Monge-Ampère (MA) PDE with non standard/non local boundary conditions (BC). We would like to use the new and efficient wide-stencil Finite Difference MA solver developed by Oberman and Froese but we do not know how to deal with the OTP equivalent BCs. We pursue the investigation of the two following innovative strategies : 1. Iteratively construct Neumann BCs such that the solution of the MA equation satisfies the OTP BC in the limit. 2. Merge the data in all of space and design simplified asymptotic local BCs at infinity which can be used to formulate local transparent BC on a truncated domain.
6.7.3. **Topological Effects in Quantum Mechanics and High-Velocity Estimates**

**Participant:** Ricardo Weder.

This work is done in collaboration with Miguel Ballesteros. High-velocity -or high-energy- estimates for scattering solutions to the Schrödinger equation are important for many reasons. For example, in topological effects in quantum mechanics, where the space accessible to the particles has a non-trivial topology, like, for example, in the celebrated magnetic Aharonov-Bohm effect, where an electron is constrained to be on the exterior of a torus that contains a magnetic flux inside. Here, the solution acquires a phase if the electron travels inside the hole of the magnet and, on the contrary, it acquires no phase if the particle travels outside the hole. We obtain precise high-velocity estimates for the scattering solutions, that prove that quantum mechanics actually predicts the existence of the magnetic Aharonov-Bohm effect, under the conditions of the celebrated Tonomura et al. experiments. Moreover, in the case of the electric Aharonov-Bohm effect, we provide precise conditions for the validity of the Aharonov-Bohm Ansatz and we give a rigorous proof that quantum mechanics predicts the existence of this effect.

6.7.4. **Entanglement Creation in Low-Energy Scattering**

**Participant:** Ricardo Weder.

We study the entanglement creation in the low-energy scattering of two particles of mass, $m_1, m_2$ in three dimensions. We consider a general class of interaction potentials that are not required to be spherically symmetric. The incoming asymptotic state, before the collision, is a product of two normalized Gaussian states with the same variance, $\sigma$, and opposite mean momentum. After the scattering the particles are in the outgoing asymptotic state that is not a product state. We take as a measure of the entanglement created by the collision the purity of one of the particles in the outgoing asymptotic state. In the incoming asymptotic state the purity is one. We provide a rigorous explicit computation, with error bound, of the leading order of the purity at low-energy. The leading order depends strongly in the difference of the masses. The entanglement takes its minimum when the masses are equal, and it increases rapidly with the difference of the masses. It is quite remarkable that the anisotropy of the potential plays no role, on spite of the fact that entanglement is a second order effect.

6.7.5. **Open Scattering Channels in Manifolds with Horns**

**Participant:** Ricardo Weder.

This work is done in collaboration with Olaf Post (Humboldt University, Berlin) and Rainer Hempel (Mount Allison University, Sackville New Brunswick). In the framework of time-dependent geometric scattering theory, we study the existence and completeness of the wave operators for perturbations of the Riemannian metric for the Laplacian on a complete manifold of dimension $n$. The smallness condition for the perturbation is expressed in purely geometric terms using the harmonic radius; therefore, the size of the perturbation can be controlled in terms of local bounds on the radius of injectivity and the Ricci-curvature, and no global assumption is needed. As an application of these ideas we obtain a stability result for the scattering matrix. As a consequence we find that a scattering channel which interacts with other channels preserves this property under small perturbations.
6. New Results

6.1. Dependable Distributed Real-time Embedded Systems

Participants: Pascal Fradet, Alain Girault [contact person], Emil Dumitrescu.

6.1.1. The TSH multi-criteria scheduling heuristic

For autonomous critical real-time embedded systems (e.g., satellite), guaranteeing a very high level of reliability is as important as keeping the power consumption as low as possible. We have designed an off-line scheduling heuristics which, from a given software application graph and a given multiprocessor architecture (homogeneous and fully connected), produces a static multiprocessor schedule that optimizes three criteria: its length (crucial for real-time systems), its reliability (crucial for dependable systems), and its power consumption (crucial for autonomous systems). Our tricriteria scheduling heuristics, TSH, uses the active replication of the operations and the data-dependencies to increase the reliability, and uses dynamic voltage and frequency scaling to lower the power consumption [17]. By running TSH on a single problem instance, we are able to provide the Pareto front for this instance in 3D, therefore exposing the user to several tradeoffs between the power consumption, the reliability and the execution time. Thanks to extensive simulation results, we have shown how TSH behaves in practice. Firstly, we have compared TSH versus an optimal Mixed Linear Integer Program on small instances; the experimental results show that TSH behaves very well compared to the the ILP. Secondly, we have compared TSH versus the ECS heuristic (Energy-Conscious Scheduling [84]); the experimental results show that TSH performs systematically better than ECS.

This is a joint work with Ismail Assayad (U. Casablanca, Morocco) and Hamoudi Kalla (U. Batna, Algeria), who both visit the team regularly.

6.1.2. Automating the Addition of Fault Tolerance with Discrete Controller Synthesis

In collaboration with Emil Dumitrescu (INSA Lyon), Hervé Marchand (VERTECS team from Rennes), and Eric Rutten (SARDES team from Grenoble), we have defined a complete framework for the automatic design of fault tolerant embedded systems, based on discrete controller synthesis (DCS) [88]. Its interest lies in the ability to obtain automatically systems satisfying by construction formal properties specified a priori. Our aim is to demonstrate the feasibility of this approach for fault tolerance. We start with a fault intolerant program, modeled as the synchronous parallel composition of finite labeled transition systems. We specify formally a fault hypothesis, state fault tolerance requirements and use DCS to obtain automatically a program having the same behavior as the initial fault intolerant one in the absence of faults, and satisfying the fault tolerance requirements under the fault hypothesis. Our original contribution resides in the demonstration that DCS can be elegantly used to design fault tolerant systems, with guarantees on key properties of the obtained system, such as the fault tolerance level, the satisfaction of quantitative constraints, and so on. We have shown with numerous examples taken from case studies that our method can address different kinds of failures (crash, value, or Byzantine) affecting different kinds of hardware components (processors, communication links, actuators, or sensors). Besides, we have shown that our method also offers an optimality criterion very useful to synthesize fault tolerant systems compliant to the constraints of embedded systems, like power consumption or execution times. In summary, our framework for fault tolerance has the following advantages [67]:

- The automation, because DCS produces automatically a fault tolerant system from an initial fault intolerant one.
- The separation of concerns, because the fault intolerant system can be designed independently from the fault tolerance requirements.
- The flexibility, because, once the system is entirely modeled, it is easy to try several fault hypotheses, several environment models, several fault tolerance goals, several degraded modes, and so on.
• The safety, because, in case of positive result obtained by DCS, the specified fault tolerance properties are guaranteed by construction on the controlled system.
• The optimality when optimal synthesis is used, modulo the potential numerical equalities (hence a non strict optimality). We consider weights cumulated along bounded-length paths. We have adapted our models in order to take into account the additive costs of, e.g., execution time or power consumption, and adapting synthesis algorithms in order to support the association of costs with transitions, and the handling of these new cost functions in the optimal synthesis [59].

We therefore combine, on the one hand, guarantees on the safety of the execution by tolerating faults, and on the other hand, guarantees on the worst cumulated consumption of the resulting dynamically reconfiguring fault tolerant system. Recently, we have incorporated multi-criteria optimization results in this work, to take into account several weight functions: for instance the execution costs of several tasks, the execution of which must be controlled thanks to DCS. We therefore propose several synthesis algorithms, to aggregate the costs into a single cost function, to hierarchize the costs (e.g., to reflect the priorities of the tasks), or to compute the Pareto front of non-dominated solutions.

6.2. Controller Synthesis for the Safe Design of Embedded Systems
Participants: Gwenaël Delaval [contact person], Gregor Goessler, Sebti Mouelhi.

6.2.1. Synthesis of Switching Controllers using Approximately Bisimilar Multiscale Abstractions

The use of discrete abstractions for continuous dynamics has become standard in hybrid systems design (see e.g. [92] and the references therein). The main advantage of this approach is that it offers the possibility to leverage controller synthesis techniques developed in the areas of supervisory control of discrete-event systems [88]. The first attempts to compute discrete abstractions for hybrid systems were based on traditional systems behavioral relationships such as simulation or bisimulation, initially proposed for discrete systems most notably in the area of formal methods. These notions require inclusion or equivalence of observed behaviors which is often too restrictive when dealing with systems observed over metric spaces. For such systems, a more natural abstraction requirement is to ask for closeness of observed behaviors. This leads to the notions of approximate simulation and bisimulation introduced in [63].

These notions enabled the computation of approximately equivalent discrete abstractions for several classes of dynamical systems, including nonlinear control systems with or without disturbances, and switched systems. These approaches are based on sampling of time and space where the sampling parameters must satisfy some relation in order to obtain abstractions of a prescribed precision. In particular, the smaller the time sampling parameter, the finer the lattice used for approximating the state-space; this may result in abstractions with a very large number of states when the sampling period is small. However, there are a number of applications where sampling has to be fast; though this is generally necessary only on a small part of the state-space.

In [22] we have presented a novel class of multiscale discrete abstractions for incrementally stable switched systems that allows us to deal with fast switching while keeping the number of states in the abstraction at a reasonable level. We assume that the controller of the switched system has to decide the control input and the time period during which it will be applied before the controller executes again. In this context, it is natural to consider abstractions where transitions have various durations. For transitions of longer duration, it is sufficient to consider abstract states on a coarse lattice. For transitions of shorter duration, it becomes necessary to use finer lattices. These finer lattices are effectively used only on a restricted area of the state-space where the fast switching occurs.

These abstractions allow us to use multiscale iterative approaches for controller synthesis as follows. An initial controller is synthesized based on the dynamics of the abstraction at the coarsest scale where only transitions of longer duration are enabled. An analysis of this initial controller allows us to identify regions of the state-space where transitions of shorter duration may be useful (e.g., to improve the performance of the controller). Then, the controller is refined by enabling transitions of shorter duration in the identified regions. The last two steps can be repeated until we are satisfied with the obtained controller.
In [21] we propose a technique for the synthesis of safety controllers for switched systems using multi-scale abstractions. We present a synthesis algorithm that exploits the specificities of multi-scale abstractions. The finest scales of the abstraction are effectively explored only when fast switching is needed, that is when the system approaches the unsafe set. We provide experimental results that show drastic improvements of the complexity of controller synthesis using multi-scale abstractions instead of uniform abstractions.

### 6.2.2. Modular Discrete Controller Synthesis

Discrete controller synthesis (DCS) [88] allows to design programs in a mixed imperative/declarative way. From a program with some freedom degrees left by the programmer (e.g., free controllable variables), and a temporal property to enforce which is not \( \text{a priori} \) verified by the initial program, DCS tools compute off-line automatically a controller which will constrain the program (by e.g., giving values to controllable variables) such that, whatever the values of inputs from the environment, the controlled program satisfies the temporal property.

Our motivation w.r.t. DCS concerns its modular application, improving the scalability of the technique by using contract enforcement and abstraction of components. Moreover, our aim is to integrate DCS into a compilation chain, and thereby improve its usability by programmers, not experts in discrete control. This work has been implemented into the HEPTAGON/BZR language and compiler [57]. This work is done in collaboration with Hervé Marchand (VERTECS team from Rennes) and Éric Rutten (SARDES team from Grenoble).

The implemented tool allows the generation of the synthesized controller under the form of an HEPTAGON node, which can in turn be analyzed and compiled, together with the HEPTAGON source from which it has been generated. This full integration allows this method to aim different target languages (currently C, JAVA or VHDL), and its integrated use in different contexts.

A formal semantics of BZR has been defined, taking into account its underlying nondeterminism related to the presence of controllable variables.

This language has been used in different contexts. In [15], BZR is used for the generation of discrete handlers of real-time continuous control tasks, in the framework of the ORCCAD \(^{31}\) tool. BZR has also been used in a case-study of a Fractal designed HTTP server [19]. The purpose of the synthesized controller is to control the automatic reconfigurations of the system (e.g., start of new components, migrations of some components from one computing element to another), in order to preserve some properties (either functional, e.g., exclusivity of activities of two components, or non-functional, e.g., bounded overall load of the system).

### 6.3. Automatic Distribution of Synchronous Programs

**Participants:** Gwenaël Delaval [contact person], Alain Girault, Gregor Goessler, Xavier Nicollin, Gideon Smeding.

#### 6.3.1. Modular Distribution

Synchronous programming languages describe functionally centralized systems, where every value, input, output, or function is always directly available for every operation. However, most embedded systems are nowadays composed of several computing resources. The aim of this work is to provide a language-oriented solution to describe *functionally distributed reactive systems*. This research is conducted within the INRIA large scale action SYNCHRONE and is a joint work with Marc Pouzet (ENS, PARKAS team from Rocquencourt) and Xavier Nicollin (Grenoble INP, VERIMAG lab).

We are working on type systems to formalize, in a uniform way, both the clock calculus and the location calculus of a synchronous data-flow programming language (the HEPTAGON language, inspired from LUCID SYNCHRONE [45]). On one hand, the clock calculus infers the clock of each variable in the program and checks the clock consistency: e.g., a time-homogeneous function, like \(+\), should be applied to variables with identical clocks. On the other hand, the location calculus infers the spatial distribution of computations and checks the spatial consistency: e.g., a centralized operator, like \(+\), should be applied to variables located at

\(^{31}\)Open Robot Controller Computer-Aided Design
the same location. Compared to the PhD of Gwenaël Delaval [55], [56], the goal is to achieve modular distribution. By modular, we mean that we want to compile each function of the program into a single function capable of running on any computing location. We make use of our uniform type system to express the computing locations as first-class abstract types, exactly like clocks, which allows us to compile a typed variable (typed by both the clock and the location calculi) into if ... then ... else ... structures, whose conditions will be valuations of the clock and location variables.

We currently work on an example of software-defined radio. We have shown on this example how to use a modified clock calculus to describe the localisation of values as clocks, and the architecture as clocks (for the computing resources) and their relations (for communication links).

6.3.2. Distribution of Synchronous Programs under Real-Time Constraints

With the objective to distribute synchronous data-flow programs (e.g. LUSTRE) over GALS architectures, preserving only explicitly specified properties, we have developed a quantitative clock calculus to (1) describe timing properties of the architecture’s clock domain, and (2) describe the properties of the synchronous program to be preserved. The clock calculus is inspired by the network calculus [83], with the difference that clocks are described only with respect to one-another, not with respect to real-time.

As a first result, we have applied our clock calculus to analyze the properties of periodic synchronous data-flow programs executed on a network of processors. Because our clock calculus is relational, it can model and preserve correlated variations of streams. In particular, the common case of a data-flow system that splits a stream for separate treatment, and joins them afterwards, this analysis yields more precise result than comparable methods.

We aim to extend the analysis to account for shared resources and synchronization protocols, so as to distribute synchronous programs preserving specified properties.

6.4. New Programming Languages for Embedded Systems

Participants: Alain Girault [contact person], Pascal Fradet, Petro Poplavko, Vagelis Bebelis, Bertrand Jeannet, Peter Schrammel.

6.4.1. The DSystemJ programming language

In collaboration with Avinash Malik (IBM Watson) and Zoran Salcic (University of Auckland), we have designed the SYSTEMJ programming language [9], which implements the Globally Asynchronous Locally Synchronous (GALS) Model of Computation (MoC) over JAVA. In a nutshell, SYSTEMJ uses the notion of clock domains (CD) to design portions of the system that must operate at unrelated clocks. CDs communicate with each other via asynchronous rendez-vous. Then, a CD consists of one or several reactions, which react synchronously in lock-step and communicate with each other via synchronous broadcast of signals. Finally, all the data computations are implemented in JAVA.

We have further extended SYSTEMJ to allow programmers to design dynamic GALS systems: this is the new language DSYSTEMJ [27], [12], aimed at dynamic distributed systems that use socket based communication protocols for communicating between components. DSYSTEMJ allows the creation and control at runtime of CDs, their mobility on a distributed execution platform, as well as the runtime reconfiguration of the system’s functionality and topology. We have defined the formal semantics of DSYSTEMJ, based on the Dynamic GALS MoC: it offers very safe mechanisms for implementation of distributed systems, as well as potential for their formal verification. The runtime support is implemented in the SYSTEMJ language, which can as such be considered as a static subset of DSYSTEMJ.

This work has been done within the AFMES associated team with the Electric and Computer Engineering Department of the University of Auckland.
6.4.2. The PRET-C programming language for time-predictable systems

Typical safety critical embedded applications, ranging from complex aircraft flight controllers to embedded health devices require worst case guarantees on their timing behavior. The problem is that general-purpose processors, being highly speculative, are intrinsically non-deterministic, and thus are not ideally suited for implementing such systems: either the computed worst-case execution time is highly pessimistic, or heroic efforts are required to accurately model the caches, pipeline, and speculative execution [93]. For similar reasons, using an RTOS to guarantee the determinism of a program’s behavior, along with temporal guarantees, is not feasible. The ability to analyze temporal bounds is dependent on the selected programming language, compiler tool chain, operating system, and the target hardware.

To alleviate these problems, we have defined a synchronous variant of C called PRET-C, together with Sidharta Andalam and Partha Roop (University of Auckland). PRET-C offers constructs for reactive inputs/outputs; it supports a notion of logical time, synchronous concurrency, and preemption [40]. We have also designed the ARPRET architecture for efficient and predictable execution of PRET-C. ARPRET inherits from the long lasting research effort on reactive processors conducted at the University of Auckland. Finally, all timing constraints are precisely verified using a Worst Case Reaction Time (WCRT) analyzer. While there has been a considerable body of work on the timing analysis of procedural programs [93], such analysis for synchronous programs has received less attention. Current state-of-the-art analyses for synchronous programs use integer linear programming (ILP) combined with path pruning techniques to achieve tight results. These approaches first convert a concurrent synchronous program into a sequential program. ILP constraints are then derived from this sequential program to compute the longest tick length. For PRET-C, we have proposed an alternative approach based on model checking [16]. Unlike conventional programs, synchronous programs are concurrent and state-space oriented, making them ideal for model checking based analysis. Our analysis of the abstracted state-space of the program is combined with expressive data-flow information, to facilitate effective path pruning. We have demonstrated through extensive experimentation that the proposed approach is both scalable and about 67% tighter compared to the existing approaches (namely Protothreads [60] and SC [94]).

This overall framework provides an ideal platform for designing and verifying precision timed real-time systems. It has been conducted within the AFMES associated team with the Electric and Computer Engineering Department of the University of Auckland, and is the topic of the PhD of Sidharta Andalam.

6.4.3. Analysis and Scheduling of Parametric Data-Flow Models

Recent data-flow programming environments support applications whose behavior is characterized by dynamic variations in resource requirements. The high expressive power of the underlying models (e.g., Kahn Process Networks, the CAL actor language) makes it challenging to ensure predictable behavior. In particular, checking liveness (i.e., no part of the system will deadlock) and boundedness (i.e., the system can be executed in finite memory) is known to be hard or even undecidable for such models. This situation is troublesome for the design of high-quality embedded systems.

We have introduced the schedulable parametric data-flow (SPDF) model of computation (MoC) for dynamic streaming applications [23], [32], [36], [34], [35]. SPDF extends the standard data flow model by allowing rates to be parametric (e.g., of the form $2xy$). SPDF was designed to be statically analyzable while retaining sufficient expressive power. We formulated sufficient and general static criteria for boundedness and liveness. In SPDF, parameters can be changed dynamically even within iterations. The safety of dynamic parameter changes can be checked and their implementation made explicit in the graph. These different analyses are made possible using well-defined static operations on symbolic expressions. The same holds for quasi-static scheduling which is the first step towards code generation for multi-core systems.

We are now considering other kinds of analyses for this new data-flow MoC. The objective of these analyses is to generate distributed schedules optimizing both the power consumption and the execution time of applications. The targeted hardware is P2012, a new embedded many-core platform designed by STMicroelectronics consisting of several clusters (9 in the current implementation) interconnected through a 2D mesh asynchronous NoC. Each cluster comprises 16 identical computing cores and is equipped with
a hardware mechanism for DVFS (dynamic voltage and frequency scaling). As a first step, we have studied energy efficient scheduling of simple data-flow graphs for that platform [81]. The next step is to extend the approach to SPDF.

This line of research will be followed in the PhD thesis of Vagelis Bebelis which has just started. It will be conducted in collaboration with STMicroelectronics.

6.4.4. Translating Hybrid Data-Flow Languages to Hybrid Automata

Hybrid systems are used to model embedded computing systems interacting with their physical environment. There is a conceptual mismatch between high-level hybrid system languages like SIMULINK, which are used for simulation, and hybrid automata, the most suitable representation for safety verification. Indeed, in simulation languages the interaction between discrete and continuous execution steps is specified using the concept of zero-crossings, whereas hybrid automata exploit the notion of staying conditions.

In the context of the INRIA large scale action SYNCHRONICS (see § 8.1.4), we studied how to translate the ZELUS hybrid data-flow language [43] developed in this project into logico-numerical hybrid automata by carefully pointing out this issue. We investigated various zero-crossing semantics, proposed a sound translation, and discussed to which extent the original semantics is preserved. This work has been accepted to the conference HSCC’2012 (Hybrid Systems: Computation and Control).

This work is part of the PhD thesis of Peter Schrammel.

6.5. Static Analysis and Abstract Interpretation

Participants: Alain Girault, Bertrand Jeannet [contact person], Lies Lakhdar-Chaouch, Peter Schrammel, Pascal Sotin.

6.5.1. Numerical and logico-numerical abstract acceleration

Acceleration methods are used for computing precisely the effects of loops in the reachability analysis of counter machine models. Applying these methods to synchronous data-flow programs with Boolean and numerical variables, e.g., LUSTRE programs, firstly requires the enumeration of the Boolean states in order to obtain a control graph with numerical variables only. Secondly, acceleration methods have to deal with the non-determinism introduced by numerical input variables.

Concerning the latter problem, we pushed further the work presented in [90] that extended the concept of abstract acceleration of Gonnord et al. [69], [68] to numerical input variables, and we wrote a journal version [13]. The original contributions of [13] compared to [91] is abstract backward acceleration (for backward analysis) and a detailed comparison of the abstract acceleration approach with the derivative closure approach of [39], which is related to methods based on transitive closures of relations.

We then worked more on the first point, which is to apply acceleration techniques to data-flow programs without resorting to an exhaustive enumeration of Boolean states. To this end, we introduced (1) logico-numerical abstract acceleration methods for CFGs with Boolean and numerical variables and (2) partitioning techniques that make logical-numerical abstract acceleration effective. Experimental results showed that incorporating these methods in a verification tool based on abstract interpretation provides not only significant advantage in terms of accuracy, but also a gain in performance in comparison to standard techniques. This work was published in [28].

This line of work is part of the PhD thesis of Peter Schrammel.

6.5.2. Improving dynamic approximations in static analysis

Abstract interpretation [51] formalizes two kind of approximations that can be done in the static analysis of programs:
6.5.2.2. Policy Iteration.

6.5.2.1. Widening with thresholds.

A classical technique for improving the precision is “widening with thresholds”, which bounds the extrapolation. The idea is to parameterize \( \nabla \) with a finite set \( \mathcal{C} \) of threshold constraints, and to keep in the result \( R = P \nabla \mathcal{C} Q \) those constraints \( c \in \mathcal{C} \) that are still satisfied by \( Q \): \( P \nabla \mathcal{C} Q = (P \nabla Q) \cap \{ c \in \mathcal{C} \mid Q \supseteq c \} \). In practice, one extrapolates up to some threshold; in the next iteration, either the threshold is still satisfied and the result is better than with the standard widening, or it is violated and one extrapolates up to the remaining thresholds.

The benefit of this refinement strongly depends on the choice of relevant thresholds. In [33], [26] we proposed a semantic-based technique for automatically inferring such thresholds, which applies to any control graph, be it intraprocedural, interprocedural or concurrent, without specific assumptions on the abstract domain. Despite its technical simplicity, we showed that our technique is able to infer the relevant thresholds in many practical cases.

6.5.2.2. Policy Iteration.

Another direction we investigated for solving the fix-point equation \( Y = G(Y), Y \in A \) is the use of Policy Iteration, which is a method for the exact solving of optimization and game theory problems, formulated as equations on min max affine expressions. In this context, a policy \( \pi \) is a strategy for the min-player, which gives rise to a simplified equation \( X = F^\pi(X), F^\pi \geq F, X \in \mathbb{R}^n \) which is easier to solve that the initial equation \( X = F(X), X \in \mathbb{R}^n \). Policy iteration iterates on policies rather than iterating the application of \( F \) (as in Kleene iteration), using the property that the least fixpoint of \( F \) corresponds to the least fixpoint of \( F^\pi \) for some \( \pi \).

[50] showed that the problem of finding the least fixpoint of semantic equations on some abstract domains can be reduced to such equations on min max affine expressions, that can then be solved using Policy Iteration instead of the traditional Kleene iteration with widening described above.

We first investigated the integration of the concept of Policy Iteration in a generic way into existing numerical abstract domains. We implemented it in the APRON library (see module 5.4). This allows the applicability of Policy Iteration in static analysis to be considerably extended.

In particular we considered the verification of programs manipulating Boolean and numerical variables, and we provided an efficient method to integrate the concept of policy in the logico-numerical abstract domain BDDAPRON that mixes Boolean and numerical properties (see module 5.4). This enabled the application of the policy iteration solving method to much more complex programs, that are not purely numerical any more. This work was published in [30].
6.5.3. Analysis of imperative programs

We also studied the analysis of imperative programs. Even if it is preferable to analyze embedded systems described in higher-level languages such as synchronous languages, it is also useful to be able to analyze C programs. Moreover, it enables a wider diffusion of the analysis techniques developed in the team.

6.5.3.1. Inferring Effective Types for Static Analysis of C Programs

This work is a step in the project of connecting the C language to our analysis tool INTERPROC/CONCURINTERPROC (see section 5.5.4). The starting point is the connection made by the industrial partner EADS-IW in the context of the ANR project ASOPT (§ 8.1.2) from a subset of the C language to INTERPROC. This translation uses the NEWSPEAK intermediate language promoted by EADS [77].

```c
typedef struct {
    int n;
} t;

int main()
{
    t x; t* y;
    int *p,*q;
    y = alloc(t); p = &(y->n);
    y = &x; q = &(y->n);
    *p = 1; *q = 2; *p = *p < 1;
    return *p;
}
```

Initial program.

```c
typedef enum {
    10=0,11=1,12=2
} e;

typedef struct {
    e n;
} t;

int main()
{
    t x; t* y;
    e *p,*q;
    y = alloc(t); p = &(y->n);
    y = &x; q = &(y->n);
    *p = l1; *q = l2; *p = (*p==l0)?l1:l0;
    return *p;
}
```

Transformed program.

Figure 3. Inferring finite types in C programs

The problem addressed here is that the C language does not have a specific Boolean type: Boolean values are encoded with integers. This is also true for enumerated types, that may be freely and silently cast to and from integers. On the other hand, our verification tool INTERPROC that infers the possible values of variables at each program point may benefit from the information that some integer variables are used solely as Boolean or as enumerated type variables, or more generally as finite type variables with a small domain. Indeed, specialized and efficient symbolic representations such as BDDs are used for representing properties on such variables, whereas approximated representations like intervals and octagons are used for larger domain integers and floating-points variables.

Driven by this motivation, we proposed in [25] a static analysis for inferring more precise types for the variables of a C program, corresponding to their effective use. The analysis addresses a subset of the C99 language, including pointers, structures and dynamic allocation. The principle of the method is very different from type inference techniques used in functional programming languages such as ML, where the types are inferred from the context of use. Instead, our analysis can be seen as a simple points-to analysis, followed by a disjunction version of a constant propagation analysis, and terminated by a program transformation that generates a strongly typed program. Fig. 3 illustrates this process. On this example, we discover that the program is a finite-state one, to which exact analysis technique can be applied.

6.5.3.2. Interprocedural analysis with pointers to the stack

This work addressed the problem of interprocedural analysis when side-effect are performed on the stack containing local variables. Indeed, in any language with procedures calls and pointers as parameters (C, Ada) an instruction can modify memory locations anywhere in the call-stack. The presence of such side effects
breaks most generic interprocedural analysis methods, which assume that only the top of the stack may be modified. In [29] we presented a method that addresses this issue, based on the definition of an equivalent local semantics in which writing through pointers has a local effect on the stack. Our second contribution in this context is an adequate representation of summary functions that models the effect of a procedure, not only on the values of its scalar and pointer variables, but also on the values contained in pointed memory locations. Our implementation in the interprocedural analyzer PINTERPROC (see §5.5.4) results in a verification tool that infers relational properties on the value of Boolean, numerical, and pointer variables.

6.6. Component-Based Construction

**Participants:** Lacramioara Astefanoaei, Alain Girault, Gregor Goessler [contact person], Roopak Sinha, Gideon Smeding.

6.6.1. Incremental converter synthesis

We have proposed and implemented a formal incremental converter-generation algorithm for system-on-chip (SoC) designs. The approach generates a converter, if one exists, to control the interaction between multiple intellectual property (IP) protocols with possible control and data mismatches, and allows pre-converted systems to be re-converted with additional IPs in the future. IP protocols are represented using labeled transition systems (LTS), a simple but elegant abstraction framework which can be extracted from and converted to standard IP description languages such as VHDL. The user can provide control properties, each stated as an LTS with accepting states, to describe desired aspects of the converted system, including fairness and liveness. Furthermore, data specifications can be provided to bound data channels between interacting IPs such that they do not over/under flow. The approach takes into account the uncontrollable environment of a system by allowing users to identify signals exchanged between the SoC and the environment, which the converter can neither suppress nor generate.

Given these inputs, the conversion algorithm first computes the reachable state-space of a maximal non-deterministic converter that ensures (i) the satisfaction of the given data specifications and (ii) the trace equivalence with the given control specifications, using a greatest fix-point computation. It then checks, using the standard algorithm for Büchi games, whether the converter can ensure the satisfaction of the given control specifications (reachability of accepting states) regardless of how the environment behaves. If this is found to be true, deterministic converters can be automatically generated from the maximal non-deterministic converter generated during the first step. The algorithm is proven to be sound and complete, with a polynomial complexity in the state-space sizes of given IP protocols and specifications. It is also shown that it can be used for incremental design of SoCs, where IPs and specifications are added to an SoC in steps. Incremental design allows to constrain the combinatorial explosion of the explored state-space in each step, and also reduces on-chip wire congestion by decentralizing the conversion process.

A Java implementation has been created, and experimental results show that the algorithm can handle complex IP mismatches and specifications in medium to large AMBA-based SoC systems. Future work involves creating a library of commonly-encountered specifications in SoC design such as sharing of control signals between interacting IPs using buffers, signal lifespans, and the generation of optimal converters based on quantitative criteria such as minimal power usage.

This work has been done within the AFMES associated team with the Electric and Computer Engineering Department of the University of Auckland.

6.6.2. Causality Analysis in Contract Violation

Establishing liabilities in case of litigation is generally a delicate matter. It becomes even more challenging when IT systems are involved. Generally speaking, a party can be declared liable for a damage if a fault can be attributed to that party and this fault has caused the damage. The two key issues are thus to establish convincing evidence with respect to (1) the occurrence of the fault and (2) the causality relation between the fault and the damage. The first issue concerns the technique used to log the relevant events of the system and to ensure that the logs can be produced (and have some value) in court. The second issue is especially complex when several
faults are detected in the logs and the impact of these faults on the occurrence of the failure has to be assessed. In [6] we have focused on this second issue and proposed a formal framework for reasoning about causality. A system based on this framework could be used to provide relevant information to the expert, the judge, or the parties themselves (in case of amicable settlement) to analyze the origin of the failure of an IT system.

The notion of causality has been studied for a long time in computer science, but with very different perspectives and goals. In the distributed systems community, causality (following Lamport’s seminal paper [82]) is seen essentially as a temporal property. In our context, the temporal ordering contributes to the analysis, but it is obviously not sufficient to establish the logical causality required to rule on a matter of liability: the fact that an event \( e_1 \) has occurred before an event \( e_2 \) does not imply that \( e_1 \) was the cause for \( e_2 \) (or that \( e_2 \) would not have occurred if \( e_1 \) had not occurred).

Our formal model is based on components interacting according to well identified interaction models [5]. Each component is associated with an individual contract which specifies its expected behavior. The system itself is associated with a global contract which is assumed to be implied by the composition of the individual contracts.

In [6] we have defined several variants of logical causality. The first variant, necessary causality, characterizes cases when the global contract would not have been violated if the local contract had been fulfilled. The second variant, sufficient causality, characterizes cases when the global contract would have been violated even if all the other components had fulfilled their contracts. In other words, the violation of its contract by a single component was sufficient to violate the global contract.

We are currently extending to framework to other models of computation and communication, in particular, to timed automata.

### 6.6.3. Realizability of Choreographies for Services Interacting Asynchronously

Choreography specification languages describe from a global point of view interactions among a set of services in a system to be designed. Given a choreography specification, the goal is to obtain a distributed implementation of the choreography as a system of communicating peers. These peers can be given as input (e.g., obtained using discovery techniques) or automatically generated by projection from the choreography. Checking whether some set of peers implements a choreography specification is called realizability. This check is in general undecidable if asynchronous communication is considered, that is, services interact through message buffers.

In [24] we consider conversation protocols as a choreography specification language, and leverage a recent decidability result [54] to check automatically the realizability of these specifications by a set of peers under an asynchronous communication model with a priori unbounded buffers.

### 6.6.4. A Theory of Fault Recovery for Component-Based Models

In [18] we have introduced a theory of fault recovery for component-based models. A model is specified in terms of a set of atomic components that are incrementally composed and synchronized by a set of glue operators. We define what it means for such models to provide a recovery mechanism, so that the model converges to its normal behavior in the presence of faults. We identify corrector (atomic or composite) components whose presence in a model is essential to guarantee recovery after the occurrence of faults. We also formalize component based models that effectively separate recovery from functional concerns.

### 6.7. Aspect-Oriented Programming

**Participants:** Henri-Charles Blondeel, Pascal Fradet [contact person], Alain Girault, Marnes Hoff.

The goal of Aspect-Oriented Programming (AOP) is to isolate aspects (such as security, synchronization, or error handling) which cross-cut the program basic functionality and whose implementation usually yields tangled code. In AOP, such aspects are specified separately and integrated into the program by an automatic transformation process called weaving.
Although this paradigm has great practical potential, it still lacks formalization and undisciplined uses make reasoning on programs very difficult. Our work on AOP addresses these issues by studying foundational issues (semantics, analysis, verification) and by considering domain-specific aspects (availability, fault tolerance or refinement aspects) as formal properties.

6.7.1. Aspects Preserving Properties

Aspect Oriented Programming can arbitrarily distort the semantics of programs. In particular, weaving can invalidate crucial safety and liveness properties of the base program.

We have identified categories of aspects that preserve some classes of properties [10]. Our categories of aspects comprise, among others, observers, aborters, and confiners. For example, observers do not modify the base program’s state and control-flow (e.g., persistence, profiling, and debugging aspects). These categories are defined formally based on a language independent abstract semantic framework. The classes of properties are defined as subsets of LTL for deterministic programs and CTL* for non-deterministic ones. We have formally proved that, for any program, the weaving of any aspect in a category preserves any property in the related class.

In a second step, we have designed for each aspect category a specialized aspect language which ensures that any aspect written in that language belongs to the corresponding category. These languages preserve the corresponding classes of properties by construction.

This work was conducted in collaboration with Rémi Douence from the ASCOLAINRIA team at École des Mines de Nantes.

6.7.2. Fault Tolerance Aspects

In the recent years, we have studied the implementation of specific fault tolerance techniques in real-time embedded systems using program transformation [1]. We are now investigating the use of fault-tolerance aspects in digital circuits. To this aim, we consider program transformations for hardware description languages (HDL). Our goal is to design an aspect language allowing users to specify and tune a wide range of fault tolerance techniques, while ensuring that the woven HDL program remains synthesizable. The advantage would be to produce fault-tolerant circuits by specifying fault-tolerant strategies separately from the functional specifications.

We have reviewed the different fault tolerant techniques used in integrated circuits: concurrent error detection, error detecting and correcting codes (Hamming, Berger codes, ...), spatial and time redundancy. We have designed a simple hardware description language inspired from Lustre and Lucid Synchrone. It is a core functional language manipulating synchronous boolean streams. Faults are represented by bit flips and we take into account all fault models of the form “at most $k$ faults within $n$ clock signals”. The language semantics as well as the fault model have been formalized in Coq. The next step is to express standard fault tolerance techniques as program transformations and prove that they allow to tolerate all faults of a given model.

6.7.3. Refinement Aspects

Chemical programming describes computation in terms of a chemical solution in which molecules (representing data) interact freely according to reaction rules (representing the program). Solutions are represented by multisets of elements and reactions by rewrite rules which consume and produce new elements according to conditions. This paradigm makes it possible to express programs without artificial sequentiality in a very abstract way. It bridges the gap between specification and implementation languages.

A drawback of chemical languages is that their very high-level nature usually leads to very inefficient programs. We have proposed a refinement oriented approach where the basic functionality is expressed as a chemical program whereas efficiency is achieved separately by:

- structuring the multiset with a data type defining neighborhood relations;
- describing the selection of elements according to their neighborhood;
- specifying the evaluation strategy (i.e., the application of rules and termination).
Using these three implementation aspects (data structure, selection and strategy), the chemical program can then be refined automatically into an efficient low-level program. The crucial methodological advantage is that logical issues are decoupled from efficiency issues.

This research, that takes place within the AUTOCHEM project (see Section 8.1.1), is done in collaboration with Jean-Louis Giavitto (Ircam, Paris). It is the subject matter of Marnes Hoff’s PhD thesis.
POPS Project-Team

5. New Results

5.1. RFID and Internet of Things

Participants: Roudy Dagher, Nathalie Mitton, Roberto Quilez, Loic Schmidt, David Simplot-Ryl, Lei Zhang.

5.1.1. Reader anti-collision protocol

In a Radio-Frequency IDentification network, while several readers are placed close together to improve coverage and consequently read rate, reader-reader collision problems happen frequently and inevitably. High probability of collision not only impairs the benefit of multi-reader deployment, but also results in misreadings in moving RFID tags. In order to eliminate or reduce reader collisions, we propose in [28] an Adaptive Color based Reader Anti-collision Scheduling algorithm (ACoRAS) for 13.56 MHz RFID technology where every reader is assigned a set of colors that allows it to read tags during a specific time slot within a time frame. Only the reader holding a color (token) can read at a time. Due to application constraints, the number of available colors should be limited, a perfect coloring scheme is not always feasible. ACoRAS tries to assign colors in such a way that overlapping areas at a given time are reduced. To the best of our knowledge ACoRAS is the first reader anti-collision algorithm which considers, within its design, both application and hardware requirements in reading tags. We show, through extensive simulations, that ACoRAS outperforms several anticollision methods and detects more than 99% of mobile tags while fitting application requirements.

5.1.2. Distributed ALE

Following the Internet of Things concept [14], each object is associated with a unique identifier which will allow to retrieve information about it in large databases. In the process of managing a large amount of objects, and consequently a large amount of events from readers, without overloading the network, these events have to be filtered and aggregated. This is the aim of the Application Level Events (ALE) standard from EPCGlobal, which receives events from readers and sends a useful and well constructed report to the business application. The ALE may be connected to several hundreds of readers. As the number of readers may increase with the increase of the company, a bottleneck may appear with all readers events sent to the ALE. A solution for scalability is to distribute the ALE. In [37], we propose an efficient way to solve this problem based on a Distributed Hash table (DHT). One role of the ALE is to insulate business application from technical concern so in our solution, we present a mechanism to distribute the ALE using Chord, a well-known peer-to-peer lookup system, and being transparent for business applications. This solution is compliant with the EPCglobal existing standard, scalable, robust and transparent for other layers of the middleware. We show that our solution generates only 10% overhead than in a nominal case while offering a better robustness and scalability when numbers of tags and readers increase significantly.

5.1.3. Advance Internet of Things

The Internet of Things (IoT) is a network of Internet-enabled objects, whose original purpose would be to interconnect all things in our daily life to build an always connected world. However, most of studies in the current IoT scientific community only focus on the radio-frequency identification (RFID) and wireless sensor network (WSN) based objects and lose the generality features endowed by the original definition of IoT. Furthermore, the emergence and proliferation of smart objects have been significantly changing our daily lives. It has been becoming evident that the objects should far beyond only "be identified and interconnected", but can also be controlled in an intelligent and transparent way independent of third party object (user) profiles and space and time span. In [39], we proposes a standardization scheme for a new paradigm: Advanced Internet of Things (AIIoT), which is based on our proposed Unified Object Description Language (UODL) and allows to identify and interconnect every object and event with a standard format, and makes it easier and flexible for the third party control and management by integrating multiple services issued from cloud computing.
The purpose of our proposed AIoT scheme is to build a smart world of always on, always-awareness, always-connected, always-controllable, and establish an “intelligent networking” based relationship among the objects, service suppliers and the third party users. In the scope of AIoT, all the objects are transparent across the networks and can be identified and controlled (with security guarantees) via a standard prototype anytime and anywhere.

5.2. Topology control and neighbor discovery

Participants: Xu Li, Nathalie Mitton, Jovan Radak, David Simplot-Ryl, Isabelle Simplot-Ryl.

5.2.1. Topology control

Topology control is a tool for self-organizing wireless networks locally. It allows a node to consider only a subset of links/neighbors in order to later reduce computing and memory complexity. Topology control in wireless sensor networks is an important issue for scalability and energy efficiency. It is often based on graph reduction performed through the use of Gabriel Graph or Relative Neighborhood Graph. This graph reduction is usually based on geometric values.

In [35] we tackle the problem of possible connectivity loss in the reduced graph by applying a battery level based reduction graph. Experiments are conducted to evaluate our proposition. Results are compared with RNG [52] reduction which takes into account only the strength of the received signal (RSSI). Results show that our algorithm maintains network connectivity longer than solutions from the literature and balances the energy consumption over nodes.

In [31], we propose a radically new family of geometric graphs, i.e., Hypocomb, Reduced Hypocomb and Local Hypocomb for topology control. The first two are extracted from a complete graph; the last is extracted from a Unit Disk Graph (UDG). We analytically study their properties including connectivity, planarity and degree bound. All these graphs are connected (provided the original graph is connected) planar. Hypocomb has unbounded degree while Reduced Hypocomb and Local Hypocomb have maximum degree 6 and 8, respectively. To our knowledge, Local Hypocomb is the first strictly-localized, degree-bounded planar graph computed using merely 1-hop neighbor position information. We present a construction algorithm for these graphs and analyze its time complexity. Hypocomb family graphs are promising for wireless ad hoc networking. We report our numerical results on their average degree and their impact on FACE [49] routing. We discuss their potential applications and some open problems.

5.2.2. Neighbor discovery

To perform topology control, a node needs to discover its neighbors. Hello protocol is the basic technique for neighborhood discovery in wireless ad hoc networks. It requires nodes to claim their existence/aliiveness by periodic "hello" messages. Central to a hello protocol is the determination of hello message transmission rate. No fixed optimal rate exists in the presence of node mobility. The rate should in fact adapt to it, high for high mobility and low for low mobility. In [30], we propose a novel mobility prediction based hello protocol, named ARH (Autoregressive Hello protocol). Each node predicts its own position by an ever-updated autoregression-based mobility model, and neighboring nodes predict its position by the same model. The node transmits "hello" message (for location update) only when the predicted location is too different from the true location (causing topology distortion), triggering mobility model correction on both itself and each of its neighbors. ARH evolves along with network dynamics, and seamlessly tunes itself to the optimal configuration on the fly using local knowledge only. Through simulation, we demonstrate the effectiveness and efficiency of ARH, in comparison with the only competitive protocol TAP (Turnover based Adaptive hello Protocol). With a small model order, ARH achieves the same high neighborhood discovery performance as TAP, with dramatically reduced message overhead (about 50% lower hello rate).
5.2.3. Address allocation

In [9], we propose a localized address autoconfiguration (LaConf) scheme for wireless ad hoc networks. Address allocation information is maintained on the network border nodes, called addressing agents (AAs), which are locally identified by a geographic routing protocol GFG (Greedy-FACE-Greedy). When a node joins the network, it acquires an address from a neighboring AA (if any exists) by local communication or from the head AA (a geographic extreme AA) by GFG-based multi-hop communication. A Geographic Hash Table (GHT) is adopted for duplicate address detection. Each address is hashed to a unique location in the network field, and the associated assignment information is stored along the face perimeter enclosing that location (in the planar graph). When a node receives an address assignment, it consults with the perimeter nodes around the hash location of the assigned address about any conflicts. AAs detect network partitions and mergers locally according to neighborhood change and triggers AA re-selection and network re-configuration (if necessary). We propose to apply a Connected Dominating Set (CDS) to improve the performance. We also evaluate LaConf through simulation using different planar graphs.

5.3. Routing

Participants: Nicolas Gouvy, Xu Li, Nathalie Mitton, David Simplot-Ryl.

In mobile wireless sensor networks, flows sent from data collecting sensors to a sink could traverse inefficient resource expensive paths. Such paths may have several negative effects such as devices battery depletion that may cause the network to be disconnected and packets to experience arbitrary delays. This is particularly problematic in event-based sensor networks (deployed in disaster recovery missions) where flows are of great importance. In [27], we use node mobility to improve energy consumption of computed paths. Mobility is a two-sword edge, however. Moving a node may render the network disconnected and useless. We propose CoMNet (Connectivity preservation Mobile routing protocol for actuator and sensor NETworks), a localized mechanism that modifies the network topology to support resource efficient transmissions. To the best of our knowledge, CoMNet is the first georouting algorithm which considers controlled mobility to improve routing energy consumption while ensuring network connectivity. CoMNet is based on (i) a cost to progress metric which optimizes both sending and moving costs, (ii) the use of a connected dominating set to maintain network connectivity. CoMNet is general enough to be applied to various networks (actuator, sensor). Our simulations show that CoMNet guarantees network connectivity and is effective in achieving high delivery rates and substantial energy savings compared to traditional approaches. CoMNET has then been extended in [26] to multi-hop movement.

In [12] we propose a novel localized Integrated Location Service and Routing (ILSR) scheme, based on the geographic routing protocol GFG, for data communications from sensors to a mobile sink in wireless sensor networks. The objective is to enable each sensor to maintain a slow-varying routing next hop to the sink rather than the precise knowledge of quick-varying sink position. In ILSR, sink updates location to neighboring sensors after or before a link breaks and whenever a link creation is observed. Location update relies on flooding, restricted within necessary area, where sensors experience (next hop) change in GFG routing to the sink. Dedicated location update message is additionally routed to selected nodes for prevention of routing failure. Considering both unpredictable and predictable (controllable) sink mobility, we present two versions. We prove that both of them guarantee delivery in a connected network modeled as unit disk graph. ILSR is the first localized protocol that has this property. We further propose to reduce message cost, without jeopardizing this property, by dynamically controlling the level of location update. A few add-on techniques are as well suggested to enhance the algorithm performance. We compare ILSR with an existing competing algorithm through simulation. It is observed that ILSR generates routes close to shortest paths at dramatically lower (90% lower) message cost.

In [29], we propose a novel trust management scheme for improving routing reliability in wireless ad hoc networks. It is grounded on two classic autoregression models, namely Autoregressive (AR) model and Autoregressive with exogenous inputs (ARX) model. According to this scheme, a node periodically measures the packet forwarding ratio of its every neighbor as the trust observation about that neighbor. These measurements constitute a time series of data. The node has such a time series for each neighbor. By applying
an autoregression model to these time series, it predicts the neighbors future packet forwarding ratios as their trust estimates, which in turn facilitate it to make intelligent routing decisions. With an AR model being applied, the node only uses its own observations for prediction; with an ARX model, it will also take into account recommendations from other neighbors. We evaluate the performance of the scheme when AR, ARX or a previously proposed Bayesian model is used. Simulation results indicate that the ARX model is the best choice in terms of accuracy.

5.4. Self-deployment, localization and area coverage

Participants: Milan Erdelj, Xu Li, Enrico Natalizio, Nathalie Mitton, Tahiry Razafindralambo, David Simplot-Ryl, Isabelle Simplot-Ryl.

5.4.1. Deployment

First steps in order to perform any task, a network needs to be deployed and nodes need to discover each other. To the best of our knowledge, very few scenarios when robots self-deploy to afterwards themselves constitute the network nodes or drop off sensor nodes have been investigated so far and none of them ensure the network connectivity at every step. In [15], we consider the self-deployment of wireless sensor networks. We present a mechanism which allows to preserve network connectivity during the deployment of mobile wireless sensors. Our algorithm is localized and is based on a subset of neighbors for motion decision. Our algorithm maintains a connected topology regardless of the direction chosen by each sensor. To preserve connectivity, the distance covered by the mobile nodes is constrained by the connectivity of the node to its neighbors in a connected subgraph like the relative neighborhood graph. We show the connectivity preservation property of our algorithm through analysis and present some simulation results on different deployment schemes such as full coverage, point of interest coverage or barrier coverage.

Another approach is the one proposed in [34] in which node placement is performed off-line with objective to optimize a criterion. Based on the specific application, different objectives can be taken into account such as energy consumption, throughput, delay, coverage, etc. Also many schemes have been proposed in order to optimize a specific quality of service (QoS) parameter. Power consumption is an essential issue in wireless multimedia sensor networks (WMSNs) due to the elevated processing capabilities requested by the video acquisition hardware installed on the generic sensor node. Hence, node placement scheme in WMSNs greatly impacts the overall network lifetime. [34] first proposes a suitable hardware architecture to implement a feasible WMS node based on off-the-shelf technology, then it evaluates the energy consumption obtained throughout a wise “energy-spaced” placement of the wireless nodes without affecting the video quality of multimedia traffic. In [4], we propose to use a neural network as a controller for nodes mobility and a genetic algorithm for the training of the neural network through reinforcement learning. This kind of scheme is extremely adaptive, since it can be easily modified in order to consider different objectives and QoS parameters. In fact, it is sufficient to consider a different kind of input for the neural network to aim for a different objective. All things considered, we propose a new method for programming a WSRN and we show practically how the technique works, when the coverage of the network is the QoS parameter to optimize. Simulation results show the flexibility and effectiveness of this approach even when the application scenario changes (e.g., by introducing physical obstacles).

5.4.2. Coverage

The coverage of Points of Interest (PoI) is a classical requirement in mobile wireless sensor applications. Optimizing the sensors self-deployment over a PoI while maintaining the connectivity between the sensors and the sink is thus a fundamental issue. [22] addresses the problem of autonomous deployment of mobile sensors that need to cover a predefined PoI with a connectivity constraints and provides the solution to it using Relative Neighborhood Graphs (RNG) [52]. Our deployment scheme minimizes the number of sensors used for connectivity thus increasing the number of monitoring sensors. Analytical results, simulation results and real implementation are provided to show the efficiency of our algorithm. To the best of our knowledge, only [21] both preserves the network connectivity and validates its proposition through experimentations with real wireless robots. This work has been extended to discovery and coverage of multi-point of interested in [
Indeed, the problems of multiple PoI coverage, environment exploration and data report are still solved separately and there are no works that combine the aforementioned problems into a single deployment scheme. In [21], we present a novel approach for mobile sensor deployment, where we combine multiple PoI coverage with network connectivity preservation and environment exploration in order to capture the dynamics of the monitored area. We examine the performance of our scheme through extensive simulation campaigns.

As sensors are energy constrained devices, one challenge in wireless sensor networks (WSNs) is to guarantee coverage and meanwhile maximize network lifetime. In [7], we leverage prediction to solve this challenging problem, by exploiting temporal-spatial correlations among sensory data. The basic idea lies in that a sensor node can be turned off safely when its sensory information can be inferred through some prediction methods, like Bayesian inference. We adopt the concept of entropy in information theory to evaluate the information uncertainty about the region of interest (RoI). We formulate the problem as a minimum weight submodular set cover problem, which is known to be NP hard. To address this problem, an efficient centralized truncated greedy algorithm (TGA) is proposed. We prove the performance guarantee of TGA in terms of the ratio of aggregate weight obtained by TGA to that by the optimal algorithm. Considering the decentralization nature of WSNs, we further present a distributed version of TGA, denoted as DTGA, which can obtain the same solution as TGA. The implementation issues such as network connectivity and communication cost are extensively discussed. We perform real data experiments as well as simulations to demonstrate the advantage of DTGA over the only existing competing algorithm and the impacts of different parameters associated with data correlations on the network lifetime.

5.4.3. Localization

In mobile-beacon assisted sensor localization, beacon mobility scheduling aims to determine the best beacon trajectory so that each sensor receives sufficient beacon signals with minimum delay. We propose a novel DeteRministic bEAcon Mobility Scheduling (DREAMS) algorithm [32], [10], without requiring any prior knowledge of the sensory field. In this algorithm, beacon trajectory is defined as the track of depth-first traversal (DFT) of the network graph, thus deterministic. The mobile beacon performs DFT under the instruction of nearby sensors on the fly. It moves from sensor to sensor in an intelligent heuristic manner according to RSS (Received Signal Strength)-based distance measurements. We prove that DREAMS guarantees full localization (every sensor is localized) when the measurements are noise-free. Then we suggest to apply node elimination and topology control (Local Minimum Spanning Tree) to shorten beacon tour and reduce delay. Through simulation we show that DREAMS guarantees full localization even with noisy distance measurements. We evaluate its performance on localization delay and communication overhead in comparison with a previously proposed static path based scheduling method.

5.5. Platforms and Substitution Networks

5.5.1. Platforms

In the framework of the ANR SensLAB project, a wireless sensor testbed has been set up in Lille in order to allow the evaluation through experiments of scalable wireless sensor network protocols and applications. All functionalities offered by the platform have then been presented in [17], [16], [42]. SensLAB’s main and most important goal is to offer an accurate open access multiusers scientific tool to support the design, the development tuning, and the experimentation of real large-scale sensor network applications. The SensLAB testbed is composed of 1024 nodes over 4 sites. Each site hosts 256 sensor nodes with specific characteristics in order to offer a wide spectrum of possibilities and heterogeneity. Within a given site, each one of the 256 nodes is able both to communicate via its radio interface to its neighbors and to be configured as a sink node to exchange data with any other "sink node". The hardware and software architectures that allow to reserve, configure, deploy firmwares and gather experimental data and monitoring information are described. We also present demonstration examples to illustrate the use of the SensLAB testbed and encourage researchers to test
and benchmark their applications/protocols on a large scale WSN testbed. A survey of platforms similar to SensLAB can be found in [6].

5.5.2. Emulation

Although some platforms like SensLAB are very convenient, they do not always fit the application requirements and setting up experimental testbed of large scale wireless sensor networks requires huge cost, space and human resources. A more affordable approach is needed to provide preliminary insights on network protocols performance. To overcome the need for significant number of sensors required to perform a realistic experiment, and/or to experiments with high density networks, we introduce in [43] a novel approach: emulation by using all available sensors as candidate forwarding neighbors of the node S currently holding the packet. Destination position is virtual. After successfully sending message to forwarding node B over realistic wireless channel, the position of virtual destination is adjusted by translating it for vector BS and possibly rotating it to change the neighborhood configuration. The same node S then again selects new forwarding neighbor. Such selection of best forwarding neighbor continues until virtual destination appears close to a real node, and the later then becomes final destination node. Compared to real testbeds, our emulation has advantages of testing networks with very large densities (which may not be possible in small scale implementations), and in unlimited scalability of our physical implementations (e.g. we can emulate network with a million nodes).

5.5.3. Substitution network

A substitution network is a rapidly deployable backup wireless solution to quickly react to network topology changes due to failures or to flash crowd effects on the base network. Unlike other ad hoc and mesh solutions, a substitution network does not attempt to provide new services to customers but rather to restore and maintain at least some of the services available before the failure. Furthermore, a substitution network is not deployed directly for customers but to help the base network to provide services to customers. Therefore, a substitution network is not, by definition, a stand-alone network. [36] describes the quality of service architecture for substitution networks and discuss provisioning, maintenance, and adaptation of QoS inside and between the base network and the substitution network. In the same context, [33] shows the impact of the router mobility on the QoS of such networks.

5.6. Data collection and management

Participants: Thierry Delot, Geoffroy Cogniaux, Arnaud Fontaine, Alia Ghaddar, Michael Hauspie, Samuel Hym, Xu Li, Nathalie Mitton, Tahiry Razafindralambo, David Simplot-Ryl, Isabelle Simplot-Ryl.

5.6.1. Data collection

Wireless sensors networks (WSNs) are deployed to collect huge amounts of data from the environment. This produced data has to be delivered through sensor’s wireless interface using multi-hop communications toward a sink. The position of the sink impacts the performance of the wireless sensor network regarding delay and energy consumption especially for relaying sensors. Optimizing the data gathering process in multi-hop wireless sensor networks is, therefore, a key issue. [19] and [18] address the problem of data collection using mobile sinks in a WSN. We provide a framework that studies the trade-off between energy consumption and delay of data collection. This framework provides solutions that allow decision makers to optimally design the data collection plan in wireless sensor networks with mobile sinks.

In [20], [5], we focus on information gathering in vehicular ad hoc networks. Until now, only a few research works have addressed this problem. They have lead to solutions relying on push models, where potentially useful data are pushed towards vehicles. To the best of our knowledge, no work has tackled the use of pull models in VANETs. Such models would allow users to send queries to a set of cars in order to find the desired information. In order to propose such a query processing scheme, the main challenge to address is to route the different results towards their recipient in a highly dynamic network where the nodes move very quickly. To solve this issue, we propose GeoVanet, a DHT-based geographic routing protocol which ensures that the sender of a query can get a consistent answer. Our goal is not to compute the query result "instantaneously" but to ensure that the user will be able to retrieve it within a bounded time. To prove the effectiveness of GeoVanet,
an experimental evaluation is provided in the paper. It shows that up to 80% of the available query results are delivered to the user.

Another way to optimize data collection is to send data only when necessary. Knowledge discovery and data analysis in resource constrained wireless sensor networks faces different challenges. One of the main challenges is to identify misbehaviors or anomalies with high accuracy while minimizing energy consumption in the network. In [25], we extend a previous work of us and we present an algorithm for temporal anomalies detection in wireless sensor networks. Our experiments results show that our algorithm can efficiently and accurately detect anomalies in sensor measurements. It also produces low false alarm rate for slow variation time series measurements without harvesting the source of energy.

In data aggregation, sensor measurements from the whole sensory field or a sub-field are collected as a single report at an actor using aggregate functions such as sum, average, maximum, minimum, count, deviation, etc. We propose a localized Delay-bounded and Energy-efficient Data Aggregation (DEDA) protocol [11], [38] for request-driven wireless sensor networks with IEEE 802.11 CSMA/CA MAC layer. This protocol uses a novel two-stage delay model, which measures end-to-end delay using either hop count or degree sum along a routing path depending on traffic intensity. It models the network as a unit disk graph (UDG) and constructs a localized minimal spanning tree (LMST) sub-graph. Using only edges from LMST, it builds a shortest path (thus energy-efficient) tree rooted at the actor for data aggregation. The tree is used without modification if it generates acceptable delay, compared with a given delay bound. Otherwise, it is adjusted by replacing LMST sub-paths with UDG edges. The adjustment is done locally on the fly, according to the Desired Progress (DEP) value computed at each node. We further propose to integrate DEDA with a localized sensor activity scheduling algorithm and a localized connected dominating set algorithm, yielding two DEDA variants, to improve its energy efficiency and delay reliability. Through an extensive set of simulation, we evaluate the performance of DEDA with various network parameters. Our simulation results indicate that DEDA far outperforms the only existing competing protocol.

5.6.2. Data management

The use of reliable high-level languages based on virtual machines, such as java, is now possible on systems as small as smart cards or sensors. However, the potential of these languages is widely limited by hardware constraints such as memory storage capacity etc. We claim that lock may be leveraged by coupling cache mechanisms with external memory storages. [40] is a preliminary study of the set up of such an approach. Thanks to simulation based results, we identify three main factors which tend to decrease the performances of cache setting code in Java.

5.6.3. Data security

[41], [24] presents the enforcement of control flow policies for Java bytecode devoted to open and constrained devices. On-device enforcement of security policies mostly relies on run-time monitoring or inline checking code, which is not appropriate for strongly constrained devices such as mobile phones and smart-cards. We present a proof-carrying code approach with on-device lightweight verification of control flow policies statically at loading time. Policies are expressed by finite automata, the technique is in-between security automata and control flow security policies of Jensen et al. Our approach is suitable for evolving, open and constrained Java-based systems as it is compositional, to avoid re-verification of already verified bytecode upon loading of new bytecode, and it is regressive, to cleanly support bytecode unloading.

While mobile devices have become ubiquitous and generally multi-application capable, their operating systems provide few high-level mechanisms to protect services offered by application vendors against potentially hostile applications coexisting on the device. In [23], we tackle the issue of controlling application interactions including collusion in Java-based systems running on open, constrained devices such as smart cards or mobile phones. We present a model specially designed to be embedded in constrained devices to verify at install-time that interactions between applications abide by the security policies of each involved application without resulting in run-time computation overheads; this models deals with application (un)installations and policy changes in an incremental fashion. We show the feasibility of our approach and its security
enhancements on a multi-application use case for GlobalPlatform/Java Card smart cards. This approach is developed in EVe - TCF.

Telecommunication software systems, containing security vulnerabilities, continue to be created and released to consumers. We need to adopt improved software engineering practices to reduce the security vulnerabilities in modern systems. Contracts can provide a useful mechanism for the identification, tracking, and validation of security vulnerabilities. In [8], we propose a new contract-based security assertion monitoring framework (CB SAMF) that is intended to reduce the number of security vulnerabilities that are exploitable across multiple software layers, and to be used in an enhanced systems development life cycle (SDLC). We show how contract-based security assertion monitoring can be achieved in a live environment on Linux. Through security activities integrated into the SDLC we can identify potential security vulnerabilities in telecommunication systems, which in turn are used for the creation of contracts defining security assertions. Our contract model is then exercised, as runtime probes, against two common security related vulnerabilities in the form of a buffer overflow and a denial of service.
6. New Results

6.1. A Lightweight Augmented Virtuality System for Providing a Faithful and Spatially Manipulable Visual Hand Representation

Participants: Sabine Coquillart, Olivier Martin, Andreas Pusch.

We introduced the technical foundations of a system designed to embed a lightweight, faithful and spatially manipulable representation of the user’s hand into an otherwise virtual world - Augmented Virtuality (AV). A highly intuitive control during pointing-like near space interaction can be provided to the user, as well as a very flexible means to experimenters, in a variety of contexts. Our approach essentially relies on stereoscopic video see-through Augmented Reality (AR) technology and a generic, extendible framework for managing 3-D visual hand displacements. Research from human-computer interaction, perception and motor control has contributed to the elaboration of our proposal which combines a) acting in co-location, b) avoiding occlusion violations by assuring a correct scene depth ordering and c) providing a convincing visual feedback of the user’s hand. This system has already successfully been used in one case and further promising applications are studied [17], [18].

6.2. Effects of Hand Feedback Fidelity on Near Space Pointing Performance and User Acceptance

Participants: Sabine Coquillart, Olivier Martin, Andreas Pusch.

We conducted an experiment to test the effects of different hand representations on near space pointing performance and user preference. Subjects were presented with varying levels of hand realism, including real hand video, a high and a low level 3D hand model and an ordinary 3D pointer arrow. Behavioural data revealed that an abstract hand substitute like a 3D pointer arrow leads to significantly larger position estimation errors in terms of lateral target overshotting when touching virtual surfaces with only visual hand movement constraints. Further, questionnaire results show that a higher fidelity hand is preferred over lower fidelity representations for different aspects of the task [18].
6. New Results

6.1. Models of Programming

- P. Herms, together with C. Marché and B. Monate (CEA List), developed a certified VC generator, using Coq. The program for VC calculus and its specifications are both written in Coq, but the code is crafted so that it can be extracted automatically into a stand-alone executable. It is also designed in a way that allows the use of arbitrary first-order theorem provers to discharge the generated obligations \[37\]. This is a first step towards a certified VC generator for C programs annotated with ACSL \[54\].

- Until now, we only considered the proof of sequential programs. However the rely/guarantee approach give a natural way to extend deductive verification to concurrent programs. During his internship supervised by C. Paulin, N. Gaspar explored this idea. He formalised in Coq the axiomatic semantics of a simple concurrent language using the rely-guarantee approach \[43\] and proposed a translation of this language into Why programs in order to automatically generate the proof obligations.

- W. Urribarri, together with C. Paulin, proposed an extension of the Why language with modules and functors together with a refinement calculus in order to organise large developments in a structured and abstract way. She built a prototype implementation of this calculus.

- D. Baelde, in cooperation with P. Courtieu (CNAM), D. Gross-Amblard (U. Bourgogne and Rennes), C. Paulin and X. Urbain proposed a formal proof of security for two watermarking algorithms. The proof uses a reduction of an arbitrary attack unmarking the data to the discovery of a secret key. It has been fully formalized in Coq using the ALEA library. This work has been presented at the conference TYPES 2011 and a paper is in preparation.

- Generating multimedia streams, such as in a netradio, is a task which is complex and difficult to adapt to every users’ needs. D. Baelde, in cooperation with R. Beauxis (Tulane University, LA, USA) and S. Mimram (CEA List) introduce a novel approach, based on a dedicated high-level functional programming language, called Liquidsoap, for generating, manipulating and broadcasting multimedia streams \[20\]. Unlike traditional approaches, which are based on configuration files or static graphical interfaces, it also allows the user to build complex and highly customized systems. This language is based on a model for streams and contains operators and constructions, which make it adapted to the generation of streams. The interpreter of the language also ensures many properties concerning the good execution of the stream generation.

6.2. Proofs of Imperative Programs

- The Why3 reimplementation of the Why platform, started in 2010, was publicly released in 2011 \[35\]. The main developers are A. Paskevich, J.-C. Filliâtre, F. Bobot, and C. Marché. The language of Why, both programming and annotation parts, was significantly extended: algebraic types, records, pattern matching, recursive logical definitions are now supported. These logical declarations are structured in modules (a.k.a. theories). The module language comes with an original mechanism for reusing theories in specialized contexts using partial instantiations. These new features have been presented at the first international workshop on intermediate verification languages (BOOGIE 2011) \[21\] and will be presented at VSTTE 2012 \[69\].
• A. Tafat and C. Marché used the Why3 system to perform a complete proof of the “Binary Heaps” challenge [41] from the VACID-0 international collection [76]. Solving this challenge is a case study for a general approach of abstract interfaces for C programs, currently under development by A. Tafat, based on initial ideas described together with S. Boulmé which were published in a 2011 special issue [29].

• In 2011, we set up a web gallery to publicly expose the programs that we specified and proved. This is the so-called ProVal collection of verified programs, and available at URL http://proval.lri.fr/gallery/index.en.html.

• K. Krishnamani and C. Marché proposed a technique for automatically generating loop invariants in C programs. It is based on the well-known predicate abstraction approach, which is adapted to take into account pre-existing specifications, and to proceed modularly, that is each function of a program is processed independently, with its own sets of predicates. The approach is also extended in order to generate universally quantified invariants [38]. The prototype is available as a Frama-C plugin at URL http://proval.lri.fr/agen.

• C. Dross, together with Y. Moy (AdaCore) and J.-C. Filliâtre, addressed the problem of verifying programs involving containers. Containers such as lists, vectors, sets or maps are an attractive alternative to ad-hoc data structures based on pointers. C. Dross gave a definition of containers whose aim is to facilitate their use in certified software, using modern proof technology and novel specification languages. Correct usage of containers and user-provided correctness properties can be checked either by execution during testing or by formal proof with an automatic prover. It relies on a formal semantics for containers and an axiomatization of this semantics targeted at automatic provers. C. Dross proved in Coq that the formal semantics is consistent and that the axiomatization thereof is correct. This work was presented at TAP 2011 [26].

• Proving that pointer programs preserve data invariants, in a modular way, is known to be a challenge. R. Bardou and C. Marché designed a new approach based on advanced static typing systems (based on memory regions and permissions) to control memory updates and ownership of data [11]. A prototype implementation is built, called Capucine, available for download at http://romain.bardou.fr/capucine. To demonstrate the ability of this approach, the challenge “sparse arrays” of the VACID-0 benchmarks [76] has been certified [30].

• Separation logic has shown to be an elegant way to deal with programs which use data-structures with pointers. However it requires a specific logical language, provers, and specific reasoning techniques. In his PhD, F. Bobot introduced a technique to express ideas from separation logic in the traditional framework of deductive verification [12]. He proposed to derive “separation predicates” from user-supplied inductive definitions. These predicates come with suitable axiomatization, including frame rules, expressed in usual first-order logic. This translation takes special care to ensure the best use of automated theorem provers.

6.3. Automated Deduction

• In his thesis [14], S. Lescuyer formalized and designed purely reflexive tactics for automated deduction in Coq.

• É. Contejean, together with Pierre Courtieu, Julien Forest, Olivier Pons and Xavier Urbain (Cedric Laboratory, CNAM & ENSIIE) presented the last version of the rewriting toolkit CiME3 at RTA 2011 [25]. Amongst other original features, this version enjoys two kinds of engines: to handle and discover proofs of various properties of rewriting systems, and to generate Coq scripts from proof traces given in certification problem format in order to certify them with a skeptical proof assistant like Coq. Thus, these features open the way for using CiME3 to add automation to proofs of termination or confluence in a formal development in the Coq proof assistant.
• In their TACAS paper [24], S. Conchon, É. Contejean and M. Iguernelala present a modular extension of ground AC-completion for deciding formulas in the combination of the theory of equality with user-defined AC symbols, uninterpreted symbols and an arbitrary signature disjoint Shostak theory X.

• F. Bobot and A. Paskevich studied translation from a first-order logic with polymorphic types à la ML (which is the base logic of the Why platform and the Alt-Ergo theorem prover) to a many-sorted or one-sorted logic implemented in mainstream automated theorem provers. They devised a three-stage scheme where the last stage eliminates polymorphic types while adding the necessary “annotations” to preserve soundness, and the first two stages serve to protect certain terms so that they can keep their original types and unannotated form. Such protection allows to make use of provers’ built-in theories and operations. This work generalizes the previous study by S. Lescuyer and J.-F. Couchot [65] onto arbitrary monomorphic types, e.g. array types. It was presented at FroCoS 2011 [22] (see also an extended version with full proofs [42]). These results are part of F. Bobot’s PhD thesis [12].

6.4. Floating-Point and Numerical Programs

• T. Nguyen and C. Marché have worked on how to prove floating-point programs while taking into account architecture- and compiler-dependent features such as the use of the x87 stack in Intel microprocessors. This is done by analyzing the assembly code generated by the compiler [40], [28]

• S. Boldo and C. Marché published a survey article on the proofs of numerical C programs using both automatic provers and Coq [15].

• S. Boldo and T. Nguyen have worked on how to prove numerical programs on multiple architectures and compilers [17]. More precisely, it covers all the compiler choices about the use of extended registers, FMA, and reorganization of additions.

• S. Boldo and J.-M. Müller (CNRS, Arénaire, LIP, ÉNS Lyon) have worked on new floating-point algorithms for computing the exact and approximated errors of the FMA (fused multiply-and-add) [16].

• S. Boldo and G. Melquiond have developed in Coq a comprehensive formalization of floating-point arithmetic: core definitions, axiomatic and computational rounding operations, high-level properties [23]. It provides a framework for developers to formally certify numerical applications.

• G. Melquiond, in collaboration with F. de Dinechin (Arénaire, LIP, ÉNS Lyon) and C. Lauter (Intel Hillsboro), has improved the methodology for formally proving floating-point mathematical functions when their correctness depends on relative errors [19].

• S. Boldo, J.-C. Filliâtre and G. Melquiond, in collaboration with F. Clément (Estime, INRIA Paris-Rocquencourt) and M. Mayero (University Paris 13) have finished a full formal proof of a program solving a partial differential equation (the wave equation) using a finite difference scheme [36]. This proof includes both the mathematical convergence proof (method error) [57], a tricky floating-point proof [56] and proofs of the absence of runtime errors.

• C. Lelay, under the supervision of S. Boldo and G. Melquiond, has worked on differentiability in Coq. The goal was to prove the existence of a solution to the wave equation thanks to D’Alembert’s formula and to automatize the process as much as possible [44] [77].

• G. Melquiond, in collaboration with W. G. Nowak (Institute of Mathematics, Austria) and P. Zimmermann (Caramel, INRIA Nancy-Lorraine), has designed new methods for computing guaranteed enclosures of the Masser-Gramain constant, a two-dimensional analogue of the Euler-Mascheroni constant [86].

• G. Melquiond, in collaboration with J-M. Muller (CNRS, Arénaire, LIP, ÉNS Lyon) and E. Martin-Dorel (Arénaire, LIP, ÉNS Lyon), has worked on weakening the assumptions floating-point error-free transformations rely on [39].
PULSAR Project-Team

6. New Results

6.1. Introduction

This year Pulsar has tackled several issues related to its two main research axes: scene understanding for activity recognition and software engineering for activity recognition.

6.1.1. Scene Understanding for Activity Recognition

This year Pulsar has proposed new algorithms in computer vision (people head and face detection and people re-identification), in reasoning (activity recognition and uncertainty handling). More precisely, the new results for this research axis concern:

- People detection in monocular video sequences (6.2)
- Online Parameter Tuning for Object Tracking Algorithms (6.3)
- Fiber Based Video Segmentation (6.4)
- Multiple Birth and Cut Algorithm for Multiple Object Detection (6.5)
- Exhaustive Family of Energies Minimizable Exactly by a Graph Cut (6.6)
- Steepest Descent in Banach Spaces with Application to Piecewise-Rigid Evolution of Curves (6.7)
- Object Tracking Using a Particle Filter based on SIFT Features (6.8)
- Human Re-identification using Riemannian Manifolds (6.9)
- Global Tracking of Multiples Actors (6.10)
- Crowd Data Collection from Video Recordings (6.11)
- Events Recognition and Performance Evaluation (6.12)
- Group interaction and group tracking for video-surveillance in underground railway stations (6.13)
- Action Recognition in Videos (6.14)
- Activity Recognition Applied on Health Care Application (6.15)
- A Cognitive Vision System for Nuclear Fusion Device Monitoring (6.16)
- Scenario Recognition with depth camera (6.17)
- Trajectory Clustering for Activity Learning (6.18)

6.1.2. Software Engineering for Activity Recognition

Participants: François Brémont, Bernard Boulay, Hervé Falciani, Daniel Gaffé, Julien Gueytat, Sabine Moisan, Annie Ressouche, Jean-Paul Rigault, Leonardo Rocha, Sagar Sen, Daniel Zullo.
This year Pulsar has improved the SUP platform. This latter is the backbone of the team experiments to implement the new algorithms proposed by the team in perception, understanding and learning. We improve our meta-modeling approach to support the development of video surveillance applications based on SUP. We continue the development of a scenario recognition module relying on formal methods to support activity recognition in SUP platform. We also continue to study the definition of multiple services for device adaptive platform for scenario recognition. Finally, we are implementing the new theoretical results obtained last year to improve the Clem toolkit.

The new results related to this research axis concern:

- SUP Software Platform (6.19)
- Model-Driven Engineering and Video-surveillance (6.20)
- Scenario Analysis Module (6.22)
- Multiple Services for Device Adaptive Platform for Scenario Recognition (6.23)
- The Clem Toolkit (6.24)

### 6.2. People detection in monocular video sequences

**Participants:** Etienne Corvee, François Brémond, Silviu-Tudor Serban, Vasanth Bathrinaryanan.

A video understanding system analyzes human activity by detecting people in video sequences and tracking their displacement and movement throughout the sequences. The better the detection quality, the higher the semantic level of the information is. People activity can differ greatly from one application to another e.g. the presence of a person in one zone can simply be detected from a moving pixel region in a manually specified zone whereas detecting people fighting in a subway requires more complex information. For people activity to be recognized, one needs to detect people accurately in videos and at real time frame rate. Current state of the art algorithms provide generic people detection solutions but with limited accuracy. In the people monitoring domain, although cameras remain mostly fixed, many issues occur in images. For example, outdoor scenes display strong varying lighting conditions (e.g. sunny/cloudy illumination, important shadows), public spaces can be often crowded (e.g. subways, malls) and images can be obtained with a low resolution and can be highly compressed. Hence, detecting and tracking objects in such complex environment remains a delicate task to perform. In addition, detecting people has to face one major difficulty which is caused by occlusion where important information is hidden. When people overlap onto the image plane, their foreground pixels cannot be separated using a standard thresholding operation from a background reference frame. Therefore vision algorithms need to use information held by the underlying pixels and located at specific locations such as body parts.

We have extended our work by implementing and testing a novel people, head and face detection algorithm using Local Binary Pattern based features and Haar like features. The traditional and efficient Adaboost training scheme is adopted to train object features from publicly available databases. This work has been published in the ICVS Workshop [36].

The work has been tested for group tracking in Vanaheim videos (see section 8.2.1.2) and for people tracking in Videold videos. The Videold project aims to re-identify people across a network of non overlapping cameras using iris, face and human appearance recognition. An example of tracked people, head and faces in a testing database is shown in figure 7. An example of re-identified face is shown in figure 8 by the Videold interface in a Paris underground video.

We have evaluated our people detection algorithm on the test human dataset provided by INRIA against state of the art algorithms which we refer as HOG [59] and LBP-HOG [77]. The INRIA human dataset is composed of 1132 human images and 453 images of background scenes containing no human. The results are displayed in figure 9 which shows that we obtain slightly better performances than the HOG-LBP technique in terms of missed detection rate vs. FPPI i.e. False Positive Per Image. In this figure, two extreme functioning modes could be chosen: approximately 2 noisy detections are obtained every 1000 background images for 50% true positive detections or 1 noisy detection every 2 frames for a detection rate of approximately 88%.
Figure 7. Example of tracked people, head and face

Figure 8. Face recognition in Paris underground
The same evaluation scheme of people detection above is used for face detection evaluation. The FPPI rates are obtained on 997 NICTA [66] background images of 720x576 pixels. 180 faces provided by a CMU test face image database are used to evaluate true positive rates. We have compared our results with the 2 versions of Haar feature provided by the OpenCv library i.e. the standard ‘default’ and alternative ‘alt’ training parameters. The results in table 1 show that the Haar ‘alt’ technique performs better than the traditional Haar one. And our haar based technique called CCR provides similar face detection rates while giving a less false alarm rate. The proposed approach is approximately 1% less successful in detecting faces than the Haar technique while this latter is 32% more noisy than our CCR technique.

6.3. Online Parameter Tuning for Object Tracking Algorithms

Participants: Duc Phu Chau, Monique Thonnat, François Brémond.

Many approaches have been proposed to track mobile objects in a scene. However the quality of tracking algorithms always depends on scene properties such as: mobile object density, contrast intensity, scene depth and object size. The selection of a tracking algorithm for an unknown scene becomes a hard task. Even when the tracker has appropriately selected, it is difficult to tune online its parameters to get the best performance. Therefore we propose a new control approach for mobile object tracking. More precisely in order to cope with the tracking context variations, this approach learns how to tune the parameters of object appearance-based tracking algorithms. The tracking context of a video sequence is defined as a set of features: density of mobile objects, their occlusion level, their contrasts with regard to the background and their 2D areas. In an offline supervised learning phase, satisfactory tracking parameters are searched for each training video sequence. Then these video sequences are classified by clustering their contextual features. Each context cluster is associated with the learned tracking parameters. In the online control phase, two approaches are...
propose a context, once a context change is detected, the tracking parameters are tuned for the new context using the learned values. In the second approach, the parameter tuning is performed when the context changes and the tracking quality (computed by an online performance evaluation algorithm [56]) is not good enough. An online learning process enables to update the context/parameter relations.

We have also proposed two new tracking algorithms to experiment the proposed control method. The first tracker relies on a Kalman filter and a global tracking which aims at fusing trajectories belonging to the same mobile object. This work has been published in [35]. The second tracker relies on the similarities of eight object descriptors (2D and 3D positions, area, shape ratio, HOG, color histogram, color covariance, and dominant color) to build object trajectories. This work has been published in [34].

The proposed controller has been experimented on a long, complex video belonging to the Caretaker European project 1 (see figure 10 (a)) and 26 videos of Caviar dataset 2 (see figure 10 (b)). For the Caretaker video, when the controller is used, the tracking quality increases from 52% to 78%. For the Caviar dataset, the experimental results show that the tracking performance increases from 78.3% to 84.4% when using the controller. The tracking results on Caviar videos with the proposed controller are as good as the ones obtained with manual parameter tuning.

6.4. Fiber Based Video Segmentation

Participants: Ratnesh Kumar, Guillaume Charpiat, Monique Thonnat.

The aim of this work is to segment objects in videos by considering videos as 3D volumetric data (space×time). Figure 11 shows 2D slices of a video volume. Bottom right corner of each figure shows the current temporal depth in the volume, while top right shows the X-time slice and bottom left shows Y-time slice. In this 3D representation of videos, points of static background form straight lines of homogeneous intensity over time, while points of moving objects form curved lines. Analogous to the fibers in MRI images of human brains, we name fibers, these straight and curved lines of homogeneous intensity. So, in our case, to segment the whole video volume data, we are interested in a dense estimation of fibers involving all pixels.

For the detection of these fibers, we use motion flow vectors and intensity correlation of 2D patches over time. As these techniques are not reliable everywhere in the image domain, we sort the fibers based on the reliability of the detections from these techniques. The subsequent goal is then to pick high ranked fibers to propagate motion information and boundary fronts to other regions of the 3D volume.

1 http://cordis.europa.eu/ist/kct/caretaker_synopsis.htm
2 http://homepages.inf.ed.ac.uk/rbf/CAVIARDATA1/
To reliably propagate information from a fiber, we express the reliability of detection of a fiber and the cost of propagation of information from it. The later can be based on a distance measure of a pixel from a fiber, while reliability of a fiber involves motion coherency, color homogeneity, duration along time axis etc.

Our work closely relates to [72]. A video is represented by a set of particles (trajectory of an image point sample). The algorithm then extends and truncates particle trajectories to model motion near occlusion boundaries.

Figure 12 shows some straight fibers found in a video volume. The reliability of these fibers is based on temporal length. Fibers which have temporal span same as that of the video are colored in green, while fibers which have temporal span of less than 10% of the video are colored blue. Red colored fibers have temporal length in between green and blue colored fibers.

6.5. Multiple Birth and Cut Algorithm for Multiple Object Detection

Participant: Guillaume Charpiat.

In collaboration with the Ariana team (Ahmed Gamal-Eldin, Xavier Descombes and Josiane Zerubia), we developed a new optimization method which we call Multiple Birth and Cut (MBC). It combines the recently proposed Multiple Birth and Death (MBD) algorithm and the Graph-Cut algorithm. MBD and MBC optimization methods are applied to energy minimization of an object based model, the marked point process. The most important advantage of the MBC over MBD is the reduction of number of parameters. By proposing good candidates throughout the selection phase in the birth step, the speed of convergence is increased. In
this selection phase, the best candidates are chosen from object sets by a belief propagation algorithm. The algorithm is applied on the flamingo counting problem in a colony [37], [26].

6.6. Exhaustive Family of Energies Minimizable Exactly by a Graph Cut

Participant: Guillaume Charpiat.

Graph cuts are widely used in many fields of computer vision in order to minimize in small polynomial time complexity certain classes of energies. These specific classes depend on the way chosen to build the graphs representing the problems to solve. We study here all possible ways of building graphs and the associated energies minimized, leading to the exhaustive family of energies minimizable exactly by a graph cut. To do this, we consider the issue of coding pixel labels as states of the graph, i.e. the choice of state interpretations. The family obtained comprises many new classes, in particular energies that do not satisfy the submodularity condition, including energies that are even not permuted-submodular.

We studied in details a generating subfamily, in particular we proposed a canonical form to represent Markov random fields, which proves useful to recognize energies in this subfamily in linear complexity almost surely, and then to build the associated graph in quasilinear time. We performed a few experiments to illustrate the new possibilities offered [33]. We have also started to use this technique to minimize exactly approximations of Markov random field energies instead of minimizing approximately the exact energies, by projecting energies on the family we know to solve globally efficiently.

6.7. Steepest Descent in Banach Spaces with Application to Piecewise-Rigid Evolution of Curves

Participant: Guillaume Charpiat.

This is joint work with Gabriel Peyré (CNRS, Ceremade, Université Paris-Dauphine). We intend to favor piecewise-rigid motions, i.e. articulated movements, during shape evolutions, especially when computing morphings or image segmentation with shape prior. To do this, we first need a dissimilarity measure between shapes, whose gradient is meaningful. We formulate one using kernels and bistochastization.

The parameters of these kernels are automatically estimated in a fixed-point scheme that guarantees physical relevance, and the notion of bistochastization is extended to continuous distributions. Finally, piecewise rigidity is ensured during gradient descents by a change of the norm from which the gradient is derived. This norm is formulated so as to favor sparse second derivatives, which produces articulated movements without knowing by advance the location of the articulations.

The formula of the norm is actually elegantly simple, involving simple geometric quantities, derivatives, and the $L_1$ norm. Note that this norm does not derive from an inner product but defines a gradient in the sense of [5] as the minimizer of an energy. It turns out that in our case the energy defining the gradient is actually convex, and efficient minimization follows.

6.8. Object Tracking Using a Particle Filter based on SIFT Features

Participants: Malik Souded, François Brémond.

The approach consists in detecting SIFT points of interest on the objects to track, calculating their SIFT descriptors, tracking these points with a particle filter, and finally achieving tracking process by linking them along the time with links which are weighted by measures on SIFT descriptors and reliability.

The main contributions in this work are on three points.

The first point consists in techniques of detection and selection of SIFT points, allowing a better distribution of points of interest on the target and allowing better management of partial occlusions, and secondly an optimized computing time thanks to the parallelization of these SIFT computation on modern processors (see figure 13).
The second point concerns the weighting of the particles during tracking. This is done with a combination of two kinds of information: the similarity measure of the SIFT descriptor and the state of motion of pixels corresponding to the particles. This allows more robust tracking of SIFT points regardless of the quality of the background subtraction providing the detected objects.

The last point concerns the selection of temporal links between tracked objects and detected ones. These links are selected according to their weight. The weight of each link is based on the proportion of common SIFT points to both objects (two successive images) potentially linked, and the reliability of each of these SIFT point. This reliability is calculated for each point by measuring the variation of the SIFT descriptor during the tracking time.

The occlusion management is performed using three types of information: SIFT descriptors used for tracking (matching after reappearance) the dominant colors of the object of interest and finally the width, height, and speed (in real world) of the object, which are learned in Gaussian models during the tracking (tracking being used with video cameras which have been calibrated), see figure 14.

The approach was tested on 121 sequences of four different datasets: 80 sequences from CAVIAR, 34 sequences from ETISEO, 3 sequences from PETS2001 and 2 sequences from VS_PETS2003. The obtained results are satisfying. The comparison of these results with the state of the art shows improvements for the benchmarking dataset (ETISEO). The following table compares the proposed approach and state of the art results on ETISEO data base:

### 6.9. Human Re-identification using Riemannian Manifolds

**Participants:** Sławomir Bąk, Etienne Corvée, François Brémond, Monique Thonnat.

This work addresses the human re-identification problem, which is defined as a requirement to determine whether a given individual has already appeared over a network of cameras. This problem is particularly hard by significant appearance changes across different camera views. In order to re-identify people, a human signature should handle difference in illumination, pose and camera parameters.
We propose new appearance models based on the mean riemannian covariance (MRC) matrices combining the appearance information from multiple images. These mean covariance matrices not only keep information on feature distribution but also carry out essential cues about temporal changes of an appearance. Using MRC-s, we propose two methods for an appearance representation:

- **Learned Covariance Patches (LCP)** [25] - a distinctive representation is extracted by a boosting scheme. The structure of MRC patches (size, position) is learned using boosting algorithm based on confidence-rated predictions (see Fig. 15 (a)). These confidence-rated coefficients are employed to weight appearance characteristics of a specific individual w.r.t. the reference (training) dataset of humans.

- **Mean Riemannian Covariance Grid (MRCG)** [30] - less computationally demanding technique than LCP. We represent a human appearance by a grid of MRC cells (see Fig. 15 (b)). Relevant cells are identified by an efficient discriminant analysis. This analysis takes into account variance of MRC patch in the class of humans (reference dataset). MRC is assumed to be more significant when its variance is larger in the class of humans: (1) the most common patterns belong to the background (the variance is small); (2) the patterns which are far from the rest are at the same time the most discriminative (the variance is large). All operations, such as mean or variance, are performed on covariance manifold specified as Riemannian.

Both methods are evaluated and compared with the state of the art using publicly available datasets. We demonstrate that the proposed approaches outperform state of the art methods. Further, we extract new sets of individuals from i-LIDS data to investigate more carefully advantages of using many images for human re-identification.

The computation complexity is analyzed in the context of distance operator between two signatures. Comparing two human signatures, it is necessary to compute distance between covariance matrices, which requires solving the generalized eigenvalues problem. This operation is computationally heavy. In [31], we propose an implementation for finding generalized eigenvalues and eigenvectors for distance operator, using NVIDIA GPU architecture. We improve significantly the performance, reaching 66 speedup using Tesla S1070.
6.10. Global Tracking of Multiples Actors

**Participants:** Julien Badie, François Brémond.

We propose a new approach for long term tracking of individuals. Our main objective is to design a tracking algorithm for people reidentification [30] that can track people even if they come back in the scene after leaving it. This algorithm is based on covariance matrix and we have also added some contextual information of the scene (for instance, zones where people can enter the scene) to improve tracking performance. In addition, a basic noise detection system and a tracking correction system are proposed in order to handle short-term tracking errors such as multiplication of IDs corresponding to only one individual. The noise detection system is designed to find and remove objects that are detected in a very small number of consecutive frames (for instance 4) and disappear afterward. The tracking correction system associates IDs recently lost with IDs that have just started to be tracked based on geometrical features and 3D distance criteria.

As a result, the tracking quality is significantly improved on 5 video sequences tested from the ETISEO dataset[^3]. The people reidentification algorithm gives encouraging results for future work. The number of IDs associated to one individual is reduced (on average 50% less) and the tracking quality improves due to the IDs stability. This algorithm can detect not only people re-entering the scene but also trajectory interruptions due to occlusions or misdetections.

This approach could enable the detection of new kinds of events on video sequences such as long range people tracking on a camera network.

---

6.11. Crowd Data Collection from Video Recordings

**Participants:** Jihed Joobeur, François Brémond.

The aim of this work is to analyze crowd behaviors by detecting specific situations: panic, congestion, fighting etc. We validate our work with subway station videos from VANAHEIM project. We use Mixture of Gaussian based segmentation to extract moving point and then detecting moving objects. Subsequently inside these moving objects we detect FAST feature points and compute HOG descriptors for tracking these points. We compute different features based on these points like speed and orientation. To estimate the crowd density we use features based on Grey-Level Co-occurrence Matrix. As these features depend on the distance of people from the camera, we divide the scene into different zones which have each zone same distance from the

---

Figure 16. The green lines are the ground-truth and the blue lines are the tracking results using both reidentification and noise removal (left) and with only noise removal (right). The man is tracked throughout the whole video with a single ID (68).
camera. In each area, compiling all the information on speed, direction and learned over a threshold density of the crowd, we can learn and detect different situations. For example, if the density increases and the average speed decreases in a pre-defined zone, that may correspond to a congestion situation.

On figure 17 the FAST feature points are shown in blue points, while the tracking of these points is shown in yellow.

![Feature points detection and tracking in different zones.](image)

**Figure 17. Feature points detection and tracking in different zones.**

### 6.12. Events Recognition and Performance Evaluation

**Participants:** Ricardo Cezar Bonfim Rodrigues, François Brémond.

The goal of this work is to evaluate the accuracy and performance of events detection, see workflow in Figure 18. The experiments will be performed using the tools developed in Pulsar team, such as Scene Understand Platform (SUP) \(^4\) a plugin for events detection \([50]\) and ViSEvAl \(^5\).

The experiments were performed using video sequences of a subway station (VANAHEIN dataset) where the goal was to detect events such as people waiting, entering, buying tickets and so on. Preliminary results showed a very low accuracy and demonstrated that the scenario configuration parameters are very sensitive in this problem. It means many of the expected events were missed or misclassified, specially composite events (when more than one activity recognition is required) see some issues on Figure 19.

Based on the issues, a second experiment was configured using 3 different video sequences. In this new experiment, the scenario was adjusted to give more tolerances to people detection issues, the camera calibration was refined and some events were remodeled. After these changes the results were significantly improved. This last experiments showed that the engine proposed by Pulsar team is able to detect events accurately however events modeling can be very sensitive to the scenario configuration, see the results in Table 3.

Table 3. Results of events detection based on the people detection performed in experiment 2 using an IDIAP algorithm. The global Precision and sensibility of people detection are respectively 0.91 and 0.95.

6.13. Group interaction and group tracking for video-surveillance in underground railway stations

Participants: Sofia Zaidenberg, Bernard Boulay, Carolina Garate, Duc-Phu Chau, Etienne Corvée, François Brémont.

One goal in the European project VANAHEIM is the tracking of groups of people. Based on frame to frame mobile object tracking, we try to detect which mobiles form a group and to follow the group through its lifetime. We define a group of people as two or more people being close to each other and having similar trajectories (speed and direction). The dynamics of a group can be more or less erratic: people may join or split from the group, one or more can disappear temporarily (occlusion or disappearance from the field of view) but reappear and still be part of the group. The motion detector which detects and labels mobile objects may also fail ( misdetections or wrong labels). Analyzing trajectories over a temporal window allows handling this instability more robustly. We use the event-description language described in [50] to define events, described using basic group properties such as size, type of trajectory or number and density of people and perform the recognition of events and behaviors such as violence or vandalism ( alarming events) or a queue at the vending machine ( non-alarming events). Two approaches to this problem have been implemented. The first approach takes as input the frame-to-frame tracking results of individual mobiles and tries to gather them into groups based on their trajectories through the temporal window. Each group has a coherence coefficient. This coefficient is a weighted sum of three quantities characterizing a group: the group density (average of distances between mobiles), the similarity of mobile’s speed and the similarity of their motion directions. The update of a group consists in recalculating the group coherence with new mobiles from the current frame. If adding the mobile does not put the coherence under a defined threshold, the mobiles are added to the group. A pre-selection is made by only considering mobiles that are close enough to the center of gravity of the group. After the update step, all mobiles that have not been assigned to a group are analyzed to form new groups if possible.

A first improvement has been done by integrating the use of the LBP-based people detector described in [36]. This makes the algorithm more robust to false detections such as train doors closing. But on the other hand, it also introduces false negatives as, among other things, people are only detected if fully visible in the image. The group tracking algorithm has been tested both with the original, background subtraction-based mobile object detection ( noted S hereafter) and the LBP-based people detection ( noted LBP hereafter).

For evaluating the detection, we used 3 annotated sequences: Sequence 1 is a short sequence of 128 frames with just one ground truth object (one group), Sequence 2 has 1373 frames and 9 ground truth objects, and Sequence 3 is 17992 frames long and 25 ground truth objects were annotated. Detection and tracking results are shown in table 4.

The whole algorithm chain has been integrated into the common VANAHEIM platform and sent to partners for pre-integration.

We also used videos from the ViCoMo project, recorded in the Eindhoven airport to test our approach. No formal evaluation has been done yet on these sequences due to the lack of ground truth. Nevertheless, these videos contain several acted scenes which could be successfully recognized: groups merging, splitting and entering a forbidden zone.

This work has been published in [50].

In parallel, a new approach is being developed, making use of a long-term tracker described in [35]. This tracker provides more robust individual trajectories to the group tracker, containing less confusions in cases where people cross each other. We apply the Mean Shift clustering algorithm on trajectories of people through a sliding time window (e.g. 10 frames). If the target is lost in one or several frames, we interpolate its positions. The clustering brings together mobiles having similar trajectories, which is our definition of a group. At each frame, clusters are calculated and then a matching is done to associate clusters to existing groups in the previous frame, and thus track groups. Looking backwards (within a window) on the trajectory of a mobile we might find a mobile on that trajectory that belongs to a group. If such a group is found, it is called the probable

group of the current mobile. Each trajectory cluster is associated to the group that is the probable group of most mobiles in the cluster. Several clusters may be associated to the same group. This cluster association makes the algorithm robust to cases where one or several mobiles temporarily separate from the group. If the separation is longer than the time window, the probable group of these mobiles will be empty and a split will be detected.

Additionally, we work on improving the people detection by combining both methods: background subtraction-based and LBP-based. We compare overlapping mobiles from both methods and choose the best one based on their respective confidence values and their sizes. If a target was detected by only one of the two methods, we keep the target given that the confidence is high enough. If a mobile from the background subtraction method is big enough to cover several LBP-detected people (the LBP-based people detection output targets have the size of a human, whereas the background subtraction can detect a bigger mobile with the size of a GROUP_OF_PEOPLE), we attach the LBP-people as sub-mobiles of the group mobile so no information is lost. This method is a work in progress and no evaluation have been done yet.

Figure 20 shows two examples of group and event detection.

Participants: Piotr Bilinski, François Brémond.

The aim of this work is to learn and recognize short human actions in videos. We perform an extensive evaluation of local spatio-temporal descriptors, then we propose a new action recognition approach for RGB camera videos. We also propose a new approach for RGB-D cameras. For all our experiments, we develop an evaluation framework based on the bag-of-words model, SVM and cross-validation technique. We use the bag-of-words model to represent actions in videos and we use non-linear multi-class Support Vector Machines together with leave-one-person-out cross-validation technique to perform action classification.

Local spatio-temporal descriptors have shown to obtain very good performance for action recognition in videos. Over the last years, many different descriptors have been proposed. They are usually evaluated using too specific experimental methods and using different datasets. Moreover, existing evaluations make assumptions that do not allow to fully compare descriptors. In order to explore capabilities of descriptors, we perform an extensive evaluation of local spatio-temporal descriptors for action recognition in videos. Four widely used state-of-the-art descriptors (HOG, HOF, HOG-HOF and HOG3D) and four video datasets (Weizmann, KTH, ADL and KECK) have been selected. In contrast to other evaluations, we test all the computed descriptors, we perform experiments on several codebook sizes and use several datasets, differing in difficulty. Our results show how the recognition rate depends on the codebook size and the dataset. We
observe that usually the HOG descriptor alone performs the worst but outperforms other descriptors when it is combined with the HOF descriptor. Also, we observe that smaller codebook sizes lead to consistently good performance across different datasets. This work has been published in [32].

We also propose a new action recognition method for RGB camera videos based on feature point tracking and a new head estimation algorithm. We track feature points along a video and compute appearance features (HOG-HOF) for each trajectory. Additionally, we estimate a head position for each visible human in the video, using the following chain: segmentation, person, head and face detectors. Finally, we create an action descriptor based on the combination of all these sources of information. Our approach has been evaluated on several datasets, including two benchmarking datasets: KTH and ADL, and our new action recognition dataset. This new dataset has been created in cooperation with the CHU Nice Hospital. It refers to people performing daily living activities like: standing up, sitting down, walking, reading a magazine etc.

We also study the usefulness of low-cost RGB-D camera for action recognition task. We propose a new action recognition method using both RGB and depth information. We track feature points using RGB videos and represent trajectories in a four-dimensional space using additionally depth information. Experiments have been successfully performed on our new RGB-D action recognition dataset, recorded using Microsoft’s Kinect device.

### 6.15. Activity Recognition Applied on Health Care Application

**Participants:** Rim Romdhane, Veronique Joumier, François Brémond.

The aim of this work is to propose a constraint-based approach for video event recognition with probabilistic reasoning for handling uncertainty. This work was validated on health care applications.

#### 6.15.1. Event Recognition

We propose an activity recognition framework which is able to recognize composite events with complex temporal relationships. We consider different aspects of the uncertainty of the recognition during the event modeling and the event recognition process to overcome the noise or missing observations which characterize real world applications.
To reach this goal, we manage the uncertainty in the event modeling and event recognition processes by a combination of logical and probabilistic reasoning for handling uncertainty. We improve the event description language developed in Pulsar team and introduce a new probabilistic description based approach to gain in flexibility for event modeling by adding the notion of utility. Utility expresses the importance of sub-events to the recognition of the whole event. We compute the probability of recognition for both primitive (i.e. elementary) events and composite events based on Bayesian theory.

We compute the probability that the event $e$ is recognized given a sequence of observations $O$ as described in [48]. The observations consist of the set of the physical objects $po_e$ moving in the scene. If the probability of an event is over a predefined threshold, the event is recognized.

6.15.2. Health Care Application

The proposed event recognition approach is validated using the videos from the health care application SWEETHOME (http://cmrr-nice.fr/sweethome/) and CIUSante (https://extranet.chu-nice.fr/ciu-sante). We have worked in close collaboration with clinicians from Nice hospital to evaluate the behaviours of Alzheimer patients. We have first model 69 event models for health care application using our event modeling formalism. With the help of clinicians we have established a scenario protocol. The scenario is composed of three parts: (1) directed activities (10 min), (2) semi directed activities (20 min), (3) free activities (30 min). Experiments have been performed in a room of Nice hospital equipped with 2 video cameras where 45 elderly volunteers have spent between 15 min to 1 hour. Volunteers include Alzheimer patients, MCI (mild cognitive impairment) and healthy elderly.

The study described in [38] and [27] shows the ability of the proposed automatic video activity recognition system to detect activity changes between elderly subjects with and without dementia during a clinical experimentation. A total of 28 volunteers (11 healthy elderly subjects, 17 Alzheimer’s disease patients (AD)) participate to the experimentation. The proposed study shows that we could differentiate the two profiles of participants based on motor activity parameters, such as the duration of the recognized activities, the strike length and the walking speed, computed from the proposed automatic video activity recognition system. These primary results are promising and validating the interest of automatic analysis of video as an objective evaluation tool providing comparative results between participants and over the time.

Participants: Guillaume Charpiat, Vincent Martin, François Brémond, Monique Thonnat.

In collaboration with Victor Moncada, Jean-Marcel Travere and Thierry Loarer (CEA Cadarache), we propose a cognitive vision-based system for the intelligent monitoring of tokamaks during plasma operation, based on multi-sensor data analysis and symbolic reasoning. The practical purpose is to detect and characterize in real time abnormal events such as hot spots measured through infrared images of the in-vessel components in order to take adequate decisions. Our system is made intelligent by the use of a priori knowledge of both contextual and perceptual information for ontology-driven event modeling and task-oriented event recognition. The system is made original by combining both physics-based and perceptual information during the recognition process. Real time reasoning is achieved thanks to task-level software optimizations. The framework is generic and can be easily adapted to different fusion device environments. The developed system and its achievements on real data of the Tore Supra tokamak imaging system can be found in [39].

6.17. Scenario Recognition with depth camera

Participants: Bernard Boulay, Daniel Zullo, Swaminathan Sankaranarayanan, François Brémond.

Thanks to Microsoft and its kinect sensor, RGB-depth camera becomes popular and accessible. The basic idea of depth camera is to combine a visible camera, with an IR camera associated to a laser to determine the depth of each image pixel. This kind of sensor is well adapted for applications which monitor people (e.g. monitoring Alzheimer patient in hospital): because the people are in a predefined area and near the camera.
The depth cameras have two main advantages: first, the output image contains depth information and second, the sensor is independent from the light changes (IR sensor).

In our work, we propose to use the Kinect sensor to acquire 3D images, detect the people and recognize interesting activities (see Figure 21).

![Kinect sensor](image)

**Figure 21. People detection and activity recognition in day and night conditions with Kinect sensor.**

The nestk library is used to manage the Kinect sensor. This library is based on OpenNI framework (an open source driver) to acquire the images. Moreover, the library is able to compute some treatments (e.g., people detection) and to provide a true 3D map of the scene in the referential of the Kinect.

Basic attributes are computed for each detected person: 3D position, 3D height,... These attributes are then used to compute more complex information: speed, global posture to recognize interesting activities thanks to the ScreKs framework (scenario recognition based on expert knowledge) of the SUP platform as walking, stopping, standing, sitting,... (following a protocol delivered by doctors). Then, we have a plug and play system able to recognize basic activities associated to a person.

Moreover, if information on the scene, as interesting zones, or equipment are available, complex activities can be recognized as nurse explaining exercise or nurse switching off the light.

The next step is to use the human skeleton detection to recognize precisely the posture of the patient in order to understand more precise activities and infer a behaviour model.

### 6.18. Trajectory Clustering for Activity Learning

**Participants:** Jose Luis Patino, Guido Pusiol, Hervé Falciani, Nedra Nefzi, François Brémond, Monique Thonnat.

The discovery, in an unsupervised manner, of significant activities observed from a video sequence, and its activity model learning, are of central importance to build up on a reliable activity recognition system. We have deepened our studies on activity extraction employing trajectory information. In previous work we have shown that rich descriptors can be derived from trajectories; they help us to analyze the scene occupancy and its topology and also to identify activities [67], [68], [70], [55]. Our new results show how trajectory information can be more precisely employed, alone or in combination with other features for the extraction of activity patterns. Three application domains are currently being explored: 1) Monitoring of elderly people...
at home; 2) Monitoring the ground activities at an airport dock-station (COFRIEND project\(^6\)); 3) Monitoring activities in subway/street surveillance systems.

### 6.18.1. Monitoring of elderly people at home

We propose a novel framework to understand daily activities in home-care applications; the framework is capable of discovering, modeling and recognizing long-term activities (e.g. “Cooking”, “Eating”) occurring in unstructured scenes (i.e. “an apartment”).

The framework links visual information (i.e., tracked objects) to the discovery and recognition of activities by constructing an intermediate layer of primitive events automatically. The primitive events characterize the global spatial movements of a person in the scene (“in the kitchen”), and also the local movements of the person body parts (“opening the oven”). The primitive events are built from interesting regions, which are learned at multiple semantic resolutions (e.g. the “oven” is inside the “kitchen”). An example of the regions and possible activities for a single resolution is displayed in Fig. 22.

![Figure 22. Example of some learned regions and possible activities.](image)

A probabilistic model is learned to characterize each discovered activity. The modeled activities are automatically recognized in new unseen videos where a pop-up with a semantic description appears when an activity is detected. Examples of semantic labels are illustrated in Fig. 23 (a, b, c).

Recently we introduced 3D (MS. Kinect) information to the system. The preliminary results show an improvement superior to the 30% of the recognition quality. Also, the system can recognize activities in challenging situations as the lack of light. -See Fig.2 (b) and Fig.2 (c) -.

The approach can be used to recognize most of the interesting activities in a home-care application and has been published in [43]. Other examples and applications are available online in \[http://www-sop.inria.fr/pulsar/personnel/Guido.Pusiol/Home4/index.php\].

### 6.18.2. Monitoring the ground activities at an airport dock-station

The COFRIEND project aims at creating a system for the recognition and interpretation of human activities and behaviours at an airport dock-station. Our contribution is a novel approach for discovering, in a unsupervised manner, the significant activities from observed videos. Spatial and temporal properties from detected mobile objects are modeled employing soft computing relations, that is, spatio-temporal relations graded with

different strengths. Our system works off-line and is composed of three modules: The trajectory speed analysis module, the trajectory clustering module, and the activity analysis module. The first module is aimed at segmenting the trajectory into segments of fairly similar speed (tracklets). The second aims at obtaining behavioural displacement patterns indicating the origin and destination of mobile objects observed in the scene. We achieve this by clustering the mobile tracklets and also by discovering the topology of the scene. The latter module aims at extracting more complex patterns of activity, which include spatial information (coming from the trajectory analysis) and temporal information related to the interactions of mobiles observed in the scene, either between themselves or with contextual elements of the scene. A clustering algorithm based on the transitive closure calculation of the final relation allows finding spatio-temporal patterns of activity. An example of discovery is given in the figure below. This approach has been applied to a database containing near to 25 hours of recording of dock-station monitoring at the Toulouse airport. The discovered activities are: ‘GPU positioning’, ‘Handler deposits chocks’, ‘Frontal unloading operation’, ‘Frontal loading operation’, ‘Rear loading operation’, ‘Push back vehicle positioning’. An example of discovered activity (Frontal loading) is given on the figure 24. When comparing our results with explicit ground-truth given by a domain expert, we were able to identify the events in general with a temporal overlap of at least 50%. The comparison with a supervised method on the same data indicates that our approach is able to extract the interesting activities signalled in the ground-truth with a higher True Positive Rate (74% TPR for the supervised approach against 80% TPR with our unsupervised method). This work has been published in [42].

**Figure 23.** Examples of the recognized activities in 3D and under different light conditions.

![Figure 23](image)

**Figure 24.** Example of an activity cluster obtained. The left panel presents the tracklets of the mobiles participating in the Frontal Loading activity. Filled circles indicate the beginning of a tracklet. Empty circles indicate the end of a tracklet. The right panel presents the start frame of the activity.

### 6.18.3. Monitoring activities in subway/street surveillance systems
In this work we have built a system to extract from video and in an unsupervised manner the main activities that can be observed from the a subway scene. We have setup a processing chain broadly working on three steps: The system starts in a first step by the unsupervised learning of the main activity areas of the scene. In a second step, mobile objects are then characterized in relation to the learned activity areas: either as ‘staying in a given activity zone’ or ‘transferring from an activity zone to another’ or a sequence of the previous two behaviours if the tracking persists long enough. In a third step we employ a high-level relational clustering algorithm to group mobiles according to their behaviours and discover other characteristics from mobile objects which are strongly correlated. We have applied this algorithm to two domains. First, monitoring two hours of activities in the hall entrance of an underground station and showed what are the most active areas of the scene and how rare/abnormal (going to low occupied activity zones) and frequent activities (e.g. buying tickets) are characterized. In the second application, monitoring one hour of a bus street lane, we were able again to learn the topology of the scene and separate normal from abnormal activities. When comparing with the available ground-truth for this application, we obtained a high recall measure (0.93) with an acceptable precision (0.65). This precision value is mostly due to the different levels of abstraction between the discovered activities and the ground-truth. The incremental learning procedure employed in this work is published in [52] while the full activity extraction approach was published in [41].

6.19. SUP Software Platform

Participants: Julien Gueytat, Leonardo Rocha, Daniel Zullo, François Brémond.

SUP is a software platform developed by PULSAR team, written in C and C++ for generating activity recognition systems. These systems should be able to perceive, analyze, interpret and understand a 3D dynamic scene observed through a network of sensors.

These activity recognition systems are a combination of algorithms developed by members of Pulsar or state of the art computer vision libraries. The SUP dissemination is targeted for use in real-world applications requiring high-throughput.

SUP is made as a framework allowing several computer vision workflows to be implemented. Currently, the workflow is static for a given application but our goal is to make it dynamic. A given workflow is the composition of several plugins, each of them implementing an algorithmic step in the video processing chain (i.e. the segmentation of images, the classification of objects, etc.). The design of SUP allows to execute at run-time the selected plugins.

During 2011 several tasks have been accomplished:

- A stable packaged release is available
- 3D simulation from a scenario description
- Existing algorithms have been improved in performance and accuracy
- Kinect sensor has been added to the hardware supported

Several plugins are available:

- 2 plugins are wrappers on industrial implementations of video processing algorithms (made available by Keeneo). They allow a quick deployment of a video processing chain encompassing image acquisition, segmentation, blob construction, classification and short-term tracking. These algorithms are robust and efficient algorithms, but with the drawback that some algorithms can lack accuracy.
- Several implementations by the Pulsar team members which cover the following fields:
  1. Image acquisition from different types of image and camera video streaming.
  2. Segmentation removing the shadows.
  3. Two classifiers, one being based on postures and one on people detection.
  4. Four frame-to-frame trackers, using as algorithm:
1. a simple tracking by overlapping,
2. neural networks,
3. tracking of feature points,
4. tracking specialized for the tracking of people in a crowd.
5. Three scenario recognizers, one generic algorithm allowing expression of probabilities on the recognized events, the second one focusing on the recognition of events based on postures and the third one (see section Extendable Event Recognition algorithm: SED in this document) uses the complete ontology of the domain as a parameter (e.g. the definition of objects of interest, scenario models, etc.).
6. 3D animation generation, it generates a virtual 3D animation from information provided by different plugins of the processing chain together with 3D contextual environment.
7. 3D simulation from description, it generates a virtual 3D animation from information provided from a text file with the description of the scenario.

From a software engineering point-of-view, the goal is to obtain a flexible platform being dynamically reconfigurable for the generated scene understanding systems to be autonomous and adaptable for handling changing environment.

SUP relies on DTK, a generic platform developed by the DREAM service at INRIA Research Center Sophia-Antipolis Méditerranée.

The purpose of DTK is to provide a software infrastructure allowing the generation of a new system by the composition of plugins, each plugin being an algorithmic step of the whole processing chain. SUP is oriented to help developers building activity recognition systems and describing their own scenarios dedicated to specific applications. By relying on the DTK software infrastructure, the possibilities are:

- To simplify the exchanges of algorithms between different INRIA teams using the DTK.
- To use the facilities already provided by the DTK allowing to compose quickly existing plugins. Currently a python interface is operational, and we plan to take advantage of the graphical composer to prototype quickly new work-flows, or reconfigure existing ones, for the experimentation conducted by the team.

In order to be confident on the results obtained with the SUP platform, an important effort is done to check:

- The correct behavior of the platform from a software engineering point of view, i.e. that the functionality of the SUP software is correctly provided, or is not broken by modifications.
- A qualitative evaluation tool (see ViSEvAI in this document) for the algorithms, which compares and assesses the results obtained with the algorithms to ground truth for several reference videos.

Both kinds of test are performed on a daily basis and on several hardware/software architectures.

### 6.20. Model-Driven Engineering and Video-surveillance

**Participants:** Sabine Moisan, Jean Paul Rigault, Sagar Sen, François Brémond.

In the framework of our research on model engineering techniques for video-surveillance systems, we have focused this year on the runtime adaptation of such systems.

Video-surveillance systems are complex and exhibit high degrees of variability along several dimensions. At the specification level, the number of possible applications and type of scenarios is large. On the software architecture side, the number of components, their variations due to possible choices among different algorithms, the number of tunable parameters... make the processing chain configuration rather challenging. Moreover, the context of an application may change in real time, requiring dynamic reconfiguration of the chain. This huge variability raises problems at design time (finding the configurations needed by the chain, foreseeing the different possible contexts), at deployment time (selecting the initial configuration), and at run time (switching configurations to react to context changes).
The first step was to formalize in an unified way all the necessary concerns—at the specification as well as at the component level—and their relations. To this end, we rely on Feature Models and (semi) automatic model transformations. Feature Models are widely used to represent systems with many possible variation points. Moreover they are liable to formal analysis (using propositional logic and satisfiability techniques) and thus lead to valid configurations, by construction. We have developed two feature models, one for the specification of the application (type of application, context of execution, expected quality of service, etc.) and one for the implementation representation (components and their assembly). Each model has its own internal constraints. Moreover, the two models are not independent: they are connected by cross model transformation rules that formalize the bridge between application requirements and component assemblies that realize them.

Second, we propose a framework to derive valid possible system configurations and to adapt running configurations to context changes. Users can select features describing their application in the specification model, through a simple graphic interface. The outcome is a sub-model of the specification model. Based on the cross model transformation rules, our framework automatically transforms this sub-model into a sub-model of the component model. The latter represents all possible component configurations of the target video-surveillance system that satisfy the specifications. Both sub-models will be kept throughout the system life. They are used while the system is running to adjust its configuration in response to context changes.

To achieve this dynamic adaptation, our framework sets up three collaborating modules as shown in Figure 25:

- **the Run Time Component Manager** (RTCM) captures low level events manifesting context changes (e.g., lighting changes); it forwards them to the Configuration Adapter which returns a

---

7Here the “features” correspond to selectable concepts of the systems; they can be at any abstraction level (a feature may correspond to an specification entity such as “Intrusion detection” or to a more concrete element such as “High frame rate”). The features are organized along a tree, with logical selection relations (optional, mandatory features, exclusive choices...) and some constraints that restrict the valid combinations of features (i.e., configurations)
new component configuration; the RTCM is then responsible for applying this configuration, that is
to tune, add, remove, or replace components, and possibly to change the workflow itself.

- the **Configuration Adapter** (CA) receives change events from the RTCM, translates them into the
  feature formalism, and forwards the result to the Model Manager; in return, it obtains a sub-model of
  component configurations compatible with the change; this sub-model is a compact representation
  of a set of valid configurations and the CA is responsible to select one and to instruct the RTCM to
  apply it; this selection uses some heuristics, possibly based on a cost function such as minimizing
  the number of component changes in the processing chain or maximizing the quality of service (e.g.,
  accuracy, responsiveness).

- the **Model Manager** (MM) manages the representation of the two specialized Feature Models
  corresponding to the specification and possible component assemblies of the current application
  together with their constraints; its role is to enforce configuration validity. It is also responsible
  of the set of rules relating run time events and (de)selection of features in both models. From the
  CA, the Model Manager receives information about incoming events; it uses the rules to select or
deselect the corresponding features; it then applies constraints, rules, and model transformations to
  infer a component sub-model that represents a subset of valid component configurations and that it
  returns to the CA.

This year, we have tested our approach on simple applications using well-known libraries (OpenCV) on
different scenarios. At the moment, 77 features and $10^8$ configurations are present in the specification model
while 51 features and $10^6$ configurations are present in the component model. Once the video surveillance
designer has selected the features required by an application, before deployment, the average number of
features to consider at runtime in the component model is less than $10^4$. The configuration spaces is reduced
by several orders of magnitude and enables the use of the other tools in the end-to-end engineering process,
whereas it would not have been possible without. Our experiments show the feasibility of such an approach
with a limited performance overhead (if any) compared to traditional run time control where *ad hoc* adaptation
code is hardwired and does not rely on the run time availability of an abstract representation of the application
and its context evolution [29]. The next step will be to test our approach on our SUP platform and to study
intelligent configuration selection heuristics.

### 6.21. The Girgit Software

**Participants:** Leonardo Rocha, Sabine Moisan, Jean-Paul Rigault, Sagar Sen.

Girgit is a Python based framework to build context-aware self-adaptive software systems.

Girgit is a simple and small [1] framework that allows dynamic reconfiguration of data processing chains and
accepts any set of components for the configuration as long as they have the corresponding Python wrapper.

The basic Idea of Girgit is to provide a platform to be able to make dynamic adaptive systems. It provides
a dynamic adaptive engine that can deal with event/action pairs called rules and also provides an application
programming interface to be able to use it.

As the system is designed to be interactive, any user can interact with it, be a human operator or a reasoning
engine. Rules can be pre-loaded with the configuration, and components can launch events, this allows pre-
configured rules to be loaded at launch time of the Girgit.

Girgit has been used to evaluate the performance on real time video applications and show the architecture.
Three publications [47], [45], [46] where based on the framework.

### 6.22. Scenario Analysis Module

**Participants:** Sabine Moisan, Annie Ressouche, Jean Paul Rigault.
To generate activity recognition systems we supply a scenario analysis module (SAM) to express and recognize complex events from primitive events generated by SUP or others sensors. In this framework, this year we focus on recognition algorithm improvement in order to face the problem of large number of scenario instances recognition.

The purpose of this research axis is to offer a generic tool to express and recognize activities. Genericity means that the tool should accommodate any kind of activities and be easily specialized for a particular framework. In practice, we propose a concrete language to specify activities in the form of a set of scenarios with temporal constraints between scenarios. This language allows domain experts to describe their own scenario models. To recognize instances of these models, we consider the activity descriptions as synchronous reactive systems [69] and we apply general modeling methods [62] to express scenario behaviors. This approach facilitates scenario validation and allows us to generate a recognizer for each scenario model. The SAM module thus provides users with (1) a simulation tool to test scenario behaviors; (2) a generator of a recognizer for each scenario model; (3) an exhaustive verification of safety properties relying on model checking techniques our approach allows. The latter offers also the possibility to define safety properties to prove as “observers” [63] expressed in the scenario language.

Last year we have completed SAM in order to address the life cycle of scenario instances. For a given scenario model there may exist several (possibly many) instances at different evolution states. These instances are created and deleted dynamically, according to the input event flow. The challenge is to manage the creation/destruction of this large set of scenario instances efficiently (in time and space), to dispatch events to expecting instances, and to make them evolve independently. This year, to face this challenge we first replace some operators of the language, by others having a more strict semantics. For instance, we replace the before operator whose semantics allowed that events can meet, by two operators, a strict before and a meet. Hence, the number of events a scenario instance reacts to decreases. Second, we now generate within the recognition engine, the expected events of the next step. This avoids to run the engine automatically with events that are not relevant for the recognition process.

Presently, we still rely on the existing synchronous language (Lustre [62]) to express the equational semantics of scenario models and to generate recognizers because this language offers simulation and verification means. But, to improve efficiency, we plan to build our own compiler and to generate recognizers directly from the Boolean equation systems modeling scenario models. This implies that we must supply our own simulation tool and that we interface with a model checking tool as NuSMV [57].

Now the challenge is to take into account some uncertainty on the primitive events due to input sensor errors. In the family of synchronous languages, the Lutin language 8 could be able to automate the generation of realistic input sequences of events, taking into account probabilistic distributions over primitive events. In other words, it could generate a set of input events for which a set a constraints can be verified. In complement, it offers also means to compute the real values verifying these constraints. Thus, we think to rely on Lutin to express uncertainty on primitive events and get input events to feed scenario recognition engines.

6.23. Multiple Services for Device Adaptive Platform for Scenario Recognition

Participants: Annie Ressouche, Jean-Yves Tigli.

The aim of this research axis is to federate the inherent constraints of an activity recognition platform like SUP (see section 6.19 ) with a service oriented middleware approach dealing with dynamic evolutions of system infrastructure. The Rainbow team (Nice-Sophia Antipolis University) proposes a component-based adaptive middleware (WComp [76], [75], [64]) to dynamically adapt and recompose assemblies of components. These operations must obey the "usage contract" of components. The existing approaches don’t really ensure that this usage contract is not violated during application design. Only a formal analysis of the component behavior models associated with a well sound modeling of composition operation may guarantee the respect of the usage contract.

8 http://www-verimag.imag.fr/Lutin.html
The approach we adopted introduces in a main assembly, a synchronous component for each sub assembly connected with a critical component. This additional component implements a behavioral model of the critical component and model checking techniques apply to verify safety properties concerning this critical component. Thus, we consider that the critical component is validated.

When a critical component has multiple synchronous monitors corresponding to several concern managements in the application, we want to build an only synchronous model component which agrees with all these primitive synchronous monitors. To specify how output events sent by different synchronous monitors and connected to a critical component, we introduce a sound (with respect to our mathematical formalism) operation of composition under constraints of synchronous models (see figure 26). We proved that this operation preserves already separately verified properties of synchronous components. This operation is an answer to the multiple access to critical components. Actually, we supply a graphical interface to design both critical component behaviors and properties as observers in the synchronous language Lustre [62]. Then the validation of properties and the creation of the validated synchronous component is automatic [44], [53].

![Figure 26. Example of multiple access to alarm critical component: (a) SM - the synchronous monitors; (b) CSM - the composition under constraints operation](image)

This year we focus on the main challenge of this approach which is to deal with the possibly very large number of constraints a user must specify. Indeed, each synchronous monitor has to tell how it combines with others, then we get a combinatorial number of constraints with respect to the number of synchronous monitors and inputs of the critical component. To be adaptive with efficiency, we must face this problem. We first introduced some default rules to avoid the user to express a large number of constraints. We also studied how Abstract Interpretation technique can help us to reduce this complexity. This approach works if we forbid some “non monotonic” constraints, but this is a strong limitation. Thus, it is still a challenge for us. This drawback is a popular challenge in adaptive middleware and some results exist relying on controller synthesis methods. We are not in the exact framework where these techniques apply, but we plan to study if we can rely on some extension of these techniques.

On another hand, we also want to complement our preservation result in studying how the proof of a global property can be decomposed into the proof of local ones. In general, this decomposition (known as assume-
guarantee paradigm) is difficult to apply but there is no communication between synchronous monitors and so the decomposition could be tractable. Moreover, some works address this problem and we can rely on them.

### 6.24. The Clem Workflow

**Participants:** Annie Ressouche, Daniel Gaffé.

This research axis concerns the theoretical study of a synchronous language LE with modular compilation and the development of a toolkit (see figure 6) around the language to design, simulate, verify and generate code for programs. The novelty of the approach is the ability to manage both modularity and causality. Indeed, only few approaches consider a modular compilation because there is a deep incompatibility between causality and modularity. Thus, relying on semantics to compile a language ensures a modular approach but requires to complete the compilation process with a global causality checking. To tackle this problem, we introduced a new way to check causality from already checked sub programs and the modular approach we infer. The equational semantics compute a Boolean equation system and we ensure both modularity and causality in computing all the partial orders valid for a system and we define a way to merge two partial orders. The algorithm which computes partial orders rely on the computation of two dependency graphs: the upstream (downstream) dependency graph computes the dependencies of each variable of the system starting from the input (output) variables. This way of compiling is the corner stone of our approach. We defined three different approaches to compute the partial orders valid for an equation system:

1. **apply PERT method:** inputs (resp. outputs) have date 0 and recursively increase of dates for each vertex in the upstream (resp downstream) dependencies graph;
2. **apply graph theory:**
   - compute the adjacency matrix \( U \) of upstream (resp. downstream) dependencies graph;
   - the length of the maximal path from a variable \( v \) to system inputs is characterized by the maximal \( k \) such that \( U^k[v, i] \neq 0 \) for all inputs \( i \).
3. **apply fix point theory:** the vector of earliest (resp. lastest) dates can be computed as the least fix point of a monotonic increasing function.

The fix point characterization helps us to prove that the merge algorithm is correct (i.e. we get the same partial orders using the merge algorithm on two previously sorted equation systems or when sorting the union of the two equation systems considered).

To be modular, we defined a technique to compose two already sorted equation systems: first, we memorize the two dependency graphs of equation systems. Second, we define two merge algorithms relying on two different techniques:

1. propagation of common variables dates adjustment;
2. fix point characterization starting with the vectors of already computed dates and considering only the variables in the dependencies (upstream and downstream) of common variables

This year we began the implementation of a separated compilation of LE programs, according to these theoretical results. We define a new intermediate format (lea) to record partially compiled module, i.e module whose Boolean equation systems may be composed of non defined variables (we called them abstract). Then we are implementing a refinement operation which replaces these abstract variables by their definition and performs adjustment of the dates. According to our theoretical results, we know that the resulting sorting is the same as with a global approach. After the termination of this separated compilation of LE programs, the challenge will be to use Clem to design a large application in the domain of smart cards. The application needs more than forty LE automata in parallel and the compiled code will have more than 500 registers and thousands variables. Only a separated compilation will work.

The Clem toolkit is completely described in [28].
5. New Results

5.1. Numerical methods

5.1.1. Finite volume methods in curvilinear coordinates

Participants: Hervé Guillard, Boniface Nkonga, Afeintou Sangam.

Finite volume methods are specialized numerical techniques for the solving of divergence equations in strong conservation forms of the form

\[
\frac{\partial S}{\partial t} + \text{div}T = 0
\]  

(12)

where \(S\) is a scalar or a vector while \(T\) is a vector or a second-order tensor. Using textbook formulas for the expression of the divergence operator in curvilinear coordinates, the use of these coordinate systems instead of the Cartesian one can lead to a loss of the strong conservation form of the equations and introduce a source term in (1). Actually, this is unnecessary and one can show that whatever the system of curvilinear coordinate used, there exists a strong conservation law form of the system. However, when vector equations have to be considered (that is if \(S\) is a vector and \(T\) a tensor), it is necessary to extract from (12) scalar equations for the components of the vector \(S\) and this may destroy the strong conservation form of the equation. Following the work done in [12] where a general method (i.e that does not depend on the curvilinear system used) based on the projection of the discretized vector system have been designed, we have studied this year its application to cylindrical coordinates in the case where the geometry is a torus. This approach is robust and accurate for problems that take place for instance inside tokamak devices for magnetic confinement fusion or in toroidal plasmas occurring in stars and galaxies to take another examples. The method is now implemented in the PlaTo software.

5.1.2. Entropy preserving schemes for conservation laws

Participants: Christophe Berthon [University of Nantes], Bruno Dubroca [CEA/DAM/CESTA and University of Bordeaux 1], Afeintou Sangam.

Entropy preserving schemes for conservation laws

In collaboration with C. Berthon of University of Nantes, and B. Dubroca of CEA/DAM/CESTA and University of Bordeaux 1, we have established a new technique that proves discrete entropy inequalities of finite volume methods to approximate conservation laws. This technique is free of additional numerical models such as kinetic and relaxation schemes. Moreover, our results leads to a full class of entropy preserving schemes for general Euler equations [11]. This proposed technique has been successfully applied to two intermediates states scheme for 10-moments equations with laser source-term in context of Inertial Fusion Confinement. Moreover, the derived procedure is now extended to Saint-Venant model.

5.1.3. Mesh adaptation Methods

Participants: Anca Belme [Projet Tropics], Hubert Alcin [Projet Tropics], Alain Dervieux, Frédéric Alauzet [Projet Gamma, INRIA-Rocquencourt].

This activity results from a cooperation between Gamma, Tropics, Pumas, and Lemma company. See details in Tropics and Gamma activity reports. Its concerns Pumas’s subject through the current applications of mesh adaptation to flows with interfaces and the starting application of mesh adaptation to Large Eddy Simulation. It is also planned to use mesh adaptation for simplified plasma models in the context of ANEMOS ANR project.
5.1.4. Parallel CFD algorithms

Participants: Hubert Alcin [Tropics], Olivier Allain [Lemma], Anca Belme [Tropics], Marianna Braza [IMF-Toulouse], Alexandre Carabias [Tropics], Alain Dervieux, Bruno Koobus [Université Montpellier 2], Carine Moussaed [Université Montpellier 2], Hilde Ouvrard [IMF-Toulouse], Stephen Wornom [Lemma].

Pumas is associated to the ANR ECINADS project started in end of 2009, devoted to the design of new solution algorithms for unsteady compressible flows, adapted to scalable parallelism and to reverse (adjoint) Automatic Differentiation. See in the activity report of Tropics. The newer two-level deflation algorithm is currently applied to a simplified plasma model in the context of ANEMOS ANR.

5.2. Plasma physics

5.2.1. Analysis of the drift approximation

Participants: Hervé Guillard, Afeintou Sangam, Philippe Ghendrih [IRFM, CEA Cadarache], Yanick Sarazin [IRFM, CEA Cadarache], Patrick Tamain [IRFM, CEA Cadarache].

Drift approximation consider the slow evolution of the fields in the vicinity of a tokamak equilibrium. These models are typically used to study the micro-instabilities that are believed to be responsible of turbulent transport in tokamaks. Since the drift asymptotic uses a “slow” scaling of the velocity field, the resulting models are significantly different from the full MDH models. This is particularly true with respect to the computation of the electric field that is given by an Ohm’s law in MHD models whereas it is computed by a vorticity-like evolution equation in drift approximations. Drift asymptotic models are extremely interesting from a computational point of view since they save substantial CPU time and computer memory. However, the mathematical and numerical properties of these models are essentially unknown. We have begun a detailed study of the derivation of these models from two-fluid Braginskii-type models in order to establish the range of applicability of these asymptotic models, understand their mathematical properties and relations with the reduced MHD models and design appropriate numerical methods for their approximations.

5.2.2. Stabilized C1-Finite Element Method for MHD

Participants: Boniface Nkonga, Marie Martin.

Reduced MHD models are often used in plasma physics and therefore fast compressible waves are not taken into account. In the context of Elms instabilities investigations, full and extended MHD models are to be considered within the framework of high order finite element approximation. In order to obtain predictive simulations with reduced, full and extended MHD models, it is crucial to design numerical strategies that can face some difficulties related to the use of the classical Galerkin methods for convection dominated flows. We have developed a general VMS stabilization strategy for time dependent implicit scheme, which can be applied to MHD models in order to preserved the global accuracy of the initial Galerkin formulation and enforce physical properties as monotony and positivity. Higher order of continuity shape functions are important for accuracy and also help to obtain more robustness of the stabilization as there is no more singularities on elements edges. Numerical implementation and preliminary validations has been performed using C1-Bell shapes functions for triangular meshes. Order five accuracy of the theory is recovered for specific boundary condition. Improvement for general boundary condition is still an open issue. The next step is to combine this Bell shapes functions in the poloidal direction with B-splines functions to achieve accurate representation of complex torus as ITER.

5.2.3. Two fluid modelling of the Scrape-Off-Layer Plasma

Participants: Audrey Bonnement, Hervé Guillard, Richard Pasquetti.
A two fluid physical model has been developed in close collaboration with researchers from IRFM. It is based on an hypothesis of stationary magnetic field and the electrostatic and electroneutrality assumptions. However the usual drift assumption, e.g. used in the CEA code TOKAM3D (thesis of P. Tamain), is not used. On the basis of the conservation equations of density, electron and ion velocities, electron and ion temperatures and electrical charges, a set of 10 nonlinear coupled partial differential equations (PDE) can be set up. Our investigations rely on the development of two solvers for this set of PDE. In the frame of her thesis, A. Bonnement (co-direction H. Guillard and R. Pasquetti, financial support of INRIA and PACA region, industrial partner ASSYSTEM) uses a Finite volume / element (FV/FE) approach. The other code, developed by R. Pasquetti, focuses on the use of high order approximations: a spectral element method (SEM) is used in the poloidal plane whereas Fourier expansions are used in the toroidal direction. Each of these codes has allowed in 2010 to solve strongly anisotropic diffusion equations in 2D and axisymmetric 3D geometries for the FV/FE code and in 2D and fully 3D for the Fourier-SEM code. The FV/FE code has also been used to carry out a study of radiative layers evolution in a 2D annular configuration but also in a realistic 3D ITER configuration.

Works carried out during the year 2011 are described hereafter: – On the basis of a Godunov scheme, the FV/FEd approach has been extended to solve the axisymmetric Euler, Navier-Stokes or Braginskii like systems in the jet-tokamak geometry. With respect to Navier-Stokes, the Braginskii system is characterized by anisotropies in the transport coefficients. The mesh is unstructured: A finite element approximation is used for the diffusion terms whereas for the convective terms a finite volume approximation is used on the dual mesh. We have especially focused on the treatment of the toroidal geometry. We have also focused on the implementation of the so-called Bohm conditions, which are enforced by imposing that at the limiter the fluid velocity is colinear to the magnetic field and that the « parallel Mach number » equals or is greater than one. In these studies the governing equations are completed by constant force terms in order to model the Lorentz forces as well as sources of mass and energy. Such forcing terms allow to preserve an equilibrium state, e.g. obtained on the basis of simulations that make use of the drift assumption (see next paragraph). We have then introduced perturbations of this equilibrium state to study the evolution of the different variables (density, velocity and temperature). Various perturbations have been used to this end, fully random in order to check the stability of the equilibrium or on the contrary localized, in order to roughly model the injection of pellets inside the SOL. It is planned that Audrey Bonnement will defend her thesis in Spring 2012.

The SEM-Fourier 3D code has been extended to solve the full set of governing equations. The unknowns are then the density, the velocity of the center of mass, the electric current and potential, the ion and electron internal energies. In time, this set of PDE is solved by using an IMEX (Implicit – Explicit) approach, based on the combination of an explicit Runge-Kutta scheme for the flux terms and on a DIRK (diagonal implicit Runge Kutta) for the Lorentz terms, which indeed lead to an unconditionally unstable scheme if treated explicitly. A projection method is used to enforce the divergence free constraint of the current, so that an additional solve of a Poisson equation is required to obtain the potential. The Bohm conditions are here implemented by enforcing that the ion pressure is such that the parallel Mach number shows the expected value, i.e. equal or greater than one. The main difficulty that we presently meet is that the initial condition that we use does not correspond to an equilibrium state, so that instabilities quickly develop till yielding an unsteady flow not consistent at the limiter with the Bohm condition. Detailed analyses of these results are presently carried out with Sebastian Minjeaud (new CNRS researcher of the LJAD) to provide relevant explanations of the observed phenomena.

5.2.4. Drift approximation modelling of the Scrape-Off-Layer Plasma

Participants: Marco Bilanceri, Hervé Guillard.

Based on a fluid model using the drift velocity approximation, a simulation method have been designed to compute the flow in the scrape-off-layer of a Tokamak. The variables used by the model are the particle number, the parallel (to the magnetic field) velocity and the electric potential. The spatial approximation uses a finite volume/finite element approach and is therefore easy to apply to complex geometries. Bohm boundary conditions are used on the divertor plates of the machine. The figure 1. shows the density in a poloidal cut where the influence of the separatrix can be clearly seen.
Figure 1. Density plot in a poloidal section of a jet-like Tokamak.
5.3. Fluid Turbulence

5.3.1. Hybrid RANS-LES models

Participants: Anca Belme [Tropics], Alain Dervieux, Bruno Koobus [University of Montpellier 2], Carine Moussaïd [University of Montpellier 2], Hilde Ouvrard [IMF-Toulouse], Maria-Vittoria Salvetti [University of Pisa], Stephen Wornom [Lemma].

The purpose of our works in hybrid RANS/LES is to develop new approaches for industrial applications of LES-based analyses. In the foreseen applications (aeronautics, hydraulics), the Reynolds number can be as high as several tenth millions, a far too large number for pure LES models. However, certain regions in the flow can be much better predicted with LES than with usual statistical RANS (Reynolds averaged Navier-Stokes) models. These are mainly vortical separated regions as assumed in one of the most popular hybrid model, the hybrid Detached Eddy Simulation model. Here, “hybrid” means that a blending is applied between LES and RANS. The French-Italian team has designed a novel type of hybrid model. This year, the new model has been adapted to very high Reynolds number. Our benchmark is the flow past a circular cylinder, an ECINADS test case. Reynolds number as high as 3 Millions could be passed with good prediction of main properties like mean drag, root mean square of lift fluctuation, base pressure.

5.3.2. Acoustics

Participants: Anca Belme [Tropics], ILya Abalakin [IMM-Moscou], Alain Dervieux [Tropics], Alexandre Carabias.

A method for the simulation of aeroacoustics on the basis of these models has been designed and developed by a cooperation between the Computational Aeroacoustics Laboratory (CAL) of Institute for Mathematical Modeling at Moscow and INRIA. Further applications has been developed by the Russian team from the two common numerical scheme, the Mixed-Element-Volume at sixth-order, and the quadratic reconstruction scheme. This year the cooperation is concentrated on the study by Alexandre Carabias of a new quadratic reconstruction scheme, which extends the one developed by Hilde Ouvrard and Ilya Abalakin. A second research topic was the calculation of acoustic propagation with unsteady mesh adaptation.

5.4. Environmental flows

5.4.1. Mobile bed and sediment transport

Participants: Hervé Guillard, Boniface Nkonga, Marco Bilanceri, Maria-Vittoria Salvetti [University of Pisa, Italy], Imad Elmahi [University of Oudja, Morocco].

The numerical approximation of a model coupling the shallow-water equations with a sediment transport equation for the morphodynamics have been studied. In shallow-water problems, time advancing can be carried out by explicit schemes. However, if the interaction with the mobile bed is weak, the characteristic time scales of the flow and of the sediment transport can be very different introducing time stiffness in the global problem. For this case, it is of great interest to use implicit schemes. The time integration strategy that we have devised is based on a defect-correction approach and on a time linearization, in which the flux Jacobians are computed through automatic differentiation. The aim of the present work is to investigate the behaviour of this time scheme in different situations related to environmental flows. This work has been presented in [18] and [19].
4. New Results

4.1. Algorithms: Bandwidth Allocation in Optical Networks

Participants: Christine Fricker, Philippe Robert, James Roberts.

The development of dynamic optical switching is widely recognized as an essential requirement to meet anticipated growth in Internet traffic. Since September 2009, RAP has begun an investigation into the traffic management and performance evaluation issues that are particular to this technology. A first analysis of passive optical networks used for high speed Internet access has led to the proposal of an original dynamic bandwidth allocation algorithm and to an evaluation of its traffic capacity. Our activity on optical networking is carried out in collaboration with Orange Labs with whom we have had a research contract and are currently finalizing a new one. We have also established contacts with Alcatel-Lucent Bell Labs and had fruitful exchanges with Iraj Saniee and his team on their proposed time-domain wavelength interleaved networking architecture (TWIN).

We have also analyzed the traffic capacity of wavelength division multiplexing (WDM), passive optical networks (PONs) where user stations (optical network units) are equipped with tunable transmitters. For these systems users can use any of the multiple wavelengths to transmit their data but only within the limit determined by the number of transmitters they possess. A mean field approximation is investigated to estimate the capacity of a limited-gated multiserver polling system with a limit on the number of servers a given station can use simultaneously. The approximation provides an expression for the stability limit under very general assumptions about the traffic process and system configuration.

More generally, motivated by these next generation passive optical networks, a multi-server polling system has been studied where the number of servers that can attend to a queue simultaneously is limited. The stability condition is investigated for this model under quite general assumptions. The result is proved for unlimited service policies. The paper [1] presents a conjecture for the case of limited service policies and general service limits. A simulation study shows that the stability conditions may hold.

In 2011, we have worked on bandwidth allocation in meshed networks. A first study applies the TWIN architecture for a metropolitan area network but with an original medium access control (MAC) algorithm. This algorithm is inspired by our prior work on access networks and ensures an efficient and fair allocation of bandwidth to flows between network nodes. The paper [9] describes this network architecture and presents a performance evaluation using analytical models backed up by simulations.

The TWIN architecture is not extensible to a wide area for reasons of scalability and the excessive signalling delay between geographically distant nodes. We have therefore invented a new notion of a multipoint-to-multipoint lightpath that avoids these problems. A patent application relating to this invention has been submitted. This patent is owned by Orange following the terms of our contract with them. The second patent (that simply perfects the first invention) is jointly owned since the research was performed after the end of this contract. The submitted paper [13] describes the invention and its evaluation. A major advantage demonstrated in this paper is the energy saving achieved by the use of the proposed optical technology in place of electronic routers.

Ongoing research seeks to apply this type of networking solution to data centres, on one hand, and to geographically spread tier 1 Internet carrier networks, on the other. This work is performed in collaboration with Orange Labs and will be covered by a contract that is close to being finalized. We have also participated in the preparation of a European CELTIC project proposal that includes a work package dedicated to the development and experimentation of the network proposed in [13].

4.2. Algorithms: Content-Centric Networking

Participants: Mathieu Feuillet, Christine Fricker, Philippe Robert, James Roberts, Nada Sbihi.
RAP is participating in an ANR project named CONNECT which will contribute to the definition and evaluation of a new paradigm for the future Internet: a content-centric network (CCN) where, rather than interconnecting remote hosts like IP, the network directly manages the information objects that users publish, retrieve and exchange. CCN has been proposed by Van Jacobson and colleagues at the Palo Alto Research Center (PARC). In CCN, content is divided into packet-size chunks identified by a unique name with a particular hierarchical structure. The name and content can be cryptographically encoded and signed, providing a range of security levels. Packets in CCN carry names rather than addresses and this has a fundamental impact on the way the network works. Security concerns are addressed at the content level, relaxing requirements on hosts and the network. Users no longer need a universally known address, greatly facilitating management of mobility and intermittent connectivity. Content is supplied under receiver control, limiting scope for denial of service attacks and similar abuse. Since chunks are self-certifying, they can be freely replicated, facilitating caching and bringing significant bandwidth economies. CCN applies to both stored content and to content that is dynamically generated, as in a telephone conversation, for example. RAP is contributing to the design of CCN in two main areas:

- the design and evaluation of traffic controls recognizing that TCP is no longer applicable and queue management will require new, name-based criteria to ensure fairness and to realize service differentiation;
- the design and evaluation of replication and caching strategies that realize an optimal trade-off of expensive bandwidth for cheap memory.

The team will also contribute to the development of efficient forwarding strategies and investigate economic arguments that make CCN a viable replacement for IP.

The ANR project began in January 2011 and several task meetings have taken place. We have also held meetings with PARC establishing close cooperation with them and with some participants in the NSF project “Named Data Networking”. We also participated in the CCN Community meeting in Palo Alto where we presented our work on traffic control. A paper describing the proposed flow-aware approach and results of a performance evaluation has been accepted for the conference Infocom 2012 [15].

Work on the performance of caching in CCN is ongoing. We have investigated popularity distributions for various types of content and evaluated their impact on the memory bandwidth tradeoff to be realized by CCN.

### 4.3. Algorithms: Channel Access algorithms in wireless networks

**Participants:** Mathieu Feuillet, Philippe Robert.

This is a collaboration with Thomas Bonald (Telecom ParisTech) and Alexandre Proutière (Microsoft Research). In wireless networks, to share available bandwidth between users is necessary. The bandwidth can be divided in several channels (frequency division) or the users can share the whole bandwidth by transmitting in different time slots (time division). We are studying different algorithms that allow users of a wireless network to access the channel. Those algorithms must avoid collisions and use the available bandwidth in the most efficient way. More and more wireless networks are decentralized and those algorithms must be distributed. Moreover, in order to use bandwidth in an efficient way, it is necessary to take the network topology into account. Recent studies have shown that it is possible to use the available bandwidth in a distributed and efficient way without message passing.

We studied a simplified version of the 802.11 channel access algorithm: CSMA/CA (Carrier Sense Multiple Access With Collision Avoidance). We proved that this algorithm does not use the bandwidth in the most efficient way and we proposed in 2010 a modification of this algorithm that is efficient. This result has been extended to multi-channels networks in [8] and its extended version [12].

### 4.4. Scaling Methods: Fluid limits in wireless networks

**Participant:** Philippe Robert.
This is a collaboration with Amandine Veber (CMAP, École Polytechnique). The goal is to investigate the stability properties of wireless networks when the bandwidth allocated to a node is proportional to a function of its backlog. This is, in some sense, a generalization of processor-sharing policies. We have investigated the fluid limits of simple examples of star topologies when the function used is $\log$. We have shown that, under this scaling, some new phenomenon occurs, namely that a node may stabilize for some time at some very high level while the number of jobs of other nodes decreases at some fixed rate or remains finite, i.e. lives in the neighborhood of 0. An averaging phenomenon plays an important role for the return to equilibrium.

4.5. Algorithms: Distributed Hash Table

Participants: Mathieu Feuillet, Philippe Robert.

The Distributed Hash Table (DHTs) consists of a large set of nodes connected through the Internet. Each file contained in the DHT is stored in a small subset of these nodes. Each node breaks down periodically and it is necessary to have back-up mechanisms in order to avoid data loss. A trade-off is necessary between the bandwidth and the memory used for this back-up mechanism and the data loss rate. Back-up mechanisms already exist and have been studied thanks to simulation. To our knowledge, no theoretical study exists on this topic. We modeled this problem thanks to standard queues in order to understand the behavior of a single file and the global dynamic of the system. With a very simple centralized model, we have been able to emphasise a trade-off between capacity and life-time with respect to the duplication rate. From a mathematical point of view, we have been able to study different time scales of the system with an averaging phenomenon. An article is in preparation on this subject. A more sophisticated distributed model with mean field techniques is under investigation.

On the side of this project, we notably studied the distribution of hitting times of the classical Ehrenfest and Engset models by using martingale techniques, furthermore their asymptotic behavior has been analyzed when the size of the system increases to infinity [5].

4.6. Stochastic Modeling of Biological Networks

Participants: Emanuele Leoncini, Philippe Robert.

This is a collaboration with Vincent Fromion from INRA Jouy en Josas, which started on October 2010.

The goal is to propose a mathematical model of the production of proteins in prokaryotes. Proteins are biochemical compounds that play a key role in almost all the cell functions and are crucial for cell survival and for life in general. In bacteria the protein production system has to be capable to produce about 2500 different types of proteins in different proportions (from few dozens for the replication machinery to more than 100000 for certain key metabolic enzymes). Bacteria uses more than the 85% of their resources to the protein production, making it the most relevant process in these organisms. Moreover this production system must meet two opposing problems: on one side it must provide the minimal proteins quantities in order to ensure the smooth-running of the cell, on the other side it can not choose a “overproduction policy” for all the proteins, since this would impact the global performance of the system and of the bacterium itself.

Gene expression is intrinsically a stochastic process: gene activation/deactivation occurs by means the encounter of polymerase/repressor with the specific gene, moreover many molecules that take part in the protein production act at extremely low concentrations.

We have restated mathematically the classical model using Poisson point processes. This representation, well-known in the field of queueing networks but, as far as we know, new in the gene expression modeling, allowed us to weaken few hypothesis of the existing models, in particular the Poisson hypothesis, which is well-suited in some cases, but that, in some situations, is far from the biological reality as we consider for instance the protein assemblage.
The theoretical environment of Poisson point processes has led us to propose a new model of gene expression which captures on one side the main mechanisms of the gene expression and on the other side it tries to consider hypothesis that are more significant from a biological viewpoint. In particular we have modeled: gene activation/deactivation, mRNA production and degradation, ribosome attachment on mRNA, protein production and degradation.

We have shown how the probability distribution of the protein production and the protein lifetime may have a significant impact on the fluctuations of the number of proteins. We have obtained analytic formulas when the duration of protein assemblage and degradation follows a general probability distribution, i.e. without the Poisson hypothesis. We have used our model to compare the variances resulting by choosing different hypotheses for the probability distribution of the protein production and degradation, in particular we have hypothesize the protein assembly and degradation to be deterministic. The model has showed how, under the previous hypothesis, the variance on the number of proteins is bigger than the classical model with the Poisson hypothesis.

4.7. Stochastic networks: large bike sharing systems

**Participant:** Christine Fricker.

This is a collaboration with Nicolas Gast (EPFL) started in December 2010. Bike sharing systems were launched by numerous cities as a serious alternative in urban transportation, for example Velib (20,000 bikes, 1,500 stations). One of the major issues is the availability of the resources: bikes or free slots to return the bikes. These systems have become a hot topic in Operation Research but there are few studies on these stochastic networks. To our knowledge, no theoretical study of such bike sharing systems exists taking into account the limited capacity of the stations.

We modeled this system in a symmetrical case. Mean field limit theorems give the dynamic of a large system and the stationary behavior of a single station. Analytical results are obtained and convergence proved in the standard model via Lyapunov functions. It allows to find the best ratio of bikes per station and to measure the improvement of incentive mechanisms, as choosing among two stations for example, or redistribution of bikes by trucks. It is under investigation. Further results deal with heterogeneous systems. Our goal is to propose via a theoretical study and tests simple algorithms to improve the system behavior.

4.8. Stochastic networks: heterogeneity

**Participants:** Christine Fricker, Hanène Mohamed.

Mean field techniques applied to non-symmetrical systems are explored. It appears as a promising way to obtain analytical results on systems with clusters.

4.9. Stochastic Networks: Jackson Networks

**Participant:** Danielle Tibi.

Lyapunov functions and essential spectral radius of Jackson networks, joint work with I. Ignatiouk-Robert (University of Cergy-Pontoise). A family of explicit multiplicative Lyapunov functions is constructed for any stable Jackson network. Optimizing the multiplicative factor over this family provides an upper bound for the essential spectral radius of the associated Markov process. For some particular classes of Jackson networks, this upper bound coincides with a lower bound derived from large deviations arguments, thus providing the exact value of the essential spectral radius. The main example is given by Jackson networks with routing matrix having a tree structure (in the sense that for any node i, at most one other node can route its customers to i). The result also holds for other types of routing matrices (e.g. completely symmetrical), under some conditions over the different arrival and service rates.

4.10. Scaling Methods: Interaction of TCP Flows

**Participant:** Philippe Robert.
This is a collaboration with Carl Graham (CMAP, École Polytechnique). Mathematical modeling of data transmission in communication networks has been the subject of intense activity for some time now. For data transmission, the Internet can be described as a very large distributed system with self-adaptive capabilities to the different congestion events that regularly occur at its numerous nodes. The coexistence of numerous connections in a network with a general number of nodes has been analyzed in a previous work through a mean-field limit of a Markovian model describing the interaction of several classes of permanent connections. In [6], this line of work has been generalized to the case when connections are not permanent but can be either active (ON) when it is transmitting data along its route, or idle (OFF). This year, the analysis of dynamic arrivals and departures has been investigated. The main technical problem is that mean-field asymptotics are not anymore usable. Instead, fluid limit schemes have to be considered in a quite delicate context, random measures.
6. New Results

6.1. Theoretical and Methodological Developments

**Participants:** Cédric Joncour, Andrew Miller, Arnaud Pêcher, Pierre Pesneau, Ruslan Sadykov, Gautier Stauffer, François Vanderbeck.

We made progress in the development of theory and algorithms in the area of “Reformulation and Decomposition Approaches for MIP”, “Mixed Integer Nonlinear Programming”, and “Polyhedral Combinatorics and Graph Theory”.

6.1.1. Column Generation for Extended Formulations

Working in an extended variable space allows one to develop tight reformulations for mixed integer programs. However, the size of the extended formulation grows rapidly too large for a direct treatment by a MIP-solver. Then, one can use projection tools to derive valid inequalities for the original formulation and implement a cutting plane approach. Or, one can approximate the reformulation, using techniques such as variable aggregation or by reformulating a submodel only. Such approaches result in outer approximation of the intended extended formulation. The alternative considered in [28], [25] is an inner approximation obtained by generating dynamically the variables of the extended formulation. It assumes that the extended formulation stems from a decomposition principle: a subproblem admits an extended formulation from which an extended formulation for the original problem can be derived. Then, one can implement column generation for the extended formulation of the original problem by transposing the equivalent procedure for the Dantzig-Wolfe reformulation. Pricing subproblem solutions are expressed in the variables of the extended formulation and added to the current restricted version of the extended formulation along with the subproblem constraints that are active for the subproblem solution.

Our paper [28], [25] revisits the column-and-row generation approach. Our purpose is to show light on this approach, to emphasize its wide applicability, and to present it with a new angle as a method that is natural when considering a problem reformulation based on any extended reformulation of a subproblem, whether it yields the subproblem integer hull or just an approximation of it. In the spirit of [80], column-and-row generation is viewed herein as a generalization of standard column generation, the latter being based on a specific subproblem extended formulation. This generic view not only highlights the scope of applicability of the method, but it also leads to a more general termination condition than the traditional reduced cost criteria and to theoretically stronger dual bounds (observing that solving the integer subproblems yields Lagrangian dual bounds that might be tighter than the extended formulation LP bound). We highlight a key motivation for working in the extended space: there arises natural recombinations of previously generated columns into new subproblem solutions, which results in an acceleration of the convergence. We point out that lifting the master program in the variable space of the extended formulation can be done while carrying pricing in the compact variable space of the original formulation, using any oracle.

With [28], [25], we establish the validity of the column-and-row generation algorithm in a form that encompass all special cases of the literature. The analysis therein should help practitioners to evaluate whether this alternative procedure has potential to outperform classical column generation on a particular problem. Our numerical experiments highlight a key observation: lifting pricing problem solutions in the space of the extended formulation permits their recombination into new subproblem solutions and results in faster convergence.
6.1.2. Primal Heuristics for Branch-and-Price

Our goal is to exploit global optimization decomposition approaches to retrieve very good feasible solution to large scale problem. This required extending primal heuristic paradigms to the context of dynamic generation of the variables of the model. We highlight an important fact: such generic tools typically performs better than problem specific meta-heuristics, in terms of solution quality and computing times. Based on our application specific experience with these techniques [65], [67], [86], [87], and on a review of generic classes of column generation based primal heuristics, in [58], we are developing a full blown review of such techniques, completed with new methods and an extensive numerical study. This research is being carried on in collaboration with the members of the associated team project, SAMBA.

Significant progress has been achieved in developing generic primal heuristics that made their way into commercial mixed integer programming (MIP) solvers. Extensions to the context of a column generation solution approach are considered by our team, in search for generic black-box primal heuristics for use in Branch-and-Price approaches. As the Dantzig-Wolfe reformulation is typically tighter than the original compact formulations, techniques based on rounding its linear programming solution have better chance to yield good primal solutions. The aggregated information built into the column definition and the price coordination mechanism provide a global view at the solution space that may be lacking in somewhat more “myopic” approaches based on compact formulations. However, the dynamic generation of variables requires specific adaptation of heuristic paradigms. We focus on “diving” methods and considered their combination with sub-MIPing, relaxation induced neighborhood search, and truncated backtracking using a Limited Discrepancy Search. These add-ons serves as local-search or diversification/intensification mechanisms. We also consider feasibility pump approaches. The methods are numerically tested on standard models such as Cutting Stock, Vertex Coloring, Generalized Assignment, Lot-Sizing, and Vehicle Routing problems.

6.1.3. Combining Bender’s and Dantzig-Wolfe Decomposition

In the follow-up of [56], [88], [89], [90], we are finalizing our work on the combination of Dantzig-Wolfe and Bender’s decomposition: Bender’s Master is solved by column generation [91]. The application we considered is a multi-layer network design model arising from a real-life telecommunication application where traffic routing decisions imply the installation of expensive nodal equipment. Customer requests come in the form of bandwidth reservations for a given origin destination pair. Bandwidth requirements are expressed as a multiple of nominal granularities. Each request must be single path routed. Grooming several requests on the same wavelength and multiplexing wavelengths in the same optical stream allow the packing of more traffic. However, each addition or withdrawal of a request from a wavelength requires optical to electrical conversion for which a specific portal equipment is needed. The objective is to minimize the number of such equipment. We deal with backbone optical networks, therefore with networks with a moderate number of nodes (14 to 20) but thousands of requests. Further difficulties arise from the symmetries in wavelength assignment and traffic loading. Traditional multi-commodity network flow approaches are not suited for this problem. Four alternative models relying on Dantzig-Wolfe and/or Benders’ decomposition are introduced and compared. The formulations are strengthened using symmetry breaking restrictions, variable domain reduction, zero-one decomposition of integer variables, and cutting planes. The resulting dual bounds are compared to the values of primal solutions obtained through hierarchical optimization and rounding procedures. For realistic size instances, our best approaches provide solutions with optimality gap of approximately 5% on average in around 2 hours of computing time.

6.1.4. Branching in Branch-and-Price: a generic scheme

Our innovative branching scheme, proposed for its compatible with the column generation procedure (it implies no structural modifications to the pricing problem) is now published in Mathematical Programming A [23]. The scheme proceeds by recursively partitioning the sub-problem solution set. Branching constraints are enforced in the pricing problem instead of being dualized in a Lagrangian way. The subproblem problem is solved by a limited number of calls to the provided solver. The scheme avoids the enumeration of symmetric solutions.
6.1.5. **Strong Branching Inequalities for Convex Mixed Integer Nonlinear Programs**

Strong branching is an effective branching technique that can significantly reduce the size of the branch-and-bound tree for solving Mixed Integer Nonlinear Programming (MINLP) problems. The focus of our paper [24] is to demonstrate how to effectively use discarded information from strong branching to strengthen relaxations of MINLP problems. Valid inequalities such as branching-based linearizations, various forms of disjunctive inequalities, and mixing-type inequalities are all discussed. The inequalities span a spectrum from those that require almost no extra effort to compute to those that require the solution of an additional linear program. In the end, we perform an extensive computational study to measure the impact of each of our proposed techniques. Computational results reveal that existing algorithms can be significantly improved by leveraging the information generated as a byproduct of strong branching in the form of valid inequalities.

6.1.6. **Linear and Nonlinear Inequalities for a Nonseparable Quadratic Set**

We described some integer-programming based approaches for finding strong inequalities for the convex hull of a quadratic mixed integer nonlinear set containing two integer variables that are linked by linear constraints. This study [31] was motivated by the fact that such sets appear can be defined by a convex quadratic program, and therefore strong inequalities for this set may help to strengthen the formulation of the original problem. Some of the inequalities we define for this set are linear, while others are nonlinear (specifically conic). The techniques used to define strong inequalities include not only ideas related to recent perspective reformulations of MINLPs, but also disjunctive and lifting arguments. Initial computational tests will be presented.

6.1.7. **On the composition of convex envelopes for quadrilinear terms**

Within the framework of the spatial Branch-and-Bound algorithm for solving Mixed-Integer Nonlinear Programs, different convex relaxations can be obtained for multilinear terms by applying associativity in different ways. The two groupings \((x_1x_2)x_3x_4\) and \((x_1x_2x_3)x_4\) of a quadrilinear term, for example, give rise to two different convex relaxations. In previous work, we proved that having fewer groupings of longer terms yields tighter convex relaxations. In this paper [35], we give an alternative proof of the same fact and perform a computational study to assess the impact of the tightened convex relaxation in a spatial Branch-and-Bound setting.

6.1.8. **Stable sets in claw-free graphs**

A *stable set* is a set of pairwise non adjacent vertices in a graph and a graph is *claw-free* when no vertex contains a stable set of size three in its neighborhood. Given weights on the vertices, the stable set problem (a NP-hard problem in general) consists in selecting a set of pairwise non adjacent vertices maximizing the sum of the selected weights. The stable set problem in claw-free graphs is a fundamental generalization of the classic matching problem that was shown to be polynomial by Minty in 1980 (G. Minty. *On maximal independent sets of vertices in claw-free graphs*. J. Combinatorial Theory B, 28:284-304 (1980)). However, in contrast with matching, the polyhedral structure (i.e. the integer hull of all stable sets in a claw-free graph) is not very well understood and thus providing a ‘decent’ linear description of this polytope has thus been a major open problem in our field.

We proposed a new algorithm to find a maximum weighted stable set in a claw-free graph [45] whose complexity is now drastically better than the original algorithm by Minty \((n^4\) versus \(n^4\), where \(n\) is the number of vertices). We also provided a description of the polyhedron in an extended space (i.e. using additional artificial variables) and an efficient procedure to separate over the polytope in polynomial-time [27]. Beside those main contributions, we published another papers on the strongly minimal facets of the polytope [22].

We also published two survey papers on both the algorithmic and polyhedral aspects of the problem [32], [16].
6.1.9. Chvátal-Gomory rank of 0/1 polytopes

In [17], we study the Chvátal-Gomory rank of 0/1 polytopes. The Chvátal-Gomory procedure is a generic cutting plane procedure to derive the integer hull of polyhedra, and the rank is the number of iterations needed. We revisited a classic framework by Chvátal, Cook and Hartmann (V. Chvátal, W. Cook, and M. Hartmann. On cutting-plane proofs in combinatorial optimization. Linear Algebra and its Applications, 114/115:455-499 (1989)) to prove lower bounds on the CG-rank and we made it more accessible (the original framework was hard to apply). It allowed us to give a very simple construction and to improve the lower bound on the rank of general 0/1 polytopes (the previous weaker lower bound relied on a sophisticated existence theorem by Erdős). This result is important as it shed some new light on a supposedly well understood procedure.

6.1.10. The Circular-Chromatic number

Another central contribution of our team concerns the chromatic number of a graph (the minimum number of independent stable sets needed to cover the graph). We proved that the chromatic number and the clique number of some superclasses of perfect graphs is computable in polynomial time [19], [18]. We investigated the circular-chromatic number. It is a well-studied refinement of the chromatic number of a graph (designed for problems with periodic solutions): the chromatic number of a graph is the integer ceiling of its circular-chromatic number. Xuding Zhu noticed in 2000 that circular cliques are the relevant circular counterpart of cliques, with respect to the circular chromatic number, thereby introducing circular-perfect graphs, a super-class of perfect graphs.

We proved that the chromatic number of circular-perfect graphs is computable in polynomial time [73], thereby extending Grötschel, Lovász and Schrijver’s result to the whole family of circular-perfect graphs. We gave closed formulas for the Lovász Theta number of circular-cliques (previously, closed formulas were known for circular-cliques with clique number at most 3 only), and derived from them that the circular-chromatic number of circular-perfect graphs is computable in polynomial time [34].

6.2. Model Specific Developments and Applications

Participants: Cédric Joncour, Andrew Miller, Arnaud Pécher, Pierre Pesneau, Ruslan Sadykov, Gautier Stauffer, Damien Trut, François Vanderbeck.

The models on which we made progress can be partitioned in three areas: “Packing and Covering Problems”, “Network Design and Routing”, and “Planning, Scheduling, and Logistic Problems”.

6.2.1. Bin-Packing and Knapsack with Conflicts

The bin-packing problem consists in finding the minimum number of bin of fixed size one needs to pack a set of items of different sizes. We studied a generalization of this problem where items can be in conflicts and thus cannot be put together in the same bin. We show in [21] that the instances of the literature with 120 to 1000 items can be solved to optimality with a generic Branch-and-Price algorithm, such as our prototype BaPCod, within competitive computing time. Moreover, we solved to optimality all the 37 open instances. The approach involves generic primal heuristics, generic branching, but a specific pricing procedure.

The knapsack variant encountered in our bin packing problem resolution considers conflicts between items. This problem is quite difficult to solve compared to the usual knapsack problem. The latter is already NP-hard, but can be usually efficiently solved by dynamic programming. We have shown that when the conflict graph (the graph defining the conflicts between the items) is an interval graph, this generalization of the knapsack can also be solved quite efficiently by dynamic programming with the same complexity than the one to solve the common knapsack problem. For the case, when the conflict graph is arbitrary, we proposed a very efficient enumeration algorithm which outperforms the approaches used in the literature.
6.2.2. Using graph theory for solving orthogonal knapsack problems

We investigated the orthogonal knapsack problem, with the help of graph theory. The multi-dimensional orthogonal packing problem (OPP) is defined as follows: given a set of items with rectangular shapes, the problem is to decide whether there is a non-overlapping packing of these items in a rectangular bin. The rotation of items is not allowed. A powerful characterization of packing configurations by means of interval graphs was introduced by Fekete and Schepers using an efficient representation of all geometrically symmetric solutions by a so called packing class involving one interval graph (whose complement admits a transitive orientation: each such orientation of the edges corresponds to a specific placement of the forms) for each dimension. Though Fekete & Schepers’ framework is very efficient, we have however identified several weaknesses in their algorithms: the most obvious one is that they do not take advantage of the different possibilities to represent interval graphs.

In [13], [14], we give two new algorithms: the first one is based upon matrices with consecutive ones on each row as data structures and the second one uses so-called MPQ-trees, which were introduced by Korte and Möhring to recognize interval graphs. These two new algorithms are very efficient, as they outperform Fekete and Schepers’ on most standard benchmarks.

6.2.3. Inventory routing and pickup-and-delivery problems

Inventory routing problems combine the optimization of product deliveries (or pickups) with inventory control at customer sites. In [15], we considered the planning of single product pickups over time: each site accumulates stock at a deterministic rate; the stock is emptied on each visit. Our objective is to minimize a surrogate measure of routing cost while achieving some form of regional clustering by partitioning the sites between the vehicles. The fleet size is given but can potentially be reduced. Planning consists in assigning customers to vehicles in each time period, but the routing, i.e., the actual sequence in which vehicles visit customers, is considered as an “operational” decision. We developed a truncated branch-and-price algorithm. This exact optimization approach is combined with rounding and local search heuristics to yield both primal solutions and dual bounds that allow us to estimate the deviation from optimality of our solution. We were confronted with the issue of symmetry in time that naturally arises in building a cyclic schedule (cyclic permutations along the time axis define alternative solutions). Central to our approach is a state-space relaxation idea that allows us to avoid this drawback: the symmetry in time is eliminated by modelling an average behavior. Our algorithm provides solutions with reasonable deviation from optimality for large scale problems (260 customer sites, 60 time periods, 10 vehicles) coming from industry. The subproblem is interesting in its own right: it is a multiple-class integer knapsack problem with setups. Items are partitioned into classes whose use implies a setup cost and associated capacity consumption.

Through the internship of Damien Trut, we studied the optimization problem consisted in the planning of the pick-up of full waste container and delivery of empty container at customer sites by simple vehicles that can carry a single container, or vehicles with a trailer attached that have a total capacity of 2 containers but require more time when handling containers. The model is a multi-period, multi-vehicle, pickup and delivery problem, with “many-to-many” multi commodity transfer requirements and transhipment nodes. In its short term variant, urgent order are coming online. We developed the prototype of a branch-and-price approach for this problem. The prototype was used by Exeo to convince their customer of the potential benefit of decision aid tools to automatically generate vehicle routes. Next, we shall be considering the dimensioning of a vehicle fleet and their allocation to cluster of collect points in a periodic solution (for a PhD project).

In collaboration with the group of M-C Speranza of the university of Brescia (Italy), we study the Vehicle Routing Problem with Discrete Split Deliveries (a customer demand can be partition in integer lot assigned to different vehicles). The development is done within BaPCod with specialized pricing and branching scheme.

6.2.4. Time-Dependent Travelling Salesman Problem and Resource Constrained Shortest Path

In [12] we present a new formulation for the Time-Dependent Travelling Salesman Problem (TDTSP). The main feature of our formulation is that it uses, as a subproblem, an exact description of the n-circuit problem. We present a new extended formulation that is based on using, for each node, a stronger subproblem, namely a n-circuit subproblem with the additional constraint that the corresponding node is not repeated in the circuit.
Although the new model has more variables and constraints than the model of Picard and Queyranne (1978), the results given from our computational experiments show that the linear programming relaxation of the new model gives, for many of the instances tested, gaps that are close to zero. We also provided a complete characterization of the feasible set of the corresponding linear programming relaxation in the space of the variables of the PQ model.

Following this work, we proposed an extended formulation in terms of the Asymmetric Travelling Salesman Problem (ATSP) in [33]. A tightening the linear programming relaxation is obtained by i) enhancing the subproblem arising in the standard multicommodity flow (MCF) model for the ATSP and then ii) by using modelling enhancement techniques. We compare the linear programming relaxation of the new formulation with the linear programming relaxation of the three compact and non-dominated formulations presented in Oncan et al. (2009). As a result of this comparison we present an updated classification of formulations for the asymmetric traveling salesman problem (ATSP).

In the internship of André Linhares, we studied the Resource Constrained Shortest Path Problem (RCSPP): we presented some of the state-of-the-art dynamic programming methods for solving the RCSPP in a unified manner, and we proposed some variants of these algorithms. We assessed the effectiveness of these algorithms through computational experiments.

6.2.5. Machine scheduling

The column-and-row generation method presented in [28], [25] is quite effective for the general machine scheduling problem. In our work [29], we show indeed that one of the most efficient approaches to solve this problem is to use time-indexed Integer Programming formulation, and to deal with its huge size by generating variables and constraints dynamically. The numerical results of [29], highlight the significant reduction in computing times that results from applying the column-and-row generation approach.

In [20], we consider the scheduling jobs in parallel, i.e., jobs can be executed on more than one processor at the same time. With the emergence of new production, communication and parallel computing system, the usual scheduling requirement that a job is executed only on one processor has become, in many cases, obsolete and unfounded. In this work, we consider the NP-hard problem of scheduling malleable jobs to minimize the total weighted completion time (or mean weighted flow time). For this problem, we introduce the class of "ascending" schedules in which, for each job, the number of machines assigned to it cannot decrease over time while this job is being processed. We prove that, under a natural assumption on the processing time functions of jobs, the set of ascending schedules is dominant for the problem. This result can be used to reduce the search space while looking for an optimal solution.

6.2.6. One warehouse multi-retailer problem

The One-Warehouse Multi-retailer problem (OWMR) is a very important NP-hard inventory control problem arising in the distribution of goods when one central warehouse is supplying a set of final retailers facing demand from customers. In [30], we provide a simple and fast 2-approximation algorithm for this problem (i.e. an algorithm ensuring a deviation by a factor at most two from the optimal solution). This result is both important in practice and in theory as it allows to approximate large real-world instances of the problem (we implemented this algorithm at IBM and it is within 10% of optimality in practice) and the techniques we developed appear to apply to more general settings. We are extending our results to other inventory control problems.

6.3. Software prototypes, Generic Developments and Specific Tools

Participants: Cédric Joncour, Romain LeGuay, Pierre Pesneau, Ruslan Sadykov, François Vanderbeck.

6.3.1. BaPCod - a generic branch-and-price code

The development of the prototype software platform is now supported by our junior engineer, Romain Leguay, who started in September. He developed a new interface with the underlying MIP solver allowing multiple solvers to be called in the same run. The svn depository was re-organized in view of the increasing number of users to whom Romain offer precious support. Romain is currently redesigning parts of the code in the perspective of its parallelisation and is doing code profiling to identify bottlenecks.
The software platform BaPCod is continuously improved to include all the methodological features that arise from our research, in particular in our collaborative project with Brazil: SAMBA. BaPCod serves there as a proof-of-concept code and is useful for the transfer of knowledge between the parties, including the company GAPSO (a Brazilian spin-up launched by these academics).
We have two new institutional Beta users: EDF and Paris 6.
6. New Results

6.1. Introduction

In 2011, we focused our research on the following areas:

- distributed algorithms for large and dynamic networks,
- Complex queries over peer-to-peer networks
- Trust and reputation management on P2P networks
- dynamic adaptation of virtual machines,
- services management in large scale environments,
- Formal and practical study of optimistic replication, incorporating application semantics.
- Decentralized commitment protocols for semantic optimistic replication.

6.2. Distributed algorithms

Participants: Luciana Arantes [correspondent], Franck Petit, Maria Potop-Butucaru [correspondent], Swan Dubois, Pierre Sens, Julien Sopena.

Our current research in the context of distributed algorithms focuses on two main axes. We are interested in providing fault-tolerant and self-* (self-organizing, self-healing and self-stabilizing) solutions for fundamental problems in distributed computing. More precisely, we target the following basic blocks: mutual exclusion, resources allocation, agreement and communication primitives.

In dynamic systems we are interested in designing building blocks for distributed applications such as: failure detectors, adequate communication primitives (publish/subscribe) and overlays. Moreover, we are interested in solving fundamental problems such as synchronization, leader election, membership and naming, and diffusion of information.

6.2.1. Failure Detectors for Dynamic Systems

Since 2009, we explore a distributed computing model of dynamic networks such as (MANET or Wireless sensor networks). The temporal variations in the network topology implies that these networks can not be viewed as a static connected graph over which paths between nodes are established beforehand. Path between two nodes is in fact built over the time. Furthermore, lack of connectivity between nodes (temporal or not) makes of dynamic networks a partitionable system, i.e., a system in which nodes that do not crash or leave the system might be not capable to communicate between themselves. In 2011 we propose a new failure detector protocol which implements an eventually strong failure detectors (⋄S) on a dynamic network with an unknown membership. Failure detector is a fundamental service, able to help in the development of fault-tolerant distributed systems. Our failure detector has the interesting feature to be time-free, so that it does not rely on timers to detect failures; moreover, it tolerates mobility of nodes and message losses [41].

6.2.2. Self-* Distributed Algorithms

The main challenges of our research activity over 2011 year were to develop self-* (self-stabilizing, self-organizing and self-healing) distributed algorithms for various type of networks. Self-stabilization is a general technique to design distributed systems that can tolerate arbitrary transient faults. Since topology changes can be considered as a transient failures, self-stabilization turns out to be a good approach to deal with dynamic networks. This is particularly relevant when the distributed (self-stabilizing) protocol does not require any global parameters, like the number of nodes or the diameter of the network. With such a self-stabilizing protocol, it is not required to change global parameters in the program when nodes join or leave the system. Therefore, self-stabilization is very desirable to achieve scalability and dynamicity.

- Snap-stabilizing Committee Coordination. The classic committee coordination problem characterizes a general type of synchronization called n-ary rendezvous as follows [2]:

“Professors in a certain university have organized themselves into committees. Each committee has an unchanging membership roster of one or more professors. From time to time a professor may decide to attend a committee meeting; it starts waiting and remains waiting until a meeting of a committee of which it is a member is started. All meetings terminate in finite time. The restrictions on convening a meeting are as follows: (1) meeting of a committee may be started only if all members of that committee are waiting, and (2) no two committees may convene simultaneously, if they have a common member. The problem is to ensure that (3) if all members of a committee are waiting, then a meeting involving some member of this committee is convened.”

In [31], we propose two snap-stabilizing distributed algorithms for the committee coordination problem. Snap-stabilization is a versatile technique allowing to design algorithms that efficiently tolerate transient faults. Indeed, after a finite number of such faults (e.g. memory corruptions, message losses, etc), a snap-stabilizing algorithm immediately operates correctly, without any external intervention. The first algorithm maximizes the concurrency, whereas the latter maximizes the fairness.

- **Snap-stabilizing Message Forwarding.** We focus on end-to-end request and response delivery of messages that are carried over the network. This problem is also known as the message forwarding problem. It consists in the management of network resources in order to forward messages, i.e., protocols allowing messages to move from a sender to receiver over the network. Combined with a self-stabilizing routing protocol, achieving snap-stabilization for the message forwarding problem is a very desirable property because every message sent by the sender is delivered in finite time to the receiver. In other words, no message that was actually sent after the system started is lost. In [46], we present a snap-stabilizing algorithm for the message forwarding that works on a tree topology. It uses a constant number of buffers per link, mainly $2\delta + 1$ buffers by node, where $\delta$ is the degree of the node. Therefore, it is particularly well suited for large-scale and dynamic systems, e.g, overlays used in peer-to-peer systems.

- **Self-Organizing Swarms of Robots.**

Consider a distributed system where the computing units are weak mobile robots, i.e., devices equipped with sensors and are designed to move. By weak, we mean that the robots are anonymous, autonomous, disoriented, and oblivious, i.e., devoid of (1) any local parameter (such that an identity) allowing to differentiate any of them, (2) any central coordination mechanism or scheduler, (3) any common coordinate mechanism or common sense of direction, and (4) any way to remember any previous observation nor computation performed in any previous step. Furthermore, all the robots follow the same program (uniform or homogeneous), and there is no kind of explicit communication medium. The robots implicitly “communicate” by observing the position of the others robots. Two different environments are considered: (i) the continuous two-dimensional Euclidian space wherein robot can observe, compute and move with infinite decimal precision, and (ii) the discrete model in which the space is partitioned into a finite number of locations, conveniently represented by a graph where nodes represent locations that can be sensed, and where edges represent the possibility for a robot to move from one location to the other.

During 2011, we mainly investigated the following problems: the gathering onto the plane, and the exploration of a finite discrete environment.

1. **Gathering.** This problem can be stated as follows: Robots, initially located at various positions, gather at the same position in finite time and remain at this position thereafter. In [20], we investigate the self-stabilizing gathering problem in the plane, that is gathering the robots deterministically with no kind of restriction on the initial configuration. In particular, robots are allowed to share same positions in the initial configuration. Strong multiplicity detection is the ability for the robots to count the exact number of robots located at a given position. We show that assuming strong multiplicity detection, it is
possible to solve the self-stabilizing gathering problem with \( n \) weak robots in the semi-synchronous model if, and only if, \( n \) is odd. By contrast, we show that with an odd number of robots, the problem becomes solvable. Our proof is constructive, as we present and prove a deterministic self-stabilizing algorithm for the gathering problem.

In [19], we address the gathering in the discrete environment. We prove some asymptotical time and space complexity lower bounds to solve the problem. We propose an algorithm that is asymptotically optimal in both space and round complexities. Finally, we show that most of the assumptions we made are necessary to deterministically solve the rendezvous considering our initial scenario.

2. **Graph Exploration.**

The exploration problem is to visit a discrete and finite environment by a swarm of robots. We consider two types of explorations: The finite exploration and the perpetual exploration. The former requires that \( k \) robots, initially placed at different nodes, collectively explore a graph before stopping moving forever. By “collectively” explore we mean that every node is eventually visited by at least one robot. In [73], we propose optimal (w.r.t., the number of robots) solutions for the deterministic exploration of a grid shaped network by a team of \( k \) asynchronous oblivious robots in the asynchronous and non-atomic asynchronous model. In more details, we first show that no exploration protocol exists with less than three robots for any grid with more than three nodes, less than four robots for the \((2,2)\)-Grid, and less than five robots for the \((3,3)\)-Grid. Next, we show that the problem is solvable using only 3 robots for any \((i,j)\)-Grid, provided that \( j > 3 \). Our result is constructive as we present a deterministic algorithm that performs in the non-atomic asynchronous model. We also present specific deterministic protocols for the \((3,3)\)-Grid using five robots.

The second type of exploration is the perpetual exploration. It requires every possible location to be visited by each robot infinitely often. In [32], we investigate the exclusive perpetual exploration of grid shaped networks. We focus on the minimal number of robots that are necessary and sufficient to solve the problem in general grids. In more details, we prove that three deterministic robots are necessary and sufficient, provided that the size of the grid is \( n \times m \) with \( 3 \leq n \leq m \) or \( n = 2 \) and \( m \geq 4 \). Perhaps surprisingly, and unlike results for the exploration with stop problem (where grids are “easier” to explore and stop than rings with respect to the number of robots), exclusive perpetual exploration requires as many robots in the ring as in the grid. Furthermore, we propose a classification of configurations such that the space of configurations to be checked is drastically reduced. This pre-processing lays the bases for the automated verification of our algorithm for general grids as it permits to avoid combinatorial explosion.

6.2.3. **Combining Fault-Tolerance and Self-stabilization in Dynamic Systems**

Recently, we started to investigate complex faults scenarios. Distributed fault-tolerance can mask the effect of a limited number of permanent faults, while self-stabilization provides forward recovery after an arbitrary number of transient faults hit the system. FTSS (Fault-Tolerant Self-Stabilizing) protocols combine the best of both worlds since they tolerate simultaneously transient and (permanent) crash faults. To date, deterministic FTSS solutions either consider static (i.e., fixed point) tasks, or assume synchronous scheduling of the system components. We proposed in [30] a fault-tolerant and stabilizing simulation of an atomic register. The simulation works in asynchronous message-passing systems, and allows a minority of processes to crash. The simulation stabilizes in a pragmatic manner, by reaching a long execution in which it runs correctly. A key element in the simulation is a new combinatorial construction of a bounded labeling scheme accommodating arbitrary labels, including those not generated by the scheme itself. Our simulation uses a self-stabilizing implementation of a data-link over non-FIFO channels [61]. In [23] we present the first study of deterministic FTSS solutions for dynamic tasks in asynchronous systems, considering the unison problem as a benchmark.
Unison can be seen as a local clock synchronization problem as neighbors must maintain digital clocks at most one time unit away from each other, and increment their own clock value infinitely often. We present several impossibility results for this difficult problem and propose a FTSS solution (when the problem is solvable) for the state model that exhibits optimal fault containment.

6.3. Peer-to-peer systems

Participants: Pierre Sens [correspondent], Nicolas Hidalgo, Sergey Legtchenko, Olivier Marin, Sébastien Monnet, Gilles Muller, Maria Potop-Butucaru, Mathieu Valero.

6.3.1. Peer-to-peer storage

Distributed Hash Table (DHTs) provide a means to build a completely decentralized, large-scale persistent storage service from the individual storage capacities contributed by each node of the peer-to-peer overlay. However, persistence can only be achieved if nodes are highly available, that is, if they stay most of the time connected to the overlay. Churn (i.e., nodes connecting and disconnecting from the overlay) in peer-to-peer networks is mainly due to the fact that users have total control on theirs computers, and thus may not see any benefit in keeping its peer-to-peer client running all the time.

When connection/disconnection frequency is too high in the system, data-blocks may be lost. This is true for most current DHT-based system’s implementations. To avoid this problem, it is necessary to build really efficient replication and maintenance mechanisms. Since 2008 we study the effect of churn on an existing DHT-based P2P system namely PAST/Pastry. We have proposed RelaxDHT [25], a churn-resilient peer-to-peer DHT. RelaxDHT proposes an enhanced replication strategy with relaxed placement constraints, avoiding useless data transfers and improving transfer parallelization. This new replication strategy is able to cut down by 2 the number of data-block losses compared to PAST DHT. We are now starting to study the use of erasure coding mechanisms along with replication within DHTs. Our goal is to propose hybrid mechanisms to find a good tradeoff among 1) churn-resilience, 2) maintenance cost, and 3) storage space.

6.3.2. Overlays

Large-scale distributed systems gather thousands of peers spread all over the world. Such systems need to offer good routing performances regardless of their size and despite high churn rates. To achieve that requirement, the system must add appropriate shortcuts to its logical graph (overlay). However, to choose efficient shortcuts, peers need to obtain information about the overlay topology. In case of heterogeneous peer distributions, retrieving such information is not straightforward. Moreover, due to churn, the topology rapidly evolves, making gathered information obsolete. State of-the-art systems either avoid the problem by enforcing peers to adopt a uniform distribution or only partially fulfill these requirements. To cope with this problem, we propose DONUT [47], a mechanism to build a local map that approximates the peer distribution, allowing the peer to accurately estimate graph distance to other peers with a local algorithm. The evaluation performed with real latency and churn traces shows that our map increases the routing process efficiency by at least 20% compared to the state-of-the-art techniques. It points out that each map is lightweight and can be efficiently propagated through the network by consuming less than 10 bps on each peer.

6.3.3. Distributed trees

Publish/Subscribe implemented on top of distributed R-trees (DR-trees) overlays offer efficient DHT-free communication primitives. We have then extend the distributed R-trees (DR-trees) in order to reduce event delivery latency in order to meet the requirements of massively distributed video games such that pertinent information is quickly distributed to all the interested parties without degrading the load of nodes neither increasing the number of noisy events. In 2011, we explore how to improve robustness of distributed trees. Since each single crash can potentially break the tree structure connectivity, DR-trees are crash-sensitive. We this have proposed a fault tolerant approach which exploits replication of non leaf nodes in order to ensure the tree connectivity in presence of crashes. This work will be published in [56].
In [85], we consider a complete binary tree and construct a random pairing between leaf nodes and internal nodes. We prove that the graph obtained by contracting all pairs (leaf-internal nodes) achieves a constant node expansion with high probability. In the context of P2P overlays our result can be interpreted as follows: if each physical node participating to the tree overlay manages a random pair that couples one virtual internal node and one virtual leaf node then the physical-node layer exhibits a constant expansion with high probability which improves the robustness of the overlay.

6.3.4. Complex query over peer-to-peer networks

A major limitation of DHTs is that they only support exact-match queries. In order to offer range queries over a DHT it is necessary to build additional indexing structures. Prefix-based indexes, such as Prefix Hash Tree (PHT), are interesting approaches for building distributed indexes on top of DHTs. Nevertheless, the lookup operation of these indexes usually generates a high amount of unnecessary traffic overhead which degrades system performance by increasing response time. In [42], we propose a novel distributed cache system called Tabu Prefix Table Cache (TPT-C), aiming at improving the performance of the Prefix-trees. We have implemented our solution over PHT, and the results confirm that our searching approach reduces up to a 70% the search latency and traffic overhead. In [44], we propose DRing an efficient layered solution that directly supports range queries over a ring-like DHT structure. We improve load balancing by using only the nodes that store data, and by updating neighbour information through an optimistic approach.

6.3.5. Trust management in peer-to-peer networks

An ongoing research work focuses on trust assessment in dynamic systems. Even if it is near impossible to fully trust a node in a P2P system, managing a set of the most trusted nodes in the system can help to implement more trusted and reliable services. Using these nodes can reduce the probability of introducing malicious nodes in distributed computations. Our work aims at the following objectives: 1. To design a distributed membership algorithm for structured Peer to Peer networks in order to build a group of trusted nodes. 2. To design a maintenance algorithm to periodically clean the trusted group so as to avoid nodes whose reputation has decreased under the minimum value. 3. To provide a way for a given node X to find at least one trusted node. 4. To design a prototype of an information system, such as a news dissemination system, that relies on the trusted group. In 2011, we propose the CORPS system for building a community of reputable peers in Distributed Hash Tables [26].

6.4. Virtual machine (VM)

Participants: Harris Bakiras, Bertil Folliot, Gaël Thomas [correspondent], Gilles Muller [correspondent], Julia Lawall, Arie Middlekoop, Thomas Preud’homme, Suman Saha.

Our research interests are in improving the way systems software is developed. One theme of our research is the development of virtual machines with a specific focus on resource management, isolation and concurrency management. Another theme of our research is related to bug finding in systems software.

6.4.1. Virtual machines

Isolation in OSGi: The OSGi framework is a Java-based, centralized, component oriented platform. It is being widely adopted as an execution environment for the development of extensible applications. However, current Java Virtual Machines are unable to isolate components from each other’s. By modifying shared variables or allocating too much memory, a malicious component can freeze the complete platform. We work on I-JVM, a Java Virtual Machines that provides a lightweight approach to isolation while preserving the compatibility with legacy OSGi applications. Our evaluation of I-JVM shows that it solves the 15 known OSGi vulnerabilities due to the Java Virtual Machine with an overhead below 20%. I-JVM has been presented in DSN 2009.
VMKit: Managed Runtime Environments (MREs), such as the JVM and the CLI, form an attractive environment for program execution, by providing portability and safety, via the use of a bytecode language and automatic memory management, as well as good performance, via just-in-time (JIT) compilation. Nevertheless, developing such a fully featured MRE, including features such as a garbage collector and JIT compiler, is a herculean task. As a result, new languages cannot easily take advantage of the benefits of MREs, and it is difficult to experiment with extensions of existing MRE based languages. VMKit is a first attempt to build a common substrate that eases the development of high-level MREs. We have successfully used VMKit to build two MREs: a Java Virtual Machine (J3) and a Common Language Runtime (N3). VMKit has performance comparable to the well established open source MREs Cacao, Apache Harmony and Mono. VMKit is freely distributed under the LLVM licence with the LLVM framework developed by the University of Illinois at Urbana-Champaign and now maintained by Apple.

A third MRE is being build in cooperation with the "Algorithms, Programmes and Resolution" team in LIP6. This integrates a functional machine (the Zinc Abstract Machine) in VMKit and show that the adataption at the language level of our virtual machine. This project has been funded by the LIP6 in 2009-10 and 2010-11.

6.4.2. Semantic patches
Open source infrastructure software, such as the Linux operating system, Web browsers and n-tier servers, has become a well-recognized solution for implementing critical functions of modern life. Furthermore, companies and local governments are finding that the use of open source software reduces costs and allows them to pool their resources to build and maintain infrastructure software in critical niche areas. Nevertheless, the increasing reliance on open source infrastructure software introduces new demands in terms of security and safety. In principle, infrastructure software contains security features that protect against data loss, data corruption, and inadvertent transmission of data to third parties. In practice, however, these security features are compromised by a simple fact: software contains bugs.

We are developing a comprehensive solution to the problem of finding bugs in API usage in open source infrastructure software based on our experience in using the Coccinelle code matching and transformation tool, and our interactions with the Linux community.

Coccinelle has been successfully used for finding and fixing bugs in systems code. One of our main recent results is an extensive study of bugs in Linux 2.6 [51] that has permitted us to demonstrate that the quality of code has been improving over the last six years, even though the code size has more than doubled.

We have used Coccinelle to generate traditional patches for improving the safety of Linux. Some Linux developers have also begun to use the tool. Over 800 patches developed using Coccinelle have been integrated into the mainline Linux kernel. As part of the ABL ANR project, we are building on the results of Coccinelle by designing semantic patches to identify API protocols and detect violations in their usage [24].

Another work done as part of the ANR ABL project, and as the topic of Suman Saha’s PhD thesis, is the improvement of error handling code in Linux. We developed a program analysis for identifying the code structures used to represent error handling code and a transformation to convert existing error handling code to use gotos to shared cleanup code, which is the style preferred by the Linux community [53]. We subsequently worked on finding bugs in error handling code, following an approach that focuses on local patterns, i.e., within the current function, rather than patterns occurring across the entire code base. This approach has a low rate of false positives and can find bugs in the use of rarely called functions [39].

6.5. Hosted database replication service
Participant: Mesaac Makpangou [correspondent].

Today, the vast majority of content distributed on the web are produced by web 2.0 applications. Examples of such applications include social networks, virtual universities, multi-players games, e-commerce web sites, and search engines. These applications rely on databases to serve end-users’ requests. Hence, the success of these applications/services depends mainly on the scalability and the performance of the database backend.
The objective of our research is to provide a hosted database replication service. With respect to end-users applications, this service offers an interface to create, to register, and to access databases. Internally, each hosted database is fragmented and its fragments are replicated towards a peer-to-peer network. We anticipate that such a service may improve the performance and the availability of popular web applications, thanks to partial replications of backend databases. Partial database replication on top of a peer-to-peer network raises a number of difficult issues: (i) enforcing replica consistency in presence of update transactions, without jeopardizing the scalability and the performance of the system? (ii) accommodating the dynamic and the heterogeneity of a peer-to-peer network with the database requirements?

We designed a database access protocol, capable to spread out a transaction’s accesses over multiple database fragments replicas while guaranteeing that each transaction observes a consistent distributed snapshot of a partially replicated database. We have also proposed a replica control substrate that permits to enforce 1-Copy SI for database fragments replicated over a wide area network. For that, unlike most database replication, we separate the synchronisation from the certification concerns.

A small-scale group of schedulers that do not hold database replicas, cooperate with one another to certify update transactions. Only certified transactions are notified to replicas. Furthermore, each replica will be notified only the transactions that impact the that it stores. Thanks to this separation, we avoid waste of computation resource at replicas that will be used to decide whether to abord or commit an update transaction; Our design choices also permit to reduce bandwidth consumption.

In 2010, we focus on the development of a prototype implementation of the complete system. The current prototype includes: a tool that helps fragment a database into fragments; the support to deploy dynamically, for each fragment, the suitable number of replicas towards the network of hosting peers; the implementation of our proposal (i.e. our database access protocol and our replica control substrate); and the JDBC API extension for accessing replicated databases.

6.6. Commitment protocols for WAN replication

Participants: Marc Shapiro [correspondent], Pierre Sutra, Masoud Saeida Ardekani.

In a large-scale distributed system, replication is an essential technique for improving availability and read performance. However, writes raise the issue of consistency, especially in the presence of concurrent updates, network failures, and hardware or software crashes. So-called consensus constitutes a major primitive to solving these issues. The performance of large-scale systems depends crucially on the latency of consensus, especially in wide-area networks; to decrease it, we focus on generalised consensus algorithms, i.e., ones that leverage the commutativity of operations and/or the spontaneous ordering of messages by the network. One such algorithms is Generalized Paxos, which does not order concurrent commutative operations. However, when a collision occurs (i.e., two replicas receive non-commuting operations in a different order) Generalized Paxos requires a very high latency to recover, completely negating the gain. We designed FGGC, a new generalised consensus algorithm that minimises the cost of recovering from a collision, without decreasing resilience to faults. FGGC achieves the optimal latency (two communication steps when processes receive non-commutative operations in the same order, and three otherwise) when there are no faults. FGGC remains optimally fault-tolerant, as it tolerates \( f < \frac{n}{2} \) crash faults and requires only \( f + 1 \) processes to make progress. Our experimental evaluation of FGGC shows that it is more efficient than the competing protocols. Another topic of relevance in WANs is partial replication, i.e., where any given server holds only a fraction of all shared objects. This decreases the workload per server and improves access times. However, this makes transactional concurrency control more difficult; indeed most existing algorithms assume full replication. We designed and implemented two genuine consensus protocols for partial replication, i.e., ones in which only relevant replicas need participate in the commit of a transaction. They were evaluated experimentally above the BerkeleyDB database engine. This work is the topic of Pierre Sutra’s PhD thesis.

6.7. Optimistic approaches in collaborative editing

Participants: Marc Shapiro [correspondent], Marek Zawirski, Pierpaolo Cincilla.
In recent years, the Web has seen an explosive growth of massive collaboration tools, such as wiki and weblog systems. By the billions, users may share knowledge and collectively advance innovation, in various fields of science and art. Existing tools, such as the MediaWiki system for wikis, are popular in part because they do not require any specific skills. However, they are based on a centralised architecture and hence do not scale well. Moreover, they provide limited functionality for collaborative authoring of shared documents.

A natural research direction is to use P2P techniques to distribute collaborative documents. This raises the issue of supporting collaborative edits, and of maintaining consistency, over a massive population of users, shared documents, and sites.

In order to avoid complex and unnatural concurrency control and synchronisation, and to enable different styles of collaboration (from online “what you see is what I see” to fully asynchronous disconnected work) we invented the concept of a Commutative Replicated Data Type (CRDT). A CRDT is one where all concurrent operations commute. The replicas of a CRDT converge automatically, without complex concurrency control.

In the context of collaborative editing, we propose a novel CRDT design called Treedoc. An essential property is that the identifiers of Treedoc atoms are selected from a dense space. We study practical alternatives for implementing the identifier space based on an extended binary tree. We also focus storage alternatives for data and meta-data, and mechanisms for compacting the tree. In the best case, Treedoc incurs no overhead with respect to a linear text buffer. We validate the results with traces from existing edit histories.

Treedoc will be used in ANR projects PROSE (Section 7.1.5) and STREAMS, and will be further studied and developed in ANR project ConcoRDanT (Section 7.1.3) and under a Google European Doctoral Fellowship.

6.8. CRDTs, a principled approach to eventual consistency

Participants: Marc Shapiro [correspondent], Marek Zawirski.

Most well-studied approaches to replica consistency maintain a global total order of operations. This serialisation constitutes a performance and scalability bottleneck, while the CAP theorem imposes a trade-off between consistency and partition-tolerance. An alternative approach, eventual consistency or optimistic replication, is attractive. A replica may execute an operation without synchronising a priori with other replicas. The operation is sent asynchronously to other replicas; every replica eventually applies all updates, but possibly in different orders. This approach ensures that data remains available despite network partitions, and is perceived to scale well and to provide acceptable quality of service. The consensus bottleneck remains but is off the critical path. However, reconciliation is generally complex. There is little theoretical guidance on how to design a correct optimistic system, and ad-hoc approaches have proven brittle and error-prone. We propose a simple, theoretically sound approach to eventual consistency, the concept of a convergent or commutative replicated data type (CRDT), for which some simple mathematical properties ensure eventual consistency. Provably, any CRDT converges to a common state that is equivalent to some sequential execution. A CRDT requires no synchronisation, thus every update can execute immediately, unaffected by network latency, faults, or disconnection. It is extremely scalable and is fault-tolerant, and does not require much mechanism. Previously, only a handful of CRDTs were known. Our current research aims to push the CRDT envelope, to study the principles of CRDTs, and to design a library of useful CRDTs. So far we have designed variations on registers, counters, sets, maps (key-value stores), graphs, and sequences. Potential application areas include computation in delay-tolerant networks, latency tolerance in wide-area networks, disconnected operation, churn-tolerant peer-to-peer computing, and partition-tolerant cloud computing. CRDTs are the main topic of ANR project ConcoRDanT (Section 7.1.3). This research is also funded in part by a Google European Doctoral Fellowship.
6. New Results

6.1. White Noise-based Stochastic Calculus with respect to Multifractional Brownian Motion

Participants: Joachim Lebovits, Jacques Lévy Véhel.

The purpose of this work is to build a stochastic calculus with respect to (mBm) with a view to applications in finance and particularly to stochastic volatility models. We use an approach based on white noise theory.

6.1.1. White Noise-based Stochastic Calculus with respect to multifractional Brownian motion

The following results may be found in [28]. Integration with respect to mBm requires stochastic processes. Considering the probability space where \( \mathbb{S}(\mathbb{R}), \mathbb{B}(\mathbb{S}(\mathbb{R})), \mu \) where \( \mu \) is probability measure given by Bôcher Minlos theorem, one can build to spaces, noted \( \mathbb{S} \) and \( \mathbb{S}^* \) which will play an analogous role to the spaces \( \mathbb{S}(\mathbb{R}) \) and \( \mathbb{S}(\mathbb{R}) \) for tempered distributions. We recall that \( \mathbb{S}(\mathbb{R}) \) is the Schwartz space of rapidly decreasing functions which are infinitely differentiable and \( \mathbb{S}^* \) is the space of tempered distributions. Let us moreover note \((L^2)\) the space of random variables defined on the probability space \( (\mathbb{S}(\mathbb{R}), \mathbb{B}(\mathbb{S}(\mathbb{R})), \mu) \) which admit a second order moment. The mBm \( B^{(h)} \) has the following Wiener-Itô chaos decomposition in \((L^2)\):

\[
B^{(h)}(t) = \sum_{k=0}^{+\infty} < [0,t], M_{h(t)}(e_k) >_{L^2} \quad \text{and} \quad \int_0^t M_{h(t)}(e_k)(s) ds = \sum_{k=0}^{+\infty} \left( \int_0^t M_{h(t)}(e_k)(s) ds \right) <.,e_k>
\]

(13)

where \((e_k)_{k \in \mathbb{N}}\) denotes the family of Hermite functions, defined for every integer \( k \in \mathbb{N} \), by \( e_k(x) := \pi^{-1/4}(2^k k!)^{-1/2} e^{-x^2/2} h_k(x) \) and where \((h_k)_{k \in \mathbb{N}}\) is the family of Hermite polynomial, defined for every integer \( k \in \mathbb{N} \), by \( h_k(x) := (-1)^k e^{x^2} \frac{d^k}{dx^k}(e^{-x^2}) \). Note moreover that \( M_H \) is an operator from \( \mathbb{S}(\mathbb{R}) \) to \( L^2(\mathbb{R}) \) for every real \( H \) in \((0,1)\) and \( <.,e_k> \) is a centered random Gaussian variable with variance equal to 1 for all \( k \in \mathbb{N} \). We can now define a process, noted \( W^{(h)} \), from \( \mathbb{R} \) to \( \mathbb{S}^* \), which is the derivative of \( B^{(h)} \) in sense of \( \mathbb{S}^* \) by

\[
W^{(h)}(t) = \sum_{k=0}^{+\infty} \left[ \frac{d}{dt} \left( \int_0^t M_{h(t)}(e_k)(s) ds \right) \right] <.,e_k>.
\]

(14)

Hence we define integral with respect to mBm of any process \( \Phi: \mathbb{R} \to \mathbb{S}^* \) as being the element of \( \mathbb{S}^* \) given by:

\[
\int_{\mathbb{R}} \Phi(s, \omega) dB^{(h)}(s) = \int_{\mathbb{R}} \Phi(s) \circ W^{(h)}(s) ds \quad (\omega),
\]

(15)

where \( \circ \) denotes the Wick product on \( \mathbb{S}^* \). It is then possible to get Itô-\^{^c} formulas and Tanaka formula such as
\[
\int_0^T \frac{\partial f}{\partial x}(t, B(t)) \ dB(t) = f(T, B(T)) - f(0, 0) - \int_0^T \frac{\partial f}{\partial t}(t, B(t)) \ dt \\
- \frac{1}{2} \int_0^T \left( \frac{d}{dt} [R_h(t, t)] \right) \frac{\partial^2 f}{\partial x^2}(t, B(t)) \ dt.
\]

(16)

for functions with sub exponential growth and where the last equality holds in \(L^2\).

Once this stochastic calculus with respect to \(mBm\) is defined, we can solve differential equations arising in mathematical finance.

### 6.1.2. Multifractional stochastic volatility

Multifractional stochastic volatility

The results of this part may be found in [6]. We assume that, under the risk-neutral measure, the forward price of a risky asset is the solution of the S.D.E.

\[
\left\{ \begin{array}{l}
\ dF_t = F_t \sigma_t dW_t, \\
\ d \ln(\sigma_t) = \theta (\mu - \ln(\sigma_t)) dt + \gamma_h d^\sigma B^h_t + \gamma_\sigma dW^\sigma_t, \quad \sigma_0 > 0, \ \theta > 0,
\end{array} \right.
\]

(17)

where \(W\) and \(W^\sigma\) are two standard Brownian motions and \(B^h\) is a multifractional Brownian motion independent of \(W\) and \(W^\sigma\) with functional parameter \(h\), which is assumed to be continuously differentiable.

We assume that \(W\) is decomposed into \(\rho dW^\sigma_t + \sqrt{1 - \rho^2} dW^F_t\), where \(W^F\) is a Brownian motion independent of \(W^\sigma\). Note that \(d^\sigma B^h_t\) denotes differentiation in the sense of white Noise theory. The solution of the volatility process \((\sigma_t)_{t \in [0, T]}\)

\[
\sigma_t = \exp \left( \ln(\sigma_0) e^{-\theta t} + \mu (1 - e^{-\theta t}) + \gamma_\sigma \int_0^t e^{\theta(s-t)} dW^\sigma_s + \gamma_h e^{-\theta t} I_t (B^h) \right),
\]

(18)

where \(I_t (B^h) : \overset{a.s.}{=} e^{\theta t} B^h_t - \theta \int_0^t e^{\theta s} B^h_s ds\).

Since the solution the previous S.D.E. is not explicit for \((F_t)_{t \in [0, T]}\) we use preconditioning and then cubature methods in order to get an approximation of it. This model allows to take into account the well-known "smile" effect of volatility, as well as its evolution at various maturities.

### 6.1.3. Approximation of \(mBm\) by \(fBms\)

In [18], we establish that a sequence of well-chosen lumped fractional Brownian motions converges in law to a multifractional Brownian motion. This allows to define stochastic integrals with respect to \(mBm\) by "transporting" corresponding stochastic integrals with respect to \(fBm\).

### 6.2. Sample paths properties of the set-indexed Lévy process

**Participant:** Erick Herbin.

In collaboration with Prof. Ely Merzbach (Bar Ilan University, Israel).

In [24], the class of set-indexed Lévy processes is considered using the stationarity property defined for the set-indexed fractional Brownian motion in [23]. Following Ivanoff-Merzbach’s definitions of an indexing collection \(\mathcal{A}\) and its extensions \(\mathcal{C}_0 = \{ U \setminus V ; U, V \in \mathcal{A} \}\) and

\[
\mathcal{C} = \left\{ U \setminus \bigcup_{1 \leq \ell \leq n} V_\ell ; \ n \in \mathbb{N}; U, V_1, \cdots, V_n \in \mathcal{A} \right\},
\]

is.
a set-indexed process $X = \{X_U; \; U \in \mathcal{A}\}$ is called a **set-indexed Lévy process** if the following conditions hold

1. $X_{\mathcal{O}'} = 0$ almost surely, where $\mathcal{O}' = \bigcap_{U \in \mathcal{A}} U$.
2. the increments of $X$ are independent: for all pairwise disjoint $C_1, \ldots, C_n$ in $\mathcal{C}$, the random variables
   \[ \Delta X_{C_1}, \ldots, \Delta X_{C_n} \] are independent.
3. $X$ has $m$-stationary $C_0$-increments, i.e. for all integer $n$, all $V \in \mathcal{A}$ and for all increasing sequences $(U_i)$ and $(A_i)$ in $\mathcal{A}$, we have
   \[
   \forall i, \; m(U_i \setminus V) = m(A_i) \Rightarrow (\Delta X_{U_1 \setminus V}, \ldots, \Delta X_{U_n \setminus V}) \overset{(d)}{=} (\Delta X_{A_1}, \ldots, \Delta X_{A_n})
   \]
4. $X$ is continuous in probability.

On the contrary to previous works of Adler and Feigin (1984) on one hand, and Bass and Pyke (1984) one the other hand, the increment stationarity property allows to obtain explicit expressions for the finite-dimensional distributions of a set-indexed Lévy process. From these, we obtained a complete characterization in terms of Markov properties.

The question of continuity is more complex in the set-indexed setting than for real-parameter stochastic processes. For instance, the set-indexed Brownian motion can be not continuous for some indexing collection. We consider a weaker form of continuity, which studies the possibility of point jumps.

The **point mass jump** of a set-indexed function $x : \mathcal{A} \to \mathbb{R}$ at $t \in \mathcal{T}$ is defined by

\[
J_t(x) = \lim_{n \to \infty} \Delta x_{C_n(t)}, \quad \text{where} \quad C_n(t) = \bigcap_{C \in C_n} C,
\]

and for each $n \geq 1$, $C_n$ denotes the collection of subsets $U \setminus V$ with $U \in \mathcal{A}_n$ (a finite sub-semilattice which generates $\mathcal{A}$ as $n \to \infty$) and $V \in \mathcal{A}_n(u)$. A set-indexed function $x : \mathcal{A} \to \mathbb{R}$ is said **pointwise-continuous** if $J_t(x) = 0$, for all $t \in \mathcal{T}$.

**Theorem** Let $\{X_U; \; U \in \mathcal{A}\}$ be a set-indexed Lévy process with Gaussian increments. Then for any $U_{\text{max}} \in \mathcal{A}$ such that $m(U_{\text{max}}) < +\infty$, the sample paths of $X$ are almost surely pointwise-continuous inside $U_{\text{max}}$, i.e.

\[
P(\forall t \in U_{\text{max}}, J_t(X) = 0) = 1.
\]

In the general case, for all $\epsilon > 0$, For all $U \in \mathcal{A}$ with $U \subset U_{\text{max}}$, we define

\[
N_U(B) = \# \{ t \in U : J_t(X) \in B \},
\]

\[
X_U^B = \int_B x_N U(dx),
\]

for all $B \in \mathcal{B}_\epsilon$, the $\sigma$-field generated by the opened subsets of $\{x \in \mathbb{R} : |x| > \epsilon\}$. The sample paths of the set-indexed Lévy processes can be derived from the following Lévy-Ito decomposition proved in [24].

**Theorem** Let $(\sigma, \gamma, \nu)$ the generating triplet of the SI Lévy process $X$.

Then $X$ can be decomposed as

\[
\forall \omega \in \Omega, \forall U \in \mathcal{A}, \quad X_U(\omega) = X_U^{(0)}(\omega) + X_U^{(1)}(\omega),
\]
where

1. \( X^{(0)} = \{ X^{(0)}_U : U \in A \} \) is a set-indexed Lévy process with Gaussian increments, with generating triplet \((\sigma, \gamma, 0)\),

2. \( X^{(1)} = \{ X^{(1)}_U : U \in A \} \) is the set-indexed Lévy process with generating triplet \((0, 0, \sigma)\), defined for some \( \Omega_1 \in \mathcal{F} \) with \( P(\Omega_1) = 1 \) by

\[
\forall \omega \in \Omega_1, \quad \forall U \in A,
X^{(1)}_U(\omega) = \int_{|x| > 1} \frac{x}{N_U(dx, \omega)} + \lim_{\epsilon \downarrow 0} \int_{|x| \leq 1 \wedge |x| \leq 1} x [N_U(dx, \omega) - m(U)] \nu(dx),
\]

(21)

where \( N_U \) is defined in (13) and the last term of (14) converges uniformly in \( U \subset U_{\max} \) (for any given \( U_{\max} \in A \)) as \( \epsilon \downarrow 0 \),

3. and the processes \( X^{(0)} \) and \( X^{(1)} \) are independent.

6.3. Hölder regularity of Set-Indexed processes

Participants: Erick Herbin, Alexandre Richard.

In collaboration with Prof. Ely Merzbach (Bar Ilan University, Israel).

In the set-indexed framework of Ivanoff and Merzbach ([54]), stochastic processes can be indexed not only by \( \mathbb{R} \) but by a collection \( A \) of subsets of a measure and metric space \((\mathcal{T}, d, m)\), with some assumptions on \( A \). In [25], we introduce and study some assumptions on the metric indexing collection \((A, d_A)\) in order to obtain a Kolmogorov criterion for continuous modifications of SI stochastic processes. Under this assumption, the collection is totally bounded and a set-indexed process with good incremental moments will have a modification whose sample paths are almost surely Hölder continuous, for the distance \( d_A \).

Once this condition is established, we investigate the definition of Hölder coefficients for SI processes. From the real-parameter case, the most straightforward are the local (and pointwise) Hölder exponents around \( U_0 \in A \):

\[
\tilde{\alpha}_X(U_0) = \sup \left\{ \alpha : \limsup_{\rho \to 0} \sup_{U, V \in B_{d_A}(U_0, \rho)} \frac{|X_U - X_V|}{d_A(U, V)^\alpha} < \infty \right\}.
\]

When the processes are Gaussian, a deterministic counterpart to this exponent is defined as it is in the real-parameter framework. For all \( U_0 \in A \), we proved that almost surely, the random and the deterministic exponents are equal. Also, we proved that for the local exponents, this result holds almost surely, uniformly on \( A \).

Given the particular structure of \( A \), other coefficients of Hölder regularity were studied on \( \mathcal{C} \):

\[
\mathcal{C} = \left\{ A \setminus \bigcup_{k=1}^n B_k : A, B_1, \ldots, B_n \in A, n \in \mathbb{N} \right\}.
\]

(22)

On specific subclasses \( \mathcal{C}^l \) of \( \mathcal{C} \) (satisfying \( \bigcup_{l \geq 1} \mathcal{C}^l = \mathcal{C} \)), the local (and pointwise) \( \mathcal{C}^l \)-Hölder exponents are defined:
\[ \tilde{\alpha}_{X,c}(U_0) = \sup \left\{ \alpha : \limsup_{\rho \to 0} \sup_{U \in \mathcal{B}_d(U_0, \rho)} \frac{|\Delta X_{U,V}|}{d_{\mathcal{A}}(U,V)^{\alpha}} < \infty \right\}, \]

and this definition is proved to be independent of \( l \), leading to the definition of \( \tilde{\alpha}_{X,c}(U_0) \). It is compared to \( \tilde{\alpha}_{X}(U_0) \) and related to the Hölder exponent of the process projected on flows (a flow is a continuous increasing path in \( \mathcal{A} \)). This last technique permits to show that the pointwise Hölder exponent of the SfBm is almost surely uniformly equal to \( H \), the Hurst parameter of the SfBm. This completes some previous results on the multiparameter fractional Brownian motion.

The last exponent which is studied is the exponent of pointwise continuity:

\[ \alpha_{pc}(t) = \sup \left\{ \alpha : \limsup_{n \to \infty} \frac{1}{m(C_n(t))^{st}} \frac{|\Delta X_{C_n(t)}|}{|C_n(t)|^{\alpha}} < \infty \right\}, \]

for all \( t \in \mathcal{T} \), where \( C_n(t) \) is the smaller set of \( C_n \) containing \( t \). Almost sure results are also obtained in that case. For instance, the coefficient of pointwise continuity of a SI Brownian motion equals \( 1/2 \) a.s.

All these results are finally applied to the SfBm and the SI Ornstein-Uhlenbeck process ([1]).

### 6.4. Stochastic 2-microlocal analysis

**Participants:** Erick Herbin, Paul Balança.

Stochastic 2-microlocal analysis has been introduced in [19] to study the local regularity of stochastic processes. If \( X = (X_t)_{t \in \mathbb{R}_+} \) is a stochastic process, then for all \( t_0 \in \mathbb{R}_+ \), a function \( s' \mapsto \sigma_{X,t_0}(s') \) called the 2-microlocal frontier is defined to characterize entirely the local regularity of \( X \) at \( t_0 \). In particular, for all \( s' \in \mathbb{R} \) such that \( \sigma_{X,t_0}(s') \in (0,1) \), it is defined as

\[ \sigma_{X,t_0}(s') = \sup \left\{ \sigma : \limsup_{\rho \to 0} \sup_{u,v \in \mathcal{B}(t_0, \rho)} \frac{|X_u - X_v|}{|u - v|^{\alpha}} < \infty \right\}. \]

The 2-microlocal frontier gives a more complete picture of the regularity than classical pointwise and local Hölder exponents, which are widely used in the literature. Furthermore, it is stable under the action of (pseudo-)differential operators.

[19] mainly focused on Gaussian processes, and in particular obtained a characterization of the regularity for Wiener integrals \( X_t = \int_0^t \eta_udW_u \), with \( \eta \in L^2(\mathbb{R}) \).

Our main goal was therefore to extend this result to any stochastic integral

\[ X_t = \int_0^t H_u dM_u, \]

where \( M \) is a local martingale and \( H \) an adapted continuous process.

In fact, in [15], we first reduced this problem to the study of local martingales, and we have shown that almost surely for all \( t \in \mathbb{R}_+ \), the 2-microlocal frontier of a local martingale \( M \), with quadratic variation \( \langle M \rangle \), satisfies
∀s′ ≥ −α_{M,t}; \quad σ_{M,t}(s′) = \Sigma_{M,t}(s′) = \frac{1}{2} Σ_{(M)}(2s′),

where for any process X, Σ_{X,t} denotes the pseudo 2-microlocal frontier which is characterized as following

∀s′ ∈ ℝ; \quad Σ_{X,t}(s′) = σ_{X,t}(s′) \wedge (s′ + p_{X,t}) \wedge 1,

where p_{X,t} corresponds to

p_{X,t} = \inf \{ n ≥ 1 : X^{(n)}(t) \text{ exists and } X^{(n)}(t) ≠ 0 \},

with the usual convention \( \inf \{ \varnothing \} = +∞ \).

As the previous result is based on Dubins-Schwarz representation theorem, it can be easily extended to characterize the regularity of time-changed multifractional Brownian motions. In this case, we obtain a similar equation where \( \frac{1}{2} \) is replaced by \( H(t) \), the value of the Hurst function at \( t \).

Using this last equality, we can obtain the regularity of the stochastic integral \( X \) previously defined: almost surely for all \( t ∈ ℝ_+ \)

∀s′ ≥ −α_{X,t}; \quad σ_{X,t}(s′) = Σ_{X,t}(s′) = \frac{1}{2} Σ \int_0^t H^2_u(2s′) d⟨M⟩u,t.

In the particular case of an integration with respect to a Brownian motion \( B \), the result can be simplified using the stability under differential operators: for almost all \( ω ∈ Ω \) and for all \( t ∈ ℝ_+ \), the 2-microlocal frontier satisfies

1. if \( H(t)(ω) ≠ 0 \):

∀s′ ∈ ℝ; \quad σ_{X,t}(s′) = σ_{B,t}(s′) = \left( \frac{1}{2} + s′ \right) \wedge \frac{1}{2}.

2. if \( H(t)(ω) = 0 \):

∀s′ ≥ −α_{X,t}; \quad σ_{X,t}(s′) = \left( \frac{1}{2} + \frac{Σ_{H^2,t}(2s′)}{2} \right) \wedge \frac{1}{2},

unless \( H \) is locally equal to zero at \( t \), which induces in that case: \( σ_{X,t} = +∞ \).

Based on this last characterization, we were able to study the regularity of stochastic diffusions. In particular, we illustrated our purpose with the square of \( δ \)-dimensional Bessel processes which verify the following equation

\[ Z_t = x + 2 \int_0^t \sqrt{Z_s} dβ_s + δt. \]

### 6.5. Tempered multistable measures and processes

**Participants:** Jacques Lévy Véhel, Lining Liu.
This year, we concentrated on the following points:

- Define a new type of multistable processes called tempered multistable processes.
- Study the short time and long time behaviors of tempered multistable processes.
- Compare the multistable Lévy processes defined by finite-dimensional distributions (characteristic functions), Poisson representation and series representation.

The idea of the construction of tempered multistable measure and processes comes from the paper [63]. The interest of such processes is that they may be chosen to have moments of all orders. In addition, they are martingales. This will allow to construct stochastic (partial) differential equation driven by tempered multistable measures, which may be used to describe certain physical phenomena.

The characteristic function of a termpered multistable process $X(t)$ is

$$
\mathbb{E}(\exp iyX(t)) = \exp \left\{ \frac{1}{2} \int_0^t \left[ \left( 1 - \frac{i y}{\theta} \right)^{\alpha(x)} + \left( 1 + \frac{i y}{\theta} \right)^{\alpha(x)} - 2 \right] \theta^{\alpha(x)} dx \right\}.
$$

We have investigated the long time and short time behaviors this process:

**Short time behavior:**
Let $\alpha: \mathbb{R} \to [a, b] \subseteq (0, 2)$ be continuous. Let $u \in \mathbb{R}$ and suppose that as $v \to u$,

$$
|\alpha(u) - \alpha(v)| = o \left( \frac{1}{|\log |u - v||} \right).
$$

Then when $h \to 0$,

$$
h^{-1/\alpha(t)}[X(t + hu) - X(t)] \to Y_{\alpha(t)}(u)
$$

in finite-dimensional-distributions, where

$$
Y_{\alpha(t)}(u) = \int 1_{[0,u]}(z) dM_{\alpha(t)}(z),
$$

and $M_{\alpha(t)}$ is an $\alpha(t)$ stable measure. In an other word, $X(t) = M[0, t]$ is $1/\alpha(t)$-localisable at $t$ with local form $Y_{\alpha(t)}$.

**Long time behavior:**
Let $\alpha: \mathbb{R} \to [a, b] \subseteq (0, 2)$ be continuous and $\lim_{s \to \infty} \alpha(s) \to \alpha$. Then for $h \to \infty$

$$
h^{-1/2}[X(t + hu) - X(t)] \to \Gamma(2 - \alpha)B(u)
$$

in finite-dimensional-distributions, where $B$ is standard Brownian motion.

Let us now describe our work on the multistable Lévy motion. For $0 < a \leq b < 2$ and $\alpha: \mathbb{R} \to [a, b]$, the multistable Lévy motion $M_c$ defined by finite-dimensional distributions (characteristics function) is the process such that

$$
\mathbb{E}(\exp (i \sum_{j=1}^d \theta_j M_c(t_j))) = \exp \left( -\int \left| \sum_{j=1}^d \theta_j 1_{[0,t_j]}(s) \right|^{\alpha} ds \right); (28)
$$
There also exist a Poisson representation of multistable Lévy process $M_p$:

$$M_p(t) = \sum_{(X,Y)\in\Pi} C_{\alpha(X)} 1_{[0,t]}(X) Y^{-1/\alpha(X)} ,$$

where $(X,Y)$ be the random point of the Poisson process $\Pi$, $t > 0$, $Y^{-1/\alpha(X)} = \text{sign}(Y)|Y|^{-1/\alpha(X)}$ and

$$C_{\alpha(X)} = \left( \frac{1}{\Gamma(1-\alpha(X)) \cos \left( \frac{\pi}{2} \alpha(X) \right)} \right)^{1/\alpha(X)} ;$$

Finally, the series representation of multistable Lévy motion $M_s$ is

$$M_s(t) = \sum_{i=1}^{\infty} C_{\alpha(U_i)} \gamma_i^{-1/\alpha(U_i)} 1_{(U_i \leq t)} ,$$

where $\{\Gamma\}_{i\geq 1}$ is a sequence of arrival times of a Poisson process with unit arrival time, $\{U\}_{i\geq 1}$ is a sequence of i.i.d random variables with uniform distribution on $[0,t]$, $\{\gamma\}_{i\geq 1}$ is a sequence of i.i.d random variables with distribution $P(\gamma_i = 1) = P(\gamma_i = -1) = 1/2$. All three sequences $\{\Gamma\}_{i\geq 1}$, $\{U\}_{i\geq 1}$ and $\{\gamma\}_{i\geq 1}$ are independent, and

$$C_{\alpha(U_i)} = \left( \frac{1}{\Gamma(1-\alpha(U_i)) \cos \left( \frac{\pi}{2} \alpha(U_i) \right)} \right)^{1/\alpha(U_i)} .$$

We have proved that these three definitions yield the same process in law.

### 6.6. Local strings and the CH set

**Participant:** Jacques Lévy Véhel.

In collaboration with Prof. Franklin Mendivil (Acadia University, Canada).

We have extended the definition of fractal strings originally proposed in [59] and modified in [37] to deal with the local behaviour of fractal sets. This allows to analyze the pointwise oscillatory properties of locally self-similar sets ([38]).

We have also analyzed in details the structure of a set build by “stacking” Cantor sets with continuously varying dimensions (see figure 4). The resulting set, called "Christiane’s hair" set or CH set, displays a number of interesting properties. Each “strand of hair” is a $C^\infty$ curve. Its Hausdorff dimension is 2. Furthermore, it is Minkowski measurable in dimension 2 with vanishing Minkowski content.

### 6.7. General models for drug concentration in multi-dosing administration

**Participants:** Lisandro Fermin, Jacques Lévy Véhel.

In collaboration with P.E Lévy Véhel (University of Nice-Sophia-Antipolis and Banque Postale).
In the past two years, we have developed models for investigating the probability distribution of drug concentration in the case of non-compliance. We have focused on two aspects of practical relevance: the variability of the concentration and the regularity of its probability distribution. In a first article [29], in a series of three, is considered the case of multi-intravenous dosing using the simplest possible law to model random drug intake, i.e. a homogeneous Poisson distribution. In a second article [13], we consider the more realistic multi-oral model, and deal with the complications brought by the first-order kinetics, which are essentially technical. Finally, in [12], we put ourselves in a powerful mathematical frame, known as \textit{Piecewise Deterministic Markov process} (PDMP), that allows us to deal with general drug intake schedules, going beyond the homogeneous Poisson case. We use a PDMP to model the drug concentration in the case of multiple intravenous doses. In this particular model, we consider that the doses administration regimen is modeled by a non-homogeneous Poisson process whose jump rate is controlled by mean of a Markov chain. In this sense our PDMP model is a generalization to the continuos-models studied in [29]. In the following we detail our PDM model and the results obtained in the multi-IV case, see [12].

\textbf{The model setting}

Inspired by the PDMP model given in [47], [48], we consider a drug dosing stochastic regimen defined as follows.

Let us consider \((J_n)_{n \in \mathbb{N}}\) an irreducible Markov chain taking values in the state space \(K = \{1, ..., k\}\) with initial law \(\alpha_i = \mathbb{P}(J_0 = i)\) for all \(i \in K\) and transition probability matrix \(Q = (q_{ij})_{i,j \in K}\). We denote by \((T_n)_{n \in \mathbb{N}}\) the sequence of the random time doses and \((S_n)_{n \in \mathbb{N}}\) the time dose intervals; i.e. \(S_n = T_{n+1} - T_n\).

We consider that the doses administration regimen is modeled by mean of the Markov process \((J_n)_{n \in \mathbb{N}}\) considering the following assumptions:

- The patient takes a dose \(D_{J_n} \in \{D_i, i \in K\}\) at the time \(T_n\), where the doses \(D_i\) are all different and different of zero.
- The time dose \(S_n\) is a random variable with exponential law of parameter \(\lambda_{J_n} \in \{\lambda_i, i \in K\}\), where the jump rate \(\lambda_i\) of state \(i\) is a positive constant.

We consider that these doses translate into immediate increases of the concentration by the value \(d_i = D_i V_d\) if \(J_n = i\), where \(V_d\) is the apparent volume of distribution. After that, the effect of the dose taken at time \(T_n\) decreases exponentially fast with an exponential rate of elimination \(k_e\).

We define \((\nu_t)_{t \in \mathbb{R}}\) by \(\nu_t = \sum_{n \geq 0} J_n \mathbb{I}_{[T_n, T_{n+1})}(t)\). We denote by \((C_t)_{t \in \mathbb{R}}\) the drug concentration stochastic process which take values on \(\mathbb{R}^*_+ = [0, \infty]\), we suppose that \(\mathbb{P}(C_0 = x) = 1\). Between the jumps, the dynamical evolution of the continuous time process \((C_t)\) is modeled by the flow \(\phi(t, x) = x \exp \{-k_e t\}\).
Thus, the sample path of the stochastic process \((C_t)_{t \in \mathbb{R}_+}\) with values in \(\mathbb{R}_+\), starting from a fixed point \(x\) is given by
\[
C_t = xe^{-k_e t} + \sum_{i \geq 1} d_i e^{-k_i (t-T_i)} 1_{(t \geq T_i)}.
\] (33)

The process \((C_t, \nu_t)_{t \in \mathbb{R}_+}\) is a PDMP. From [49], we have that the infinitesimal generator \(\mathcal{U}\) of \((C_t, \nu_t)_{t \in \mathbb{R}_+}\) is given by
\[
\mathcal{U}f(x, i) = -k_e x \frac{d}{dx} f(x, i) + \lambda_i \sum_{j \in K} q_{ij} (f(x + d_j, j) - f(x, i)),
\] (34)
with \((x, i) \in E = \mathbb{R}_+^* \times K\) and \(f \in \mathbb{D}(\mathcal{U})\) the set of measurable and differentiable on the first argument.

### The characteristic function of the concentration

The characteristic function \(\varphi_0(t, x, i)\) of \(C_t\), given the starting point \((x, i)\), is the unique solution of the following system
\[
\begin{align*}
\frac{\partial \varphi_0}{\partial t}(t, x, i) &= -k_e x \frac{\partial \varphi_0}{\partial x}(t, x, i) + \lambda_i \sum_{j \in K} q_{ij} \left( e^{i \theta j e^{-k_e t}} \varphi_0(t, x, j) - \varphi_0(t, x, i) \right), \\
\varphi_0(0, x, i) &= e^{i \theta x}.
\end{align*}
\] (35)

### Variability of the concentration

From (28) we have that the expectation \(m(t, x, i) = \mathbb{E}_{(x, i)}[C_t]\) of \(C_t\), given the starting point \((x, i)\), is given by
\[
m(t, x, i) = xe^{-k_e t} + \lambda_i \sum_{j \in K} q_{ij} d_j \int_0^t e^{-k_e (t-s)} P_{\nu_0}(s) ds,
\] (36)
where \(P_{\nu_0}(t) = P(\nu_t = \nu | \nu_0 = i)\). The variance \(Var(t, i)\) of \(C_t\), given the initial state \(i\), is given by
\[
Var(t, i) = \sum_{\nu, j \in K} \lambda_{\nu} q_{\nu j} d_j^2 \int_0^t e^{-2k_e (t-s)} P_{\nu_0}(s) ds - \left( \sum_{\nu, j \in K} \lambda_{\nu} q_{\nu j} d_j \int_0^t e^{-k_e (t-s)} P_{\nu_0}(s) ds \right)^2
+ 2 \sum_{\nu, j \in K \nu' j' \in K} \lambda_{\nu} q_{\nu j} d_j \lambda_{\nu'} q_{\nu' j'} d_{j'} \int_0^t \int_0^{t-s} e^{-k_e (t-s)} P_{\nu_0}(s) e^{-k_e (t-s-\tau)} P_{\nu_0'}(\tau) d\tau ds.
\] (37)

### The distribution of limit concentration

The characteristic function \(\varphi(\theta, i)\) of the limit concentration \(C\), given the starting state \(i\), satisfies
\[-k_e \theta \frac{d}{d\theta} \varphi(\theta, i) + \lambda_i \sum_{j \in K} q_{ij} e^{i \theta d_i} \varphi(\theta, j) - \lambda_i \varphi(\theta, i) = 0.\]

Thus, the random variables \(C(t)\) converge in distribution, when \(t\) tends to infinity, to a well defined random variable \(C\) whose characteristic function is
\[ \varphi(\theta) = \sum_{j \in K} \varphi(\theta, j). \]

**Variability of the limit concentration**

We denote by \( m_i \) the mean of the limit concentration \( C \) in the state \( \nu = i \) and \( m = \sum_{i \in K} m_i \) the mean of \( C \) and \( Var \) its variance. Then,

\[
m = \frac{1}{K} \sum_{i,j \in K} \pi_i \lambda_i q_{ij} d_j,
\]

\[
m_i = \frac{1}{K} \sum_{j \in K} \pi_j \lambda_j q_{ji} d_i + \frac{1}{K} \left( \sum_{j \in K} \lambda_j q_{ji} m_j - \lambda_i m_i \right),
\]

\[
Var = \frac{1}{2K} \sum_{i,j \in K} \pi_i \lambda_i q_{ij} d_j^2 + \frac{1}{K} \sum_{i,j \in K} \lambda_i q_{ij} d_j (m_i - \pi_i m).
\]

**Regularity of the limit concentration**

The characteristic function \( \varphi \) satisfies

\[
|\varphi(\theta)| \sim K |\theta|^{-\mu_{max}}, \quad \theta \to \infty,
\]

where \( K \) is a positive constant and \( \mu_{max} = \max_{i \in K} \frac{\lambda_i}{K} \).

This result will allow us to describe in detail aspects of the limit distribution that are important for assessing the efficacy of therapy.

### 6.8. Complex systems design

**Participant:** Erick Herbin.

*In collaboration with Dassault Aviation, EADS, EDF.*

The preliminary design of complex systems can be described as an exploration process of a so-called design space, generated by the global parameters. An interactive exploration, with a decisional visualization goal, needs reduced-order models of the involved physical phenomena. We are convinced that the local regularity of phenomena is a relevant quantity to drive these approximated models. Roughly speaking, in order to be representative, a model needs more informations where the fluctuations are the more important (and consequently, where irregularity is the more important).

In collaboration with Dassault Aviation, EDF and EADS, we study how the local regularity can provide a good quantification of the concept of *granularity* of a model, in order to select the good level of fidelity adapted to a required precision.

Our works in that field can be expressed into:

- The definition and the study of stochastic partial differential equations driven by processes with prescribed regularity (that do not enter into the classical theory of stochastic integration).
- The study of the evolution of the local regularity inside stochastic partial differential equations (SPDE). Stochastic 2-microlocal analysis should provide informations about the local regularity of the solutions, in function of the coefficients of the equations. The knowledge of the fine behaviour of the solution of the SPDE will provide important informations in the view of numerical simulations.
6. New Results

6.1. Mathematical and numerical analysis of fluid-structure interaction problems

Participants: Cristóbal Bertoglio Beltran, Muriel Boulakia, Miguel Ángel Fernández Varela, Jean-Frédéric Gerbeau, Jimmy Mullaert.

- Over the last decade, the numerical simulation of incompressible fluid-structure interaction has been a very active research field and the subject of numerous works. In [19], we review some of the coupling schemes recently proposed in the literature. Some numerical results that show the effectiveness of the novel approaches are also presented.
- In [21], we propose a new class of time-marching schemes for the explicit coupling of an incompressible fluid and a general elastic solid (i.e., not necessarily thin [46] and possibly damped). We state a general energy-based stability result and illustrate the accuracy of the different variants in a numerical benchmark.
- [30]: This paper focuses on Eulerian-based algorithms for fluid-structure applications featuring large structural motions and/or deformations in the context of compressible flows. First, it presents a numerical method for treating simultaneously the fluid pressure and velocity conditions on static and dynamic embedded interfaces. This method is based on the exact solution of local, one-dimensional, fluid-structure Riemann problems. Next, it describes two consistent and conservative approaches for computing the flow-induced loads on rigid and flexible embedded structures.
- In [39], we present some issues encountered in fluid-structure interaction simulation (this text is targeted to a non-expert audience).
- In [42], we present a robust and efficient parameter estimation strategy for fluid-structure interaction problems. The method is based on a filtering algorithm restricted to the parameter space, known as the reduced order Unscented Kalman Filter. We illustrate our methodology with the estimation of the artery wall stiffness and the proximal Windkessel resistance.
- [44]: In this paper, we are interested in the three-dimensional coupling between an incompressible fluid and a rigid body. The fluid is modeled by the Navier-Stokes equations, while the solid satisfies the Newton’s laws. In the main result of the paper we prove that, with the help of a distributed control, we can drive the fluid and structure velocities to zero and the solid to a reference position provided that the initial velocities are small enough and the initial position of the structure is close to the reference position.
- In [46], we introduce a class of incremental displacement-correction schemes for the explicit coupling of a thin-structure with an incompressible fluid. We provide a general stability and convergence analysis that covers both the incremental and the non-incremental variants, and also the fully implicit case. The incremental variant with first-order extrapolation is unconditionally stable and yields optimal first-order accuracy in time.

6.2. Numerical methods for fluid mechanics and application to blood flows

Participants: Jean-Frédéric Gerbeau, Marc Thiriet, Irène Vignon-Clementel.
• [13]: In this work, a virtual planning of three different surgical Fontan repairs was performed to test the predictive capability of a closed-loop multi-scale model (3D-0D), constructed based on preoperative patient-specific data. Results from this multi-scale approach showed that the pre-operative caval flows should not be used as boundary conditions in post-operative simulations. The Y-TCPC repair seemed to perform better than all other TCPC models both at rest and under exercise conditions. Further work is needed to correlate results from these simulations with clinical outcomes.

• [18]: Flow reversal at an outlet, although perfectly physical, can lead to rapid numerical divergence in computational fluid dynamics. Several remedies have been proposed in the literature and are discussed in the present finite element study. The most robust one was found to be a boundary advective stabilization term. The comparison was done on simple examples, as well as realistic three-dimensional multi-branched models of blood flow.

• [22] & [23]: Treatments for coarctation of the aorta (CoA) can alleviate blood pressure gradients, but long-term morbidity still exists that can be explained by altered indices of hemodynamics and biomechanics. These articles present a combination of CFD methods (physiologically realistic boundary conditions and FSI with viscoelastic tissue support) to explore these indices in untreated and treated CoA, comparing them to normal subjects under rest and exercise conditions. These studies showed in particular that CoA disturbs normal patterns of wall shear stress and oscillatory shear index throughout the thoracic aorta (potentially linked to the development of atherosclerosis) and that restoring favorable anatomy may not restore normal hemodynamics.

• [24]: The objective of this work is to address the formulation of an adequate model of the external tissue environment when studying a portion of the arterial tree with fluid-structure interaction. The simulations are quantitatively assessed by detailed comparisons with dynamical medical image sequences, and the model results are shown to be in very good adequacy with the data.

• [26]: The wide range of existing viscoelastic wall models may produce significantly different blood flow, pressure, and vessel deformation solutions in cardiovascular simulations. In this paper, we have successfully implemented and verified two viscoelastic wall models in a nonlinear 1D finite element blood flow solver and analyzed differences between these models in various idealized and physiological simulations, including exercise.

• [28]: High-intensity focused ultrasound (HIFU) is used as a thermal ablation process to eliminate tumors in different body’s organs. Blood flow has a cooling effect. Conversely, ultrasounds are responsible for acoustic streaming. A three-dimensional acoustics-thermal-fluid coupling model is carried out to compute the temperature field a given hepatic cancerous region.

• [29]: Imaged-based patient-specific models of the multi-branched pulmonary arteries and superior vena cava were built for five cavopulmonary connection (i.e. Glenn) patients prior to their third surgery to alleviate their congenital heart disease. Inflow and outflow boundary conditions for computational blood flow simulations (CFD) were constructed based on an iterative procedure to match available MRI and catheterization clinical data. Common trends and differences emerged from this three-dimensional CFD study; in particular low wall shear stress was found for all subjects, which is potentially deleterious. A sensitivity analysis was performed to investigate the impact of input data (clinical and modeling) to construct boundary conditions on several clinical and mechanical indicators. Among other findings, this study suggests that although 6-10% flow split imprecision seemed reasonable in terms of patient comparison, the common practice of imposing a right pulmonary artery/left pulmonary artery flow split of 55%/45% when performing patient specific simulations should be avoided.

• [31]: A novel Y-shaped baffle has been proposed for the Fontan operation with promising initial results on idealized models or a single patient-specific model. The objective of this study is to comprehensively compare the hemodynamic performance and hepatic blood flow distribution of the Y-graft Fontan baffle with two current designs on multiple patient-specific models. Methods
include virtual geometrical design, computational fluid dynamics based on preoperative patient-specific data, particle tracking and sensitivity analysis, including rest and exercise conditions. The Y-graft Fontan design achieves overall superior hemodynamic performance compared with traditional designs. However, the results emphasize that designs should be customized for individual patients before clinical application.

6.3. Numerical methods for cardiac electrophysiology  
**Participants:** Muriel Boulakia, Miguel Ángel Fernández Varela, Jean-Frédéric Gerbeau, Vincent Martin, Elisa Schenone.

- [32]: We consider the problem of estimating some parameters of a model of electrocardiograms from the data of the Einthoven leads. The direct model is based on the bidomain equations in the heart and a Poisson equation in the torso. To keep the computational time reasonable, the evaluation of the direct problem is approximated with a reduced order model based on Proper Orthogonal Decomposition. The optimization problem is solved using an evolutionary algorithm. Numerical tests show that, with noisy synthetic data, the proposed procedure allows to recover ionic parameters and initial activation regions with a fair accuracy.

- [34] and [48]: In presence of a high magnetic field, the blood flow in the aorta induces an electrical potential which is responsible for an increase of the $T$-wave in the electrocardiogram (ECG). This phenomenon may perturb ECG-gated imaging. The aim of this numerical study is to reproduce this experimental observation through computer simulations. The proposed model consists of three components: magnetohydrodynamics (MHD) in the aorta, bidomain equations in the heart and electrical diffusion in the rest of the body. These models are strongly coupled together and solved with finite elements.

- [38]: We present an overview of our works about electrocardiogram numerical simulations.

- [45]: A reduced-order model based on Proper Orthogonal Decomposition is proposed for the bidomain equations of cardiac electrophysiology. Its accuracy is assessed through electrocardiograms in various configurations, including myocardium infarctions and long-time simulations. We show in particular that a restitution curve can efficiently be approximated by this approach. The reduced-order model is then used in an inverse problem solved by an evolutionary algorithm. Some attempts are presented to identify infarction locations from synthetic electrocardiograms.

6.4. Lung and respiration modeling  
**Participants:** Laurent Boudin, Bérénice Grec, Muriel Boulakia, Anne-Claire Egloffé, Céline Grandmont, Ayman Moussa.

- [9]: This paper is concerned with a system that couples the incompressible Navier–Stokes equations to the Vlasov–Fokker–Planck equation. Such a system arises in the modeling of sprays, where a dense phase interacts with a disperse phase. The coupling arises from the Stokes drag force exerted by a phase on the other.

- [25]: We are concerned with the global well-posedness of a two-phase flow system arising in the modelling of fluid-particle interactions. This system consists of the Vlasov-Fokker-Planck equation for the dispersed phase (particles) coupled to the incompressible Euler equations for a dense phase (fluid) through the friction forcing.

- [49]: We obtain the Maxwell-Stefan diffusion model by studying the asymptotic behaviour of a multicomponent kinetic model when the Knudsen number goes to 0.

- [50]: We are concerned here with identifiability, stability properties and estimates for the inverse problem of identifying a Robin coefficient on some non accessible part of the boundary from available data on the other part of boundary corresponding to solutions of the Stokes equations. We first study the identifiability of Robin coefficient and then we establish a stability estimate of logarithm type using Carleman inequality.
6.5. Miscellaneous

Participant: Laurent Boudin.

- [43]: We deal with a kinetic model to describe the evolution of the opinion in a closed group where there are two opposite behaviours: conciliatory and contradictory agents. We provide an existence and uniqueness result for the model and numerically test it in some relevant cases.
RESO Project-Team

6. New Results

6.1. Optimized protocols implementation and networking equipments

6.1.1. Locating Virtual Infrastructures: Users and InP Perspectives

Participants: Paulo Gonçalves, Guilherme koslovski.

This is a joint work with Pascale Vicat-Blanc (Lyatiss) and Sébastien Soudan (Lyatiss).

The Cloud Computing wave consolidates the on-demand provisioning of configurable virtual machines. Recent projects have proposed the extension of the original IaaS paradigm to provide dynamic virtual networks to interconnect virtual IT resources, composing Virtual Infrastructures (VIs). In this new scenario, users with different objectives and expectations can rent dynamically provisioned virtual infrastructures to execute their applications during a given time slot. VIs can be allocated anywhere on top of a distributed and virtualized substrate. This decoupling from the geographical location introduces concerns such as a latency increase in network communications (user’s perspective), and the fragmentation of physical resources (Infrastructure Provider’s - InP - perspective). This context motivates efforts to investigate and deploy new models and tools which consider the geographical location of virtual infrastructures. Our work concentrates on the allocation of VIs guided by both the user’s and the InP’s constraints. We propose a formulation of the allocation problem considering the user’s expectations as well as the physical-substrate provider’s goals. Our initial experiments demonstrate that it is possible to improve the quality of the virtual-infrastructure allocation (user perspective) while simultaneously decreasing the physical substrate’s fragmentation and the substrate’s cost.

6.1.2. Energy-efficient reservation infrastructure for large-scale distributed systems

Participants: Anne-Cécile Orgerie, Laurent Lefèvre, Guérin-Lassous Isabelle.

Over the past few years, the energy consumption of Information and Communication Technologies (ICT) has become a major issue. Nowadays, ICT accounts for 2% of the global CO2 emissions, an amount similar to that produced by the aviation industry. Large-scale distributed systems (e.g. Grids, Clouds and high-performance networks) are often heavy electricity consumers because – for high-availability requirements – their resources are always powered on even when they are not in use. Reservation-based systems guarantee quality of service, allow for respect of user constraints and enable fine-grained resource management. For these reasons, in the context of Anne-Cécile Orgerie Phd (defended in September 2011), we proposed an energy-efficient reservation framework to reduce the electric consumption of distributed systems and dedicated networks. The framework, called ERIDIS, is adapted to three different systems: data centers and grids, cloud environments and dedicated wired networks. By validating each derived infrastructure, we show that significant amounts of energy can be saved using ERIDIS in current and future large-scale distributed systems [54].

6.1.3. Energy efficiency in exascale infrastructures

Participants: Mehdi Diouri, Olivier Gluck, Laurent Lefevre.

Joint work with F. Cappello (JLPC, joint laboratory between INRIA and NCSA).

In Diouri’s PhD, we address the issue of energy efficiency for exascale supercomputers. We first proposed a green architecture for exascale systems gathering some new solutions to “consume less” energy and to “consume better”. This architecture involves interactions with the different actors interfering directly or indirectly with the supercomputer: its user, its administrator, its resource manager and the energy supplier. Then we were interested into leaning on this green architecture in order to propose some green services that will be offered for applications that will run on exascale systems. Our approach consists in evaluating the power overhead induced by some existing services, and by proposing a green version of these services that takes into account the constraints imposed by the different actors involved. In 2011, we specifically aimed to apply our approach for fault tolerance protocols in their normal functioning stage and in case of failure. [38]
6.1.4. Energy profiling and green leverages for high performance computing applications

Participants: Ghislain Landry Tsafack, Jean-Patrick Gelas, Laurent Lefevre.

Ghislain Landry TSAFACK CHETSA has started his PhD in January 2011, within the framework of INRIA HEMERA project, on: “Energy profiling and green leverages for high performance computing applications” (co-advisement with Jean-Marc PIERSON and Patritia STOLF from IRIT). During the course of this first year, we have investigated the possibility of characterizing distributed applications considering their energy/power profile. We first carried out a set of experiments for a better understanding of the application’s behavior and the impact that this behavior may have on its power consumption. Results led us to the assumption that any individual application run can be represented as a sequence of basic operations including computation, memory accesses, disk and network accesses over a given time period. We next relay on that assumption to define application’s energy profile. Application’s energy profile helps to prevent the fallout of any action that may be taken to reduce its power usage. To guarantee reasonable results, i.e., reduce energy with less performance degradation, we designed an energy prediction model capable of predicting power usage of a wide range of high performance computing (HPC) applications.

6.1.5. Towards virtualized home gateways

Participants: Jean-Patrick Gelas, Laurent Lefevre, Anne-Cécile Orgerie.

Joint work with Dino Lopez Pacheco (Univeristy of Nice) and Referi Assefa (Addis Abeba University, Ethiopia).

Virtualizing services located on end to end parts of the networks and making them available for a large number of applications and users is now becoming a real challenge. Within the scope of the GreenTouch project, we are exploring models, simulations tools (ECOFEN) and software prototypes able to demonstrate the impact of such approach in terms of energy reduction.

6.2. Quality of service and transport layer for future networks

6.2.1. On the Impact of the Flow-Size Distribution’s Tail Index on Network Performance with TCP Connections

Participant: Paulo Gonçalves.

This is a joint work with Oana Goga (UPMC, Lip6) and Patrick Loiseau (Eurecom).

In this work, we studied the impact of the flow-size distribution on network performance in the case of a single bottleneck with finite buffer. To tackle the case where flows are transmitted with the TCP protocol, we use real experiments and ns-2 simulations. Our preliminary results show that the distribution’s tail index impacts the performance in a more complex way than what is reported in existing literature. In particular, we exhibit situations where a heavier tail gives better performance for certain metrics. We argue that a main cause of our observed results is the transient behavior at the beginning of each flow.

6.2.2. Available Bandwidth Estimation for Multihop Wireless Networks

Participants: Isabelle Guérin Lassous, Van Nam Nguyen.

Estimating the available bandwidth in IEEE 802.11-based multi-hop wireless networks is a very difficult task due to the medium sharing among contending nodes and collisions between hidden stations. Several methods have been proposed so far for these networks to compute the available bandwidth on wireless links. If some recent solutions such as ABE and IAB now take into account collisions and their impact on the mean backoff, none of them considers the packet retransmissions due to collisions, although these retransmissions have an impact on the available bandwidth. In this work, we have proposed a new available bandwidth estimation for multi-hop wireless networks called RABE (Retransmission-based Available Bandwidth). This method integrates the average number of retransmission attempts in the available bandwidth estimation, in addition to other relevant parameters like the idle periods durations and the collision probability. RABE has been evaluated
by simulation and the obtained results show that RABE can achieve a mean error ratio of 17% in comparison with the real measurement. Furthermore RABE is at least two times more accurate than ABE and ten times more accurate than IAB.

6.2.3. On The Recovery Performance of Single- and Multipath OLSR in Wireless Multi-Hop Networks

Participants: Inès Doghri, Isabelle Guérin Lassous.

In this work, we study and improve the recovery properties of single- and multipath routing strategies when facing network failure situations. In particular, we focus our study on two MANET routing protocols: OLSR and its multipath extension MP-OLSR. In various wireless multi-hop network environments, especially in multiple chain topologies, we define and evaluate the latency introduced by these protocols to find a new path after a link failure. Theoretical estimations and simulation results show that, under dual chain-topologies, this latency can be too long and incompatible with the needs of loss and delay constrained applications. As the source nodes cannot detect link failures immediately because of the delay incurred by the well-known nature of link state protocols in general, and of OLSR Topology Control (TC) messages in particular, these nodes keep sending packets along broken paths. We thus study the inconsistencies between the actual network topology and the nodes’ own representation. After analyzing the consequences of this long latency, we seek to alleviate these problems with the introduction of adapted mechanisms. We propose three new different schemes and accordingly extend the original OLSR and MP-OLSR protocols in order to decrease the expected latency and improve the protocol performance. Simulation results show a steep decrease of the latency when using these new schemes in dual chain-topologies. We also discuss these results in terms of packet loss, end-to-end delay and overhead.

6.3. High Speed Network’s traffic metrology and statistical analysis

6.3.1. A long-range dependent model for network traffic with flow-scale correlations

Participant: Paulo Gonçalves.

This is a joint work with Patrick Loiseau (Eurecom) and Pascale Vicat-Blanc (Lyatiss).

For more than a decade, it has been observed that network traffic exhibits long-range dependence and many models have been proposed relating this property to heavy-tailed flow durations. However, none of these models consider correlations at flow scale. Such correlations exist and will become more prominent in the future Internet with the emergence of flow-aware control mechanisms correlating a flow’s transmission to its characteristics (size, duration, etc.). In our present work, we study the impact of the correlation between flow rates and durations on the long-range dependence of aggregate traffic. Our results extend those of existing models by showing that two possible regimes of long-range dependence exist at different time scales. The long-range dependence in each regime can be stronger or weaker than standard predictions, depending on the conditional statistics between the flow rates and durations. In the independent case, our proposed model consistently reduces to former approaches. The pertinence of our model is validated on real web traffic traces, and its ability to accurately explain the Hurst parameter is validated on both web traces and numerical simulations.

6.3.2. A recurrent solution of Ph/M/c/N-like and Ph/M/c-like queues

Participant: Thomas Begin.

This work has been accepted for publication by the Journal of Applied Probability [50] and was performed in collaboration with Pr. Brandwajn (UCSC).
We propose an efficient semi-numerical approach to compute the steady-state probability distribution for the number of requests at arbitrary and at arrival time instants in Ph/M/c-like systems in which the inter-arrival time distribution is represented by an acyclic set of memoryless phases. Our method is based on conditional probabilities and results in a simple computationally stable recurrence. It avoids the explicit manipulation of potentially large matrices and involves no iteration. Due to the use of conditional probabilities, it delays the onset of numerical issues related to floating-point underflow as the number of servers and/or phases increases. For generalized Coxian distributions, the computational complexity of the proposed approach grows linearly with the number of phases in the distribution.

6.3.3. A Markovian model based on SIR epidemic classification to reproduce the workload dynamics of a VoD server

Participants: Shubhabrata Roy, Thomas Begin, Paulo Gonçalves.

We have devised a Markovian model, based on the SIR epidemic classification, to reproduce the workload dynamics that can be observed on a VoD (Video on Demand) server. This model basically relies on the dynamic between three distinct populations (i.e., current watchers, past watchers and potential watchers). It also embeds events with very low probability but high impact on its overall behavior corresponding to the occurrence of a flash crowd or the the buzz effect on a VoD server. The steady-state solution to this model has shown that it exhibits a behavior qualitatively close to what can be expected from a real-life VoD server. We have also shown that the workload process as delivered this model satisfies a large deviation principle. Our future work aims at taking advantage of this information to devise a new scheme for allocating available resources in a VoD server.

6.3.4. A comparative study of existing MBAC using real network traces

Participants: Doreid Ammar, Thomas Begin, Isabelle Guérin-Lassous.

We have evaluated the respective performance of several MBACs (Measurement-based admission control) using a realistic framework in which the pattern of the background traffic follows experimental traces collected on real-life networks. This study has allowed to highlight the respective discrepancies between MBACs in terms of easiness to implement and attained performance. This work will now focus on the design of a new MBAC based on a iteratively learned model.

6.3.5. Graph Based Classification of Content and Users in BitTorrent

Participants: Paulo Gonçalves, Marina Sokol.

This is a joint work with Konstantin Avrachenkov (INRIA Maestro) and Arnaud Legout (INRIA Planete). P2P downloads still represent a large portion of today’s Internet traffic. More than 100 million users operate BitTorrent and generate more than 30% of the total Internet traffic. Recently, a significant research effort has been done to develop tools for automatic classification of Internet traffic by application. The purpose of our present work is to provide a framework for sub-classification of P2P traffic generated by the BitTorrent protocol. Unlike previous works, we cannot rely on packet level characteristics and on the standard supervised machine learning methods. The application of the standard supervised machine learning methods is based on the availability of a large set of parameters (packet size, packet inter-arrival time, etc.). Since P2P transfers are based on the same BitTorrent protocol we cannot use this set of parameters to classify P2P content and users. Instead we can make use of the bipartite user-content graph. This is a graph formed by two sets of nodes: the set of users (peers) and the set of contents (downloaded files). From this basic bipartite graph we also construct the user graph, where two users are connected if they download the same content, and the content graph, where two files are connected if they are both downloaded by at least one same user. The general intuition is that the users with similar interests download similar contents. This intuition can be rigorously formalized with the help of graph based semi-supervised learning approach.
6.3.6. **Generalized Optimization Framework for Graph-based Semi-supervised Learning**

**Participants:** Paulo Gonçalves, Marina Sokol.

This is a joint work with Konstantin Avrachenkov (INRIA Maestro).

We develop a generalized optimization framework for graph-based semi-supervised learning. The framework gives as particular cases the Standard Laplacian, Normalized Laplacian and PageRank based methods. We have also provided new probabilistic interpretation based on random walks and characterized the limiting behavior of the methods. The random walk based interpretation allows us to explain differences between the performances of methods with different smoothing kernels. It appears that the PageRank based method is robust with respect to the choice of the regularization parameter and the labelled data. We illustrate our theoretical results with two realistic datasets, characterizing different challenges: Les Miserables characters social network and Wikipedia hyper-link graph. The graph-based semi-supervised learning classifies the Wikipedia articles with very good precision and perfect recall employing only the information about the hyper-text links.

6.3.7. **On the estimation of the large deviations spectrum**

**Participant:** Paulo Gonçalves.

This is a joint work with Julien Barral (Univ. Paris 13)

We propose an estimation algorithm for large deviations spectra of measures and functions. The algorithm converges for natural examples of multifractals.

6.3.8. **Adaptive Multiscale Complexity Analysis of Fetal Heart Rate**

**Participant:** Paulo Gonçalves.

This is a joint work with Patrice Abry (ENS Lyon, CNRS) and Muriel Doret (Hospice civils de Lyon, Univ. Lyon 1)

*Per partum* fetal asphyxia is a major cause of neonatal morbidity and mortality. Fetal heart rate monitoring plays an important role in early detection of acidosis, an indicator for asphyxia. This problem is addressed in this paper by introducing a novel complexity analysis of fetal heart rate data, based on producing a collection of piecewise linear approximations of varying dimensions from which a measure of complexity is extracted. This procedure specifically accounts for the highly non-stationary context of labor by being adaptive and multiscale. Using a reference dataset, made of real *per partum* fetal heart rate data, collected *in situ* and carefully constituted by obstetricians, the behavior of the proposed approach is analyzed and illustrated. Its performance is evaluated in terms of the rate of correct acidosis detection versus the rate of false detection, as well as how early the detection is made. Computational cost is also discussed. The results are shown to be extremely promising and further potential uses of the tool are discussed.
5. New Results

5.1. Plausible Image Rendering

5.1.1. Filtering Solid Gabor Noise

Participants: Ares Lagae, George Drettakis.

Solid noise is a fundamental tool in computer graphics. Surprisingly, no existing noise function supports both high-quality anti-aliasing and continuity across sharp edges. Existing noise functions either introduce discontinuities of the solid noise at sharp edges, which is the case for wavelet noise and Gabor noise, or result in detail loss when anti-aliased, which is the case for Perlin noise and wavelet noise. In this project, we therefore present a new noise function that preserves continuity over sharp edges and supports high-quality anti-aliasing. We show that a slicing approach is required to preserve continuity across sharp edges, and we present a new noise function that supports anisotropic filtering of sliced solid noise. This is made possible by individually filtering the slices of Gabor kernels, which requires the proper treatment of phase. This in turn leads to the introduction of the phase-augmented Gabor kernel and random-phase Gabor noise, our new noise function. We demonstrate that our new noise function supports both high-quality anti-aliasing and continuity across sharp edges, as well as anisotropy. Fig. 3 shows several solid procedural textures generated with our new random-phase solid Gabor noise.

This work was presented at ACM SIGGRAPH 2011 in Vancouver and published in ACM Transactions on Graphics [18] (SIGGRAPH paper).

5.1.2. Image-Guided Weathering for Flow Phenomena

Participants: Carles Bosch, Pierre-Yves Laffont, George Drettakis.

The simulation of weathered appearance is essential in the realistic modeling of urban environments. With digital photography and Internet image collections, visual examples of weathering effects are readily available. These images, however, mix the appearance of the weathering phenomena with the specific local context. In [12], we have introduced a new methodology to estimate parameters of a phenomenological weathering simulation from existing imagery, in a form that allows new target-specific weathering effects to be produced. In addition to driving the simulation from images, we complement the visual result with details and colors extracted from the images. This methodology has been illustrated using flow stains as a representative case, demonstrating how a rich collection of flow patterns can be generated from a small set of exemplars. In Fig. 4, we show the major components required for this approach.
This work was published in ACM Transactions on Graphics [12] and also presented at ACM SIGGRAPH 2011 in Vancouver (TOG paper).

5.1.3. Relighting Photographs of Tree Canopies
Participants: Marcio Cabral, George Drettakis.

We present an image-based approach to relighting photographs of tree canopies. Our goal is to minimize capture overhead; thus the only input required is a set of photographs of the tree taken at a time of day, while allowing relighting at any other time. We first analyze lighting in a tree canopy, both theoretically and using simulations. From this analysis, we observe that tree canopy lighting is similar to volumetric illumination. We assume a single-scattering volumetric lighting model for tree canopies, and diffuse leaf reflectance. To validate our assumptions, we apply our method on several synthetic renderings of tree models, for which we are all able to compute all quantities involved.

Our method first creates a volumetric representation of the tree using 10-12 images taken at a single time of day and use a single-scattering participating media lighting model - these photos are taken from different viewpoints, around the tree. An analytical sun and sky illumination model, namely the Preetham model, provides consistent representation of lighting for the captured input and unknown target times.

We relight the input image by applying a ratio of the target and input time lighting representations. We compute this representation efficiently by simultaneously coding transmittance from the sky and to the eye in spherical harmonics. We validate our method by relighting images of synthetic trees and comparing to path-traced solutions. We also present results for photographs, validating with time-lapse ground truth sequences. An example is shown in Fig. 5. This work was published in the IEEE Transactions on Computer Graphics and Visualization [15], and was in collaboration with the past members of REVES, N. Bonneel and S. Lefebvre.

5.1.4. Silhouette-aware Warping for Image-based Rendering
Participants: Gaurav Chaurasia, George Drettakis.
Figure 5.

Mulberry tree Top row: input images and 4 target images with corresponding times of day. Middle row: 4 resulting relit images using our approach. Bottom row: $E_{in}$ and the four $E_{targ}$ images.
Figure 6. Top: Overview of our approach starting from input images to rendered novel views along with novel view generated using current state of the art IBR. Bottom: Novel views rendered using our approach.
We have presented a novel solution for image-based rendering (IBR) of urban scenes based on image warping. IBR techniques allow capture and display of 3D environments using photographs. Modern IBR pipelines reconstruct proxy geometry using multi-view stereo, reproject the photographs onto the proxy and blend them to create novel views. The success of these methods depends on accurate 3D proxies, which are difficult to obtain for complex objects such as trees and cars. Large number of input images do not improve reconstruction proportionally; surface extraction is challenging even from dense range scans for scenes containing such objects. Our approach does not depend on dense accurate geometric reconstruction; instead we compensate for sparse 3D information by variational warping. In particular, we formulate silhouette-aware warps that preserve salient depth discontinuities. This improves the rendering of difficult foreground objects, even when deviating from view interpolation. We use a semi-automatic step to identify depth discontinuities and extract a sparse set of depth constraints used to guide the warp. On the technical side, our formulation breaks new ground by demonstrating how to incorporate discontinuities in variational warps. Our framework is lightweight and results in good quality IBR for previously challenging environments as shown in figure.

Applications. Robust image-based rendering can be used to generate photo-realistic visual content easily which can be very useful for virtual reality applications. Commercial products like Google StreetView and Microsoft PhotoSynth use rudimentary image-based rendering for large scale visualization of cities. Our work advances the state of the art by treating the hardest class of scenes.

This work is a collaboration with Prof. Dr. Olga Sorkine (ETH Zurich). The work was published in the special issue of the journal Computer Graphics Forum [16], presented at the Eurographics Symposium on Rendering 2011 in Prague, Czech Republic.

5.1.5. Real Time Rough Refractions

Participant: Adrien Bousseau.

![Ground truth](a)  ![Our method](b)

*Figure 7. Compared to an expensive ray-traced reference (a), our method produces plausible results in real-time (b).*

We have proposed an algorithm to render objects made of transparent materials with rough surfaces in real-time, under environment lighting. Rough surfaces such as frosted and misted glass cause wide scattering as light enters and exits objects, which significantly complicates the rendering of such materials. We introduced two contributions to approximate the successive scattering events at interfaces, due to rough refraction: First, an approximation of the Bidirectional Transmittance Distribution Function (BTDF), using spherical Gaussians, suitable for real-time estimation of environment lighting using pre-convolution; second, a combination of cone tracing and macro-geometry filtering to efficiently integrate the scattered rays at the exiting interface of the object. Our method produces plausible results in real-time, as demonstrated by comparison against stochastic ray-tracing (Figure 7).
This work is a collaboration with Charles De Rousiers, Kartic Subr, Nicolas Holzschuch (ARTIS / INRIA Rhône-Alpes) and Ravi Ramamoorthi (UC Berkeley) as part of our CRISP associate team with UC Berkeley. The work was presented at the ACM SIGGRAPH Symposium on Interactive 3D Graphics and Games 2011 and won the best paper award.

5.1.6. Single view intrinsic images

**Participants:** Pierre-Yves Laffont, Adrien Bousseau, George Drettakis.

![Figure 8. Starting from multiple views of the scene (a), our method automatically decomposes photographs into three intrinsic components — the reflectance (b), the illumination due to sun (c) and the illumination due to sky (d). Each intrinsic component can then be manipulated independently for advanced image editing applications.](image)

We introduced a new algorithm for decomposing photographs of outdoor scenes into *intrinsic images*, i.e. independent layers for illumination and reflectance (material color).

Extracting intrinsic images from photographs is a hard problem, typically solved with image-driven methods using numerous user indications. Recent methods in computer vision allow easy acquisition of medium-quality geometric information about a scene using multiple photographs from different views. We developed a new algorithm which allows us to exploit this noisy and somewhat unreliable information to automate and improve image-driven propagation algorithms to deduce intrinsic images. In particular, we develop a new approach to estimate cast shadow regions in the image, by refining an initial estimate available from reconstructed geometric information. We use a voting algorithm in color space which robustly identifies reflectance values for sparse reconstructed 3D points, allowing us to accurately determine visibility to the sun at these points.
This information is propagated to the remaining pixels. In a final step we adapt appropriate image propagation algorithms, by replacing manual user indications by data inferred from the geometry-driven shadow and reflectance estimation. This allows us to automatically extract intrinsic images from multiple viewpoints, thus allowing many types of manipulation in images.

As illustrated on Figure 8, our method can extract reflectance at each pixel of the input photographs. The decomposition also yields separate sun illumination and sky illumination components, enabling easier manipulation of shadows and illuminant colors in image editing software.

This work won the best paper award at “les journées de l’AFIG (Association Francophone d’Informatique Graphique) 2011”, and will appear in the French journal REFIG [21].

5.1.7. Single view intrinsic images with indirect illumination

Participants: Pierre-Yves Laffont, Adrien Bousseau, George Drettakis.

Building on top of our work published in [21], we extended our intrinsic image decomposition method to handle indirect illumination, in addition to sun and sky illumination. We introduced a new algorithm to reliably identify points in shadow based on a parameterization of the reflectance with respect to sun visibility, and proposed to separate illumination components using cascaded image-based propagation algorithm. We also demonstrated direct applications of our results for the end user in widespread image editing software. This rich intrinsic image decomposition method has been submitted for publication.

5.1.8. Multi-lighting multi-view intrinsic images

Participants: Pierre-Yves Laffont, Adrien Bousseau, George Drettakis.

We compute intrinsic image decompositions using several images of the same scene under different viewpoints and lighting conditions. Such images can be easily gathered for famous landmarks, using photo sharing websites such as Flickr. Our method leverages the heterogeneity of photo collections (multiple viewpoints and lighting conditions) to guide the intrinsic image separation process. With this automatic decomposition, we aim to facilitate many image editing tasks and improve the quality of image-based rendering from photo collections.

This work is in collaboration with Frédo Durand (associate professor at MIT) and Sylvain Paris (researcher at Adobe).

5.1.9. Warping superpixels

Participants: Gaurav Chaurasia, Sylvain Duchêne, George Drettakis.

We are working on developing a novel representation of multi-view scenes in the form of superpixels. Such a representation segments the scene into semantically meaningful regions called superpixels which admit variational warps [16], thereby leveraging the power of shape-preserving warps while providing automatic silhouette and occlusion handling. This entails several contributions namely incorporating geometric priors in superpixel extraction, generating consistent warping constraints and a novel rendering pipeline that assembles warped superpixels into the novel view maintaining spatio-temporal coherence.

This work is a collaboration with Prof. Dr. Olga Sorkine (ETH Zurich).

5.1.10. State-of-the-art Report on Temporal Coherence for Stylized Animations

Participant: Adrien Bousseau.
Non-photorealistic rendering (NPR) algorithms allow the creation of images in a variety of styles, ranging from line drawing and pen-and-ink to oil painting and watercolor. These algorithms provide greater flexibility, control and automation over traditional drawing and painting. The main challenge of computer generated stylized animations is to reproduce the look of traditional drawings and paintings while minimizing distracting flickering and sliding artifacts present in hand-drawn animations. These goals are inherently conflicting and any attempt to address the temporal coherence of stylized animations is a trade-off. This survey is motivated by the growing number of methods proposed in recent years and the need for a comprehensive analysis of the trade-offs they propose. We formalized the problem of temporal coherence in terms of goals and compared existing methods accordingly (Figure 9). The goal of this report is to help uninformed readers to choose the method that best suits their needs, as well as motivate further research to address the limitations of existing methods.

Figure 9. The temporal coherence problem involves three goals represented by the axes of these diagrams. Fully ignoring one of them produces the opposite artifacts.

This work is a collaboration with Pierre Bénard and Joëlle Thollot (ARTIS / INRIA Rhône-Alpes) and was published in the journal Computer Graphics Forum [14].

5.1.11. Improving Gabor Noise
Participant: Ares Lagae.

We have recently proposed a new procedural noise function, Gabor noise, which offers a combination of properties not found in existing noise functions. In this project, we present three significant improvements to Gabor noise: (1) an isotropic kernel for Gabor noise, which speeds up isotropic Gabor noise with a factor of roughly two, (2) an error analysis of Gabor noise, which relates the kernel truncation radius to the relative error of the noise, and (3) spatially varying Gabor noise, which enables spatial variation of all noise parameters. These improvements make Gabor noise an even more attractive alternative for existing noise functions. Fig. 3 shows a procedural textures generated with our new improved Gabor noise. This work was published in IEEE Transactions on Computer Graphics and Visualization [19].

5.2. Visual Perception and Audio Rendering
5.2.1. Perception of Visual Artifacts in Image-Based Rendering of Façades

Participants: Peter Vangorp, Gaurav Chaurasia, Pierre-Yves Laffont, George Drettakis.

Image-based rendering (IBR) techniques allow users to create interactive 3D visualizations of scenes by taking a few snapshots (Figure 11 (left)). However, despite substantial progress in the field, the main barrier to better quality and more efficient IBR visualizations are several types of common, visually objectionable artifacts. These occur when scene geometry is approximate or viewpoints differ from the original shots, leading to parallax distortions (Figure 11 (mid)), blurring, ghosting (Figure 11 (right)) and popping errors that detract from the appearance of the scene. We argue that a better understanding of the causes and perceptual impact of these artifacts is the key to improving IBR methods.

We present a series of psychophysical experiments in which we systematically map out the perception of artifacts in IBR visualizations of façades as a function of the most common causes. We separate artifacts into different classes and measure how they impact visual appearance as a function of the number of images available, the geometry of the scene and the viewpoint. The results reveal a number of counter-intuitive effects in the perception of artifacts.

We summarize our results in terms of the following practical guidelines for improving existing and future IBR techniques:
When the total number of available images is small, e.g., because of storage limitations, it is preferable to use a sudden transition with its associated popping artifact rather than a gradual blending transition with its associated ghosting artifact.

Interestingly, the depth range of the façade does not affect the perceived parallax distortions, even though it clearly does affect the objective parallax distortions. Only the intended output viewing angle should be taken into account when capturing images.

For Google Street View™-like visualizations, a shorter cross-fading transition would improve the perceived quality.

This work is a collaboration with Roland W. Fleming (Justus-Liebig-University Giessen, Germany). The work was published in the special issue of the journal Computer Graphics Forum [20] and presented at the Eurographics Symposium on Rendering 2011.

5.2.2. Perception of Slanted, Textured Façades

Participants: Peter Vangorp, Adrien Bousseau, Gaurav Chaurasia, George Drettakis.

In large-scale urban visualizations, buildings are often geometrically represented by simple boxes textured with images of the façades. Any depth variations in the façade, such as balconies, are perceived to have distorted angles when the viewer is not at the capture camera position. The retinal hypothesis provides the most likely prediction of the magnitude of the perceived distortion. We conduct psychophysical experiments to measure the perceived distortion, thereby validating the retinal hypothesis, and to measure the threshold for detecting any distortion. The result is a prediction of the valid range of viewer motion for a given capture.

This work is a collaboration with Martin S. Banks (UC Berkeley).

5.2.3. Binocular and Dynamic Cues to Glossiness

Participants: Peter Vangorp, George Drettakis.

Recent advances in display technology have made it possible to present high quality stereoscopic imagery with accurate head tracking. This improves not only depth perception but also affects the perception of glossy materials. Previous work has shown that these conditions can increase the perceived gloss by a small amount. We conduct psychophysical experiments to measure this effect quantitatively.

This work is a collaboration with Roland W. Fleming (Justus-Liebig-University Giessen, Germany) and Martin S. Banks (UC Berkeley).

5.2.4. Sound Particles

Participants: Charles Verron, George Drettakis.

This research deals with a sound synthesizer dedicated to particle-based environmental effects, and intended to be used in interactive virtual environments. The synthesis engine is based on five physically-inspired basic elements (sound atoms) that can be parameterized and stochastically distributed in time and space. Physically-inspired controls simultaneously drive graphics particle models (e.g., distribution of particles, average particles velocity etc.) and sound parameters (e.g., distribution of sound atoms, spectral modifications etc.). The simultaneous audio/graphics controls result in an intricate interaction between the two modalities that enhances the naturalness of the scene. The approach is currently illustrated with three environmental phenomena: fire, wind, and rain.

5.2.5. Sound Synthesis for Crowds

Participants: Charles Verron, George Drettakis.

We are currently investigating new methods for synthesis of crowd sounds in virtual environments. Crowd sounds are constituted of many overlapping voices spatialized at different positions in the environment. A novel level of detail for crowd sounds is desirable: the cost of spatializing many individual voice sounds can be replaced by an efficient babble noise synthesis model. Furthermore, high-level control should be proposed to modify the crowd sounds by semantic parameters, related to the crowd emotional state (e.g., calm, angry...). This research should result in a new real-time crowd sound synthesizer with semantic controls for virtual environments.
5.3. Interaction and Design for Audiovisual Virtual Environments

5.3.1. Lighting Design for Material Depiction

Participants: Adrien Bousseau, Emmanuelle Chapoulie.

Shading, reflections and refractions are important visual features for understanding the shapes and materials in an image. While well designed lighting configurations can enhance these features and facilitate image perception (Figure 12 b), poor lighting design can lead to misinterpretation of image content (Figure 12 a).

Figure 12. Our method (a) automatically optimizes the lighting to enhance material-specific visual features. The lighting reveals the thin and thick parts of the subsurface scattering wax candle, it accentuates the Fresnel reflections along the side of the porcelain vase and it adds strong specular highlights to emphasize the shiny chrome metal of the sculpture. Poorly designed lighting (b) diminishes these characteristic visual features of the materials. The candle appears more like solid plastic, the vase appears to be made of diffuse clay and the sculpture no longer looks like it is made of chrome.

We have presented an automated system for optimizing and synthesizing environment maps that enhance the appearance of materials in a scene. We first identified a set of lighting design principles for material depiction. Each principle specifies the distinctive visual features of a material and describes how environment maps can emphasize those features. We then proposed a general optimization framework to solve for the environment map that best fulfill the design principles. Finally we described two techniques for transforming existing photographic environment maps to better emphasize materials. Our approach generates environment maps that enhance the depiction of a variety of materials including glass, metal, plastic, marble and velvet.

This work is a collaboration with Ravi Ramamoorthi and Maneesh Agrawala (UC Berkeley) as part of our CRISP associate team with UC Berkeley. The work was published in the special issue of the journal Computer Graphics Forum, presented at the Eurographics Symposium on Rendering 2011.

5.3.2. A Multimode Immersive Conceptual Design System for Architectural Modeling and Lighting

Participants: Marcio Cabral, Peter Vangorp, Gaurav Chaurasia, Emmanuelle Chapoulie, Martin Hachet, George Drettakis.

We developed a system which allows simple architectural design in immersive environments. The user is able to define the initial conceptual design of the model and can take into account the effects of daylight. Our system allows the manipulation of simple elements such as windows, doors and rooms while the overall model is automatically adjusted to the manipulation. The system runs on a four-sided stereoscopic, head-tracked immersive display. We also provide simple lighting design capabilities, with an abstract representation of sunlight and its effects when shining through a window. Our system provides three different modes
of interaction: a miniature-model table mode, a fullscale immersive mode and a combination of table and immersive which we call mixed mode (see Figure 13). Our goal is to study direct manipulation for basic 3D modeling in an immersive setting, in the context of conceptual or initial design for architecture. We performed an initial pilot user test to evaluate the relative merits of each mode for a set of basic tasks such as resizing and moving windows or walls, and a basic light-matching task. The study indicates that users appreciated the immersive nature of the system, and found interaction to be natural and pleasant. In addition, the results indicate that the mean performance times seem quite similar in the different modes, opening up the possibility for their combined usage for effective immersive modeling systems for novice users.

![Figure 13. (a) Table mode, (b) Immersive mode, (c) Mixed mode](image)

5.3.3. Walking in a Cube: Novel Metaphors for Safely Navigating Large Virtual Environments in Restricted Real Workspaces

Participants: Peter Vangorp, Emmanuelle Chapoulie, George Drettakis.

Immersive spaces such as 4-sided displays with stereo viewing and high-quality tracking provide a very engaging and realistic virtual experience. However, walking is inherently limited by the restricted physical space, both due to the screens (limited translation) and the missing back screen (limited rotation). We propose three novel navigation techniques that have three concurrent goals: keep the user safe from reaching the translational and rotational boundaries; increase the amount of real walking; and finally, provide a more enjoyable and ecological interaction paradigm compared to traditional controller-based approaches. We notably introduce the “Virtual Companion”, which uses a small bird to guide the user through VEs larger than the physical space. We evaluate the three new techniques through a user study with pointing and path following tasks. The study provides insight into the relative strengths of each new technique for the three aforementioned goals.

This work is a collaboration with Gabriel Cirio, Maud Marchal, and Anatole Lécuyer (VR4I / INRIA Rennes) in the context of ARC NIEVE (Section 6.2.1) and has been accepted for publication [17].

5.3.4. Inferring Normals Over Design Sketches

Participant: Adrien Bousseau.

We are currently working on a sketch-based tool to infer normals over a 2D drawing. Our tool should allow users to apply realistic and non-photorealistic shading over the drawing, with applications in product design. This work is a collaboration with Alla Sheffer (University of British Columbia), Cloud Shao and Karan Singh (University of Toronto).
5.3.5. Using natural gestures into virtual reality immersive space

**Participants:** Emmanuelle Chapoulie, George Drettakis.

We are studying the use of gestures which are as natural as possible in a context of virtual reality environments. We define a scenario which is a sequence of tasks (hiding, finding, pushing, pulling, grabbing, picking up, putting down objects) that the users will perform with hands and with wands, in order to evaluate the usability of our interaction approach. Each task will be used to evaluate a specific criterion.
5. New Results

5.1. Package understanding and Assessing

**Participants**: Stéphane Ducasse, Nicolas Anquetil, Usman Bhatti, Jannik Laval.

To support the understanding of large systems is to offer ways to understand and fix dependencies between software elements. We worked on how to semi-automatically reorganize packages to minimize coupling.

**Efficient Retrieval and Ranking of Undesired Package Cycles in Large Software Systems.** Many design guidelines state that a software system architecture should avoid cycles between its packages. Yet such cycles appear again and again in many programs. We believe that the existing approaches for cycle detection are too coarse to assist the developers to remove cycles from their programs. We describe an efficient algorithm that performs a fine-grained analysis of the cycles among the packages of an application. In addition, we define a metric to rank cycles by their level of undesirability, prioritizing the cycles that seem the least desirable to the developers. Our approach is validated on two large and mature software systems in Java and Smalltalk. [19]

**Legacy Software Restructuring: Analyzing a Concrete Case.** Software re-modularization is an old preoccupation of reverse engineering research. The advantages of a well structured or modularized system are well known. Yet after so much time and efforts, the field seems unable to come up with solutions that make a clear difference in practice. Recently, some researchers started to question whether some basic assumptions of the field were not overrated. The main one consists in evaluating the high-cohesion/low-coupling dogma with metrics of unknown relevance. In this paper, we study a real restructuring case (on the Eclipse platform) to try to better understand if (some) existing metrics would have helped the software engineers in the task. Results show that the cohesion and coupling metrics used in the experiment did not behave as expected and would probably not have helped the maintainers reach their goal. We also measured another possible restructuring which is to decrease the number of cyclic dependencies between modules. Again, the results did not meet expectations. [14]

**An empirical model for continuous and weighted metric aggregation.** It is now understood that software metrics alone are not enough to characterize software quality. To cope with this problem, most of advanced and/or industrially validated quality models aggregate software metrics: for example, cyclomatic complexity is combined with test coverage to stress the fact that it is more important to cover complex methods than accessors. Yet, aggregating and weighting metrics to produce quality indexes is a difficult task. Indeed certain weighting approaches may lead to abnormal situations where a developer increasing the quality of a software component sees the overall quality degrade. Finally, mapping combinations of metric values to quality indexes may be a problem when using thresholds. In this paper [20], we present the problems we faced when designing the Squale quality model, then we present an empirical solution based on weighted aggregations and on continuous functions. The solution has been termed the Squale quality model and validated over 4 years with two large multinational companies: Air France-KLM and PSA Peugeot-Citroen.

**Modularization Metrics: Assessing Package Organization in Legacy Large Object-Oriented Software.** In systems consisting of several thousands of classes, classes cannot be considered as units for software modularization. In such context, packages are not simply classes containers, but they also play the role of modules: a package should focus on providing well identified services to the rest of the software system. Therefore, understanding and assessing package organization is primordial for software maintenance tasks. Although there exist a lot of works proposing metrics for the quality of a single class and/or the quality of inter-class relationships, there exist few works dealing with some aspects for the quality of package organization and relationship. We believe that additional investigations are required for assessing package modularity aspects. The goal of these papers [13], [28] is to provide a complementary set of metrics that assess some modularity principles for packages in large legacy object-oriented software: Information-Hiding, Changeability and Reusability principles. Our metrics are defined with respect to object-oriented dependencies
that are caused by inheritance and method call. We validate our metrics theoretically through a careful study of the mathematical properties of each metric.

5.2. Tools and Tool Infrastructure

Participants: Stéphane Ducasse, Veronica Uquillas-Gomez, Jannik Laval.

Reengineering large applications implies an underlying tool infrastructure that can scale and also be extended. 

**Ring: a Unifying Meta-Model and Infrastructure for Smalltalk Source Code Analysis Tools.** Source code management systems record different versions of code. Tool support can then compute deltas between versions. To ease version history analysis we need adequate models to represent source code entities. As a first step to provide an infrastructure to support history analysis, this article [12] presents Ring, a unifying source code meta-model that can be used to support several activities and proposes a unified and layered approach to be the foundation for building an infrastructure for version and stream of change analyses. We re-implemented three tools based on Ring to show that it can be used as the underlying meta-model for remote and off-image browsing, scoping refactoring, and visualizing and analyzing changes. As a future work and based on Ring we will build a new generation of history analysis tools.

**AspectMaps: A Scalable Visualization of Join Point Shadows.** When using Aspect-Oriented Programming, it is sometimes difficult to determine at which join point an aspect executes. Similarly, when considering one join point, knowing which aspects will execute there and in what order is non-trivial. This makes it difficult to understand how the application will behave. A number of visualizations have been proposed that attempt to provide support for such program understanding. However, they neither scale up to large code bases nor scale down to understanding what happens at a single join point. In this paper [18], we present AspectMaps – a visualization that scales in both directions, thanks to a multi-level selective structural zoom. We show how the use of AspectMaps allows for program understanding of code with aspects, revealing both a wealth of information of what can happen at one particular join point as well as allowing to see the “big picture” on a larger code base. We demonstrate the usefulness of AspectMaps on an example and present the results of a small user study that shows that AspectMaps outperforms other aspect visualization tools.

**Challenges to support automated random testing for dynamically typed languages.** Automated random testing is a proved way to identify bugs and precondition violations, and this even in well tested libraries. In the context of statically typed languages, current automated random testing tools heavily take advantage of static method declaration (argument types, thrown exceptions) to constrain input domains while testing and to identify errors. For such reason, automated random testing has not been investigated in the context of dynamically typed languages. We present the key challenges that have to be addressed to support automated testing in dynamic languages. [17]

**SmartGroups, Focusing on Task-Relevant Source Artifacts in IDEs.** Navigating large software systems, even when using a modern IDE (Integrated Development Environment) is difficult, since conceptually related software artifacts are distributed in a huge software space. For most software maintenance tasks, only a small fraction of the entire software space is actually relevant. The IDE, however, does not reveal the task relevancy of source artifacts, thus developers cannot easily focus on the artifacts required to accomplish their tasks. Smart Groups help developers to perform software maintenance tasks by representing groups of source artifacts that are relevant for the current task. Relevancy is determined by analyzing historical navigation and modification activities, evolutionary information, and runtime information. The prediction quality of Smart Groups is validated with a benchmark evaluation using recorded development activities and evolutionary information from versioning systems. [24]

5.3. Constructs for Dynamic Languages

Participants: Stéphane Ducasse, Marcus Denker, Veronica Uquillas-Gomez, Gwenael Casaccio, Camillo Bruni, Jean-Baptiste Arnaud, Damien Pollet.

To support our research on secure dynamic languages, we focused on improving language infrastructure.
Efficient Proxies in Smalltalk. A proxy object is a surrogate or placeholder that controls access to another target object. Proxy objects are a widely used solution for different scenarios such as remote method invocation, future objects, behavioral reflection, object databases, inter-languages communications and bindings, access control, lazy or parallel evaluation, security, among others. Most proxy implementations support proxies for regular objects but they are unable to create proxies for classes or methods. Proxies can be complex to install, have a significant overhead, be limited to certain type of classes, etc. Moreover, most proxy implementations are not stratified at all and there is no separation between proxies and handlers. We present Ghost, a uniform, light-weight and stratified general purpose proxy model and its Smalltalk implementation. Ghost supports proxies for classes or methods. When a proxy takes the place of a class it intercepts both, messages received by the class and lookup of methods for messages received by instances. Similarly, if a proxy takes the place of a method, then the method execution is intercepted too. [22]

Bootstrapping a Smalltalk. Smalltalk is a reflective system. It means that it is defined in itself in a causally connected way. Traditionally, Smalltalk systems evolved by modifying and cloning what is called an image (a chunk of memory containing all the objects at a given point in time). During the evolution of the system, objects representing it are modified. However, such an image modification and cloning poses several problems: (1) There is no operational machine-executable algorithm that allows one to build a system from scratch. A system object may be modified but it may be difficult to reproduce its exact state before the changes. Therefore it is difficult to get a reproducible process. (2) As a consequence, certain classes may not have been initialized since years. (3) Finally, since the system acts as a living system, it is not simple to evolve the kernel for introducing new abstractions without performing some kind of brain surgery on oneself. There is a need to have a step by step process to build Smalltalk kernels from scratch. After an analysis of past and current practices to mutate or generate kernels, we describe a kernel bootstrap process step-by-step. First the illusion of the existence of a kernel is created via stubs objects. Second the classes and meta-classes hierarchy are generated. Code is compiled and finally information needed by the virtual machine and execution are generated and installed. [15]

Flexible Object Layouts: Enabling Lightweight Language Extensions by Intercepting Slot Access. Programming idioms, design patterns and application libraries often introduce cumbersome and repetitive boilerplate code to a software system. Language extensions and external DSLs (domain specific languages) are sometimes introduced to reduce the need for boilerplate code, but they also complicate the system by introducing the need for language dialects and inter-language mediation. To address this, we propose to extend the structural reflective model of the language with object layouts, layout scopes and slots. Based on the new reflective language model we can 1) provide behavioral hooks to object layouts that are triggered when the fields of an object are accessed and 2) simplify the implementation of state-related language extensions such as stateful traits. By doing this we show how many idiomatic use cases that normally require boilerplate code can be more effectively supported. We present an implementation in Smalltalk, and illustrate its usage through a series of extended examples. [25]

5.4. Resources

Participants: Stéphane Ducasse, Marcus Denker, Mariano Martinez-Peck, Nick Papoylias.

Resource management is important in the context of resource constrained devices as well as situations were a large amount of data is modeled but not accessed often. One example for resource constrained devices are autonomous robots. An example for large models that are accessed infrequently are typical models of systems for software re-engineering.

With Ecole des Mines de Douai we explore how to analyze and improve memory in the case of unused data.

Problems and Challenges when Building a Manager for Unused Objects. Large object-oriented applications may occupy hundreds of megabytes or even gigabytes of memory. During program execution, a large graph of objects is created and constantly changed. Most object runtimes support some kind of automatic memory management based on garbage collectors (GC) whose idea is the automatic destruction of unreferenced objects. However, there are referenced objects which are not used for a long period of time or that are
used just once. These are not garbage-collected because they are still reachable and might be used in the future. Due to these unused objects, applications use much more resources than they actually need. We present the challenges and possible approaches towards an unused object manager for Pharo. The goal is to use less memory by swapping out the unused objects to secondary memory and leaving in primary memory only those objects that are needed and used. When one of the unused objects is needed, it is brought back into primary memory. [23]

**Clustered Serialization with Fuel.** Serializing object graphs is an important activity since objects should be stored and reloaded on different environments. There is a plethora of frameworks to serialize objects based on recursive parsing of the object graphs. However such approaches are often too slow. Most approaches are limited in their provided features. For example, several serializers do not support class shape changes, global references, transient references or hooks to execute something before or after being stored or loaded. Moreover, to be faster, some serializers are not written taking into account the object-oriented paradigm and they are sometimes even implemented in the Virtual Machine hampering code portability. VM-based serializers such as ImageSegment are difficult to understand, maintain, and fix. For the final user, it means a serializer which is difficult to customize, adapt or extend to his own needs. We present a general purpose object graph serializer based on a pickling format and algorithm. We implement and validate this approach in the Pharo Smalltalk environment. We demonstrate that we can build a really fast serializer without specific VM support, with a clean object-oriented design, and providing most possible required features for a serializer. We show that our approach is faster that traditional serializers and compare favorably with ImageSegment as soon as serialized objects are not in isolation. [16]

**Towards Structural Decomposition of Reflection with Mirrors** Mirrors are meta-level entities introduced to decouple reflection from the base-level system. Current mirror-based systems focus on functional decomposition of reflection. We advocate that mirrors should also address structural decomposition. Mirrors should not only be the entry points of reflective behavior but also be the storage entities of meta-information. This decomposition can help resolve issues in terms of resource constraints (e.g. embedded systems and robotics) or security. Indeed, structural decomposition enables discarding meta-information. [21]

5.5. Empirical Studies in Software Product Line Engineering

**Participant:** Nicolas Anquetil.

Software Product Line Engineering (SPLE) is a new development paradigm that promises to offer faster development, with better quality. The idea is to develop a generic application (the Software Product Line) with pre-defined variation points. From this, new applications are derived from the generic application and the options are chosen for the possible variation points. Because it is still a new paradigm, Software Product Line development is still an active research domain where empirical research is useful to check the validity of the results.

These publications are the results of an earlier research project to which N. Anquetil participated.

**Managing information flow in the SPL development processes.** Traceability is a quality attribute in software engineering that establishes the ability to describe and follow the life of a requirement in both the forward and backward directions (i.e. from its origins throughout its specification, implementation, deployment, use and maintenance, and vice-versa). The IEEE Standard Glossary of Software Engineering Terminology defines traceability as “the degree to which a relationship can be established between two or more products of the development process, especially products having a predecessor-successor or master-subordinate relationship to one another”. According to (Palmer, 1997) “traceability gives essential assistance in understanding the relationships that exist within and across software requirements, design, and implementation”. Thus, trace relationships help in identifying the origin and rationale for artefacts generated during development lifecycle and the links between these artefacts. Identification of sources helps understanding requirements evolution and validating implementation of stakeholders’ requirements. The main advantages of traceability are: (i) to relate software artefacts and design decisions taken during the software development cycle; (ii) to give feedback to architects and designers about the current state of the development, allowing them to reconsider alternative
design decisions, and to track and understand bugs; and (iii) to ease communication between stakeholders. [26]

**Empirical research in software product line engineering.** Empirical evaluation has for many years been utilized to validate theories in other science disciplines. One of the first well-known reported examples of empirical evaluation occurred when Galileo wanted to prove that the rate of descent of objects was independent of their mass. This would disprove a theory put forward by Aristotle that the rate of descent is directly proportional to their weight. To prove his theory Galileo dropped two balls made from the same material but different masses from the top of the Tower of Pisa. When the experiment was performed Galileo’s theory was proved correct through the empirical evidence collected. What this story demonstrates is the importance of empirical validation to verify or disprove theories and hypotheses. The purpose of this publication [27] is to emphasize the importance and difficulties of empirical evaluation in the domain of SPLE.
6. New Results

6.1. High-Performance Intra-node Collective Operations

Participants: Brice Goglin, Stéphanie Moreaud.

- KNEM is known to improve the performance of point-to-point intra-node MPI communication significantly [60], [18].
- We designed an extended RMA interface in KNEM that suits the needs of point-to-point, collective and RMA operations.
- We showed that the native use of KNEM in MPI collective implementations enabled further optimization by combining the knowledge of collective algorithms with the mastering of KNEM region management and copies [35].
- This work was initiated in the context of our collaboration with the MPICH2 team and is now also pursued within the OPEN MPI project in collaboration with the University of Tennessee in Knoxville.

6.2. I/O-Affinity-aware MPI Communications

Participants: Brice Goglin, Stéphanie Moreaud.

- We demonstrated in the past that the locality of I/O devices within modern computing nodes has the significant impact of the MPI communication performance [11] (Non-Uniform I/O Access, NUIOA).
- A first way to deal with such affinities would be to privilege I/O-intensive processes by placing them near the network interfaces. However, determining the communication-intensiveness may be tricky. Also, some applications have uniform communication patterns. The other way to deal with I/O affinities is to modify the implementation of communication operations given a predetermined task placement.
- We demonstrated that the implementation of collective operations should take I/O affinities into account. Deciding which steps and leaders should be involved in the algorithms based on NUIOA effects led us to improve broadcast performance significantly [34], [18].

6.3. High-Performance Point-to-Point Communications

Participants: Alexandre Denis, Raymond Namyst.

- NEWMADELEINE is our communication library designed for high performance networks in clusters. We have worked on optimizations on low-level protocols so as to improve point-to-point performance.
- We have proposed [29] auto-tuning mechanisms for most parameters of a communication library: rendez-vous threshold, multi-rail ratio, optimization strategies.
- We have proposed a communication protocol [33] for InfiniBand that completely amortizes the cost of memory registration, through the use of a superpipeline that overlaps communication and memory copies. We have modeled the behavior of the network and proposed auto-tuning mechanism to adapt the protocol to the hardware properties.
6.4. Improve code-coupling performance in the SALOME platform
Participants: Alexandre Denis, Sébastien Barascou.
- SALOME platform is an open source software developed by EDF, CEA, and OpenCascade. It is an open simulation platform with pre-processing, post-processing, interoperability with CAD models, integration with computation kernels.
- YACS is the workflow engine used for code coupling applications in SALOME. It leverages CORBA for communications between kernels. We have ported YACS atop PadicoTM, our communication platform for grids. It enables CORBA connections to use InfiniBand networks. Benchmarks show a significant improvement in code coupling performance.

6.5. Hardware topology-aware MPI applications
Participants: Emmanuel Jeannot, Guillaume Mercier, François Tessier.
- We have expanded our previous work dealing with MPI process placement. Indeed, our approach relied on tools and techniques which were outside the scope of the MPI standard itself. In order to allow the users to utilize our work in a portable way, we enhanced some routines of the MPI standard. We worked mainly with the MPICH2 implementation but we are also working on an OPEN MPI version as well.
- Instead of modifying the binding of the MPI processes onto the physical cores on the underlying architecture, we chose to create a new communicator for which the logical topology organization is optimized for the hardware. This work has been published in [37] and show interesting performance improvements for some class of MPI applications.
- The problem of process placement, which can be reduced to a NP-hard graph partitioning problem, can be dealt with several famous applications like Scotch or ParMETIS. To evaluate these solution with TREEMATCH, we ran several benchmarks using NAS Parallel Benchmarks and a real CFD application. On the one hand we study the quality of processes permutation (which will impact the execution time) and on the other hand the computation time of the permutation. These results will allow us to conclude about the pertinence of what graph partitioner can be used to bind processes on process units or to do a dynamic processes reordering.

6.6. Mastering Heterogeneous Platforms
Participants: Cédric Augonnet, Olivier Aumage, Ludovic Courtès, Nathalie Furmento, Andra Hugo, Raymond Namyst, Samuel Thibault, Pierre-André Wacrenier.
- We continued our work on extending STARPU to master exploitation of Heterogeneous Platforms.
- We have extended the STARPU scheduler into managing parallel tasks which permit a better exploitation of CPUs and load balancing with GPUs.
- We have designed over STARPU a lightweight DSM over MPI, which permits to seamlessly execute STARPU applications over an MPI cluster of GPU-enhanced nodes.
- We have been developing a GCC plug-in which extends the C language with pragmas and attributes that make writing STARPU applications a lot easier.
- We have brought to STARPU support for automatically converting data between CPU and GPU formats (typically arrays of structures vs structures of arrays). We are now optimizing it.
- We have added an OpenCL interface to STARPU, SOCL [42], which permits to execute unmodified OpenCL applications over STARPU.
- We have introduced in STARPU theoretical bound support [27]: from a record of the set of tasks submitted by the application, STARPU uses linear programming to give the execution time of an ideal scheduling, which can then be compared with the actual results.
- We have continued collaboration with the University of Tennessee, Knoxville for STARPU support in the state-of-the-art dense linear algebra library, Magma, in particular LU [26] and QR [27] factorizations. We have also collaborated with the University of Mons [41] and Linköping [32].
- Cédric Augonnet defended his PhD on STARPU [17].
6.7. Development of a flexible heterogeneous system-on-chip platform using a mix of programmable processing elements and hardware accelerators

**Participants:** Paul-Antoine Arras, Emmanuel Jeannot, Samuel Thibault.

- Today’s embedded applications are increasingly demanding in terms of computational power, especially in real-time digital signal processing (DSP) where tight timing requirements are to be fulfilled. More specifically, when it comes to video decoding (e.g. H.264/AVC) not only has it been almost impossible for some time to run such codecs on a stand-alone embedded processor, but it now also becomes quite impractical to execute them on homogeneous multicore platforms. In this context, STMicroelectronics is developing a scalable heterogeneous system-on-chip template called P2012 and aimed at meeting the latest codecs’ requirements.

- This year, the privileged axis of research was directed towards dataflow-based models, which benefit from such strong, well-known properties as analyzability, schedulability and expressivity. Furthermore, dataflow programming has already been used extensively in DSP, yielding a number of dedicated software synthesis tools. We have proposed a first version of the programming model that will be evaluated later.

6.8. Sparse GMRES on heterogeneous platforms in oil extraction simulation

**Participants:** Olivier Aumage, Corentin Rossignon, Samuel Thibault.

- We started a study on sparse matrix factorization and system resolution on heterogeneous platforms in collaboration with Pascal Hénon from company Total, in the context of oil extraction simulation. Sparse matrix computations are notoriously difficult to efficiently run on heterogeneous platforms in the general case due to the irregular memory access patterns they generate.

- However, in the specific context of this study, Corentin Rossignon showed as part of his Master Thesis [56] that the sparsity layout of matrices generated by such oil extraction simulation problems can lead to a much higher level of efficiency on heterogeneous platforms thanks when using a suitable sparse internal representation together with carefully written operators such as the sparse matrix-vector product together with the StarPU heterogeneous scheduler.

- Corentin Rossignon is now starting a PhD. Thesis in partnership with Total to build on these promising results.

6.9. Programming models for heterogeneous platforms

**Participants:** Olivier Aumage, Cyril Roelandt, Samuel Thibault, Ludovic Courtès.

- As part of Project FP3C with Japan, we started a study on to explore the use of StarPU as possible target runtime system for the XcalableMP language and compiler developed by Prof. Sato’s team from University of Tsukuba. XcalableMP is a pragma-based language designed for parallelising application on clusters of multicore processors. The compiler is responsible to expand XcalableMP pragma into complex work mapping, communication and data redistribution commands.

- The study of porting XcalableMP on top of StarPU was conducted by Cyril Roelandt during his Master Thesis [55], starting from the idea that computing node with one or more attached accelerating expansion cards can be seen as a distributed platform. The results of the study showed that on the one side, the power of the XcalableMP language itself is very interesting for the goal of simplifying the port of applications on heterogeneous platforms. However, a current assumption of the XcalableMP model is that the compiler does not insert implicit commands and behaviour except at the exact location of pragma annotations, which limit the range of optimizations available to the dynamic scheduler and memory manager of StarPU. We will thus continue to collaborate with Prof. Sato’s team within the FP3C to see how these limitations could be reduced or lifted when using XcalableMP with StarPU.
In an effort to make it easier for C programmers to benefit from StarPU, the team-project has been working on extensions to the C language allowing important StarPU concepts to be expressed concisely. These C extensions are provided as a plug-in for the GNU Compiler Collection (GCC 1), and is now distributed as part of StarPU.

The GCC plug-in extends the syntax and semantics of C and related languages (C++, Objective-C) using attributes and pragmas. Attributes are used, for instance, to declare StarPU tasks and their implementations for the available targets (CPU, OpenCL, CUDA, etc.) Pragmas are used notably to provide programmers a way to describe data buffers that are passed to tasks, which in turn allows the StarPU run-time support to manage data transfers between main memory and GPUs as it sees fit. Finally, tasks are invoked like regular C functions.

In addition to easing application development, the GCC plug-in, thanks to its higher-level view of the program structure, is able to report certain classes of errors at compile-time, which would otherwise lead to run-time errors.

This project has been led by Ludovic Courtès of Inria’s Development and Experimentation Department (SED) at Bordeaux, as part of a joint development action with the SED.

6.10. Parallel Concha

Participants: Olivier Aumage, Marie-Christine Counilh.

- Within the ADT Ampli project, we contributed to the Concha CFD library developed by R. Becker’s Inria Team Concha in Pau. Together with R. Becker, E. Bergounioux and D. Trujillo from Concha Team, and François Rue from SED Bordeaux we designed and experimented with the MPI parallelization and the hybrid MPI+OpenMP parallelization of the library.
- The MPI parallelization is now finalized. The OpenMP level has been successfully tested on the Vanka smoother and is now being spread in the library. We will thus continue to contribute to this parallelization work, in particular with respect to the support of 3D simulation cases.

6.11. Scientific Application Analysis and Experiments

Participants: Olivier Aumage, Denis Barthou, Andres Charif-Rubial, François Tessier, Ludovic Stordeur.

- Within the context of the ANR ProHMPT project, we contributed a thorough analysis of hot spots, data structure usages and locality issues in memory accesses of an aerodynamics application from partner CEA CESTA.
- In accordance with these results, a new version of this application has been written by the CESTA Team with redesigned, locality-friendly data structures and simplified loop scheme. This new version performs much better than the previous one on both 2D and 3D cases.
- We also conducted tests about the port of selected kernels of this application on accelerated heterogeneous platforms. The results of these tests were disappointing with the first version of the application due to the layout of the main data structures that led to a lot of memory transfers between the central memory and the accelerated memory.
- We are now working on conducting these experiments with the redesigned version of the application whose new data structures should dramatically reduce the amount of data transfers.

1 See http://gcc.gnu.org/, for more information on GCC.
6.12. Virtualization of GPUs for OpenCL  
**Participants:** Sylvain Henry, Alexandre Denis, Denis Barthou.  
- We propose a new approach for OpenCL programming, using a unique virtual accelerator instead of using the physical accelerator. Placement on the real hardware is handled by the runtime instead of the user, improving productivity and performance scalability. This proposition relies on OpenCL standard but changes the way its API is used.  
- We have shown on some simple examples how this approach, using StarPU as a runtime, enables executions with a better load balance and performance. We are working on how to generalize this to more complex benchmarks. This work has been presented in Renpar[ 42 ] workshop.

6.13. Automatically Adapting Task Grain for Hybrid Architectures  
**Participants:** Sylvain Henry, Alexandre Denis, Denis Barthou.  
- Given a parallel task graph, a runtime such as StarPU can place each task on different hardware. However, there is still the need to adapt the number of tasks, the granularity of these tasks, according to the target hardware. Due to architectures with CPUs and GPUs, it is potentially interesting to have tasks of different granularities. We explore transformations that enable to either automatically split tasks into small ones, or given some user knowledge on the tasks, decide how and when to split a large task into small ones.  
- This work starts from a high-level representation of the code, using an explicit data-flow graph.

6.14. Performance modeling for power consumption reduction on the SCC  
**Participants:** Bertrand Putigny, Brice Goglin, Denis Barthou.  
- We build a model to predict performance of HPC code on the SCC ship. This model can predict runtime of regular code as well as power consumption for different frequency.  
- This allows users to choose either to optimize power consumption, power efficiency or raw performance.  
- This work has been published in an Intel Symposium [ 38 ].

6.15. Modeling cache coherence protocol overhead  
**Participants:** Bertrand Putigny, Denis Barthou, Brice Goglin.  
- We are building a fine grained cache model to understand common cache coherence issue.  
- This model is built on a set of micro-benchmarks and can also be used to improve find some bottlenecks in memory bound code. Our set of micro-benchmarks can also be used as a test bed for new architectures [ 54 ].

6.16. Memory Performance Analysis and Tool for OpenMP codes  
**Participants:** Andres Charif-Rubial, Denis Barthou.  
- We propose a performance analysis of OpenMP codes, based on memory accesses and cache hierarchies.  
- This analysis relies on memory traces for multi-threaded codes and on static analysis of binary code. Memory traces are obtained through MAQAO by static binary rewriting and are compressed online, building polyhedral iteration domains. The static analysis, mostly induction variable detection on binary code, provides the same analysis whenever possible, removing the need in some cases for dynamic instrumentation.  
- The analysis focuses on a number of issues in multi-threaded executions: thread affinity issues, false sharing, cache pollution.  
- This work is in collaboration with Exascale Computing Lab.
6.17. Data-layout Optimization for Stencil codes on multi-cores and GPUs

**Participants:** Julien Jaeger, Denis Barthou.

- We develop a new approach for stencil code generation, optimizing data-layout for multi-threaded, SIMD code on multicores and CUDA code on GPU. The transformation handles different stencil parameters, and memory constraints.
- The code generated reaches high levels of performance, outperforming related works for multicores and with similar performance on GPUs. This work is submitted to publication and was first presented in a workshop [52].
S.H.A.M.A.N Team

6. New Results

6.1. Interactive Simulation of Liver Resection PASSPORT demonstration at SIGGRAPH

The 3-year EU PASSPORT project is being finalized. In this context, we created a GPU-based interactive simulation of laparoscopic liver resection that was selected for SIGGRAPH Real Time Live! [21]. While similar medical simulators have been developed in the past, this demonstration rely on advanced methods and the computational power of today GPUs to simulate multiple organs with high-resolution deformations and collisions in real-time. We use detailed meshes generated from segmented CT scans, facilitating the reproduction of patient-specific scenarios, as is necessary for the pre-operative rehearsal of complex or risky medical cases. In the presented application, the user can examine the mechanical and collision models, and the generated contacts while the simulated patient is breathing. He can manipulate a laparoscopic instrument to navigate through the abdominal cavity, push on organs and perform a thermal ablation.

![Figure 5. Left: mechanical FEM models (4k tetrahedra), Middle: Collision surfaces (15k triangles), Right: Visual Models. Bottom: the user view during liver resection. The resulting simulation runs at 25 FPS.]

While similar medical simulators have been developed in the past 10 years, this demonstration is based on recently proposed methods: high-resolution Finite Element Model (FEM) with implicit time-integration implemented on GPU [1], volume contact constraints [2], an efficient numerical solver based on asynchronous preconditioning [17], as well as improvements in visual and haptic rendering. These methods allow to simulate in real-time all organs in the abdominal cavity using a improved level of precision compared to previous works. The FEM formulation enables to reproduce specific material properties. Contacts are handled by precise constraints with frictions on detailed surface meshes. Both methods support topological changes efficiently, as demonstrated by performing a resection of a portion of a liver, an important step in
surgical procedures performed to remove cancerous tumors. This work was presented at SIGGRAPH 2011 [21].

6.2. Biomechanical simulation of electrode migration for deep brain stimulation

Deep Brain Stimulation is a modern surgical technique for treating patients who suffer from affective or motion disorders such as Parkinson’s disease. The efficiency of the procedure relies heavily on the accuracy of the placement of a micro-electrode which sends electrical pulses to a specific part of the brain that controls motion and affective symptoms. However, targeting this small anatomical structure is rendered difficult due to a series of brain shifts that take place during and after the procedure. We introduce a biomechanical simulation of the intra and postoperative stages of the procedure in order to determine lead deformation and electrode migration due to brain shift. To achieve this goal, we propose a global approach, which accounts for brain deformation but also for the numerous interactions that take place during the procedure (contacts between the brain and the inner part of the skull and falx cerebri, effect of the cerebrospinal fluid, and biomechanical interactions between the brain and the electrodes and cannula used during the procedure). Preliminary results show a good correlation between our simulations and various results reported in the literature. This work was presented at MICCAI 2011 [16].

Figure 6. Screenshot showing the simulated deflection of the right electrode immediately after operation (left) and several weeks after the operation (right).

6.3. Preconditioner-Based Contact Response and Application to Cataract Surgery

We introduced a new method to compute, in real-time, the physical behavior of several colliding soft-tissues in a surgical simulation. The numerical approach is based on finite element modeling and allows for a fast update of a large number of tetrahedral elements. The speed-up is obtained by the use of a specific preconditioner that is updated at low frequency. The preconditioning enables an optimized computation of both large deformations and precise contact response. Moreover, homogeneous and inhomogeneous tissues are simulated with the same accuracy. This method was used in a simulation of one step in a cataract surgery procedure, which require to handle contacts with non homogeneous objects precisely. This work was presented at MICCAI 2011 [17].
6.4. Interactive Blood-Coil Simulation in Real-time during Aneurysm Embolization

We introduced a complete process for patient-specific simulations of coil embolization, from mesh generation with medical datasets to computation of coil-flow bilateral influence. We propose a new method for simulating the complex blood flow patterns that take place within the aneurysm, and for simulating the interaction of coils with this flow. Porous media was introduced to model the impact of the coil onto the flow (as a change of flow pattern and a decrease of velocity) from a statistical point of view, while the reverse effect on the coil (as a shift in the blood flow) was described by the local drag force. By solving the Navier-Stokes Equations with extra porous terms using the DEC method, the velocity field of blood flow was obtained, and then used to compute the drag force applied on the coil during aneurysm embolization. This work was published in the Computers & Graphics journal [13].

6.5. Constraint-based Haptic Rendering of Multirate Compliant Mechanisms
The research, that is published in IEEE transaction of Haptics [12], is dedicated to haptic rendering of complex physics-based environment in the context of surgical simulation. A new unified formalism for modeling the mechanical interactions between medical devices and anatomical structures and for computing accurately the haptic force feedback is presented. The approach deals with the mechanical interactions using appropriate force and/or motion transmission models named *compliant mechanisms*. These mechanisms are formulated as a constraint-based problem that is solved in two separate threads running at different frequencies. The first thread processes the whole simulation including the soft-tissue deformations, whereas the second one only deals with computer haptics. This method builds a bridge between the so called virtual mechanisms (that were proposed for haptic rendering of rigid bodies) and intermediate representations (used for rendering of complex simulations). With this approach, it is possible to describe the specific behavior of various medical devices while relying on a unified method for solving the mechanical interactions between deformable objects and haptic rendering. The technique is demonstrated in interactive simulation of flexible needle insertion through soft anatomical structures with force feedback.

![Constraint-based Haptic Rendering of Multirate Compliant Mechanisms](image)

**Figure 9. Constraint-based Haptic Rendering of Multirate Compliant Mechanisms**

6.6. **Asynchronous Haptic Simulation of Contacting Deformable Objects with Variable Stiffness**
This research, published in IROS proceedings [18], presents a new asynchronous approach for haptic rendering of deformable objects. When stiff non-linear deformations take place, they introduce important and rapid variations of the force sent to the user. This problem is similar to the stiff virtual wall for which a high refresh rate is required to obtain a stable haptic feedback. However, when dealing with several interacting deformable objects, it is usually impossible to simulate all objects at high rates. To address this problem we propose a quasi-static framework that allows for stable interactions of asynchronously computed deformable objects. In the proposed approach, a deformable object can be computed at high refresh rates, while the remaining deformable virtual objects remain computed at low refresh rates. Moreover, contacts and other constraints between the different objects of the virtual environment are accurately solved using a shared Linear Complementarity Problem (LCP). Finally, we demonstrate our method on two test cases: a snap-in example involving non-linear deformations and a virtual thread interacting with a deformable object.

6. New Results

6.1. Petri Nets and their Synthesis

Participant: Philippe Darondeau.

6.1.1. Petri Net Reachability Graphs: Decidability Status of FO Properties

In [24], we investigate the decidability and complexity status of model-checking problems on unlabelled reachability graphs of Petri nets by considering first-order, modal and pattern-based languages without labels on transitions or atomic propositions on markings. We consider several parameters to separate decidable problems from undecidable ones. Not only are we able to provide precise borders and a systematic analysis, but we also demonstrate the robustness of our proof techniques.

6.1.2. Separability in Persistent Petri Nets

We prove in [14] that the separability of plain, bounded, reversible and persistent Petri nets, a class of nets that extends the well-known live and bounded marked graphs. We establish first a weak form of separability, already known to hold for marked graphs, in which every firing sequence is simulated by a firing sequence of k parallel instances identical firing counts. We establish on top of this a strong form of separability, in which every firing sequence of is simulated by identical firing sequences.

6.1.3. Petri Net Distributability

A Petri net is distributed if, given an allocation of transitions to (geographical) locations, no two transitions at different locations share a common input place. A system is distributable if there is some distributed Petri net implementing it. We address in [23] the question of which systems can be distributed, while respecting a given allocation. The paper states the problem formally and discusses several examples illuminating — to the best of the authors’ knowledge — the current status of this work.

6.2. Heterogeneous Systems

Participants: Eric Badouel, Albert Benveniste, Timothy Bourke, Benoît Caillaud.

6.2.1. Hybrid Modeling

Hybrid modeling tools like Simulink have evolved from simulation platforms into development platforms on which testing, verification and code generation are also performed. It is critical to ensure that the results of simulation, compilation and verification are consistent. Synchronous languages have addressed these issues but only for discrete systems. Reprising earlier work [32], we present in [21] a hybrid modeler built from a synchronous language and an off-the-shelf numerical solver. The main novelty is a language with hierarchical automata that can be arbitrarily mixed with data-flow and ordinary differential equations (ODEs). A type system statically ensures that discrete state changes are aligned with zero-crossing events and that the function passed to the numerical solver has no side-effects during integration. Well-typed programs are compiled by source-to-source translation into synchronous code which is then translated into sequential code using an existing synchronous language compiler.
Starting from a minimal, yet full-featured, Lustre-like synchronous language, we present in [22] a conservative extension where data-flow equations can be mixed with ordinary differential equations (ODEs) with possible reset. A type system is proposed to statically distinguish discrete computations from continuous ones and to ensure that signals are used in their proper domains. We propose a semantics based on non-standard analysis which gives a synchronous interpretation to the whole language, clarifies the discrete/continuous interaction and the treatment of zero-crossings, and also allows the correctness of the type system to be established. The extended data-flow language is realized through a source-to-source transformation into a synchronous subset, which can then be compiled using existing tools into routines that are both efficient and bounded in their use of memory. These routines are orchestrated with a single off-the-shelf numerical solver using a simple but precise algorithm which treats causally-related cascades of zero-crossings. We have validated the viability of the approach through experiments with the Sundials library.

6.2.2. Distributed Structured Documents

Evaluation of attributes w.r.t. an attribute grammar can be obtained by inductively computing a function expressing the dependencies of the synthesized attributes on inherited attributes. This higher-order functional approach to attribute grammars leads to a straightforward implementation using a higher-order lazy functional language like Haskell. The resulting evaluation functions are, however, not easily amenable to optimization rules. We present in [12] an alternative first-order functional interpretation of attribute grammars where the input tree is replaced with an extended cyclic tree each node of which is aware of its context viewed as an additional child tree. By the way, we demonstrate that these cyclic representations of zippers (trees with their context) are natural generalizations of doubly-linked lists to trees over an arbitrary signature.

6.3. Component-Based Design

Participants: Eric Badouel, Albert Benveniste, Benoît Caillaud, Benoît Delahaye, Sophie Pinchinat.

6.3.1. The Modal Interface Theory

In [18], we present the modal interface theory, a unification of interface automata and modal specifications, two radically dissimilar models for interface theories. Interface automata is a game-based model, which allows the designer to express assumptions on the environment and which uses an optimistic view of composition: two components can be composed if there is an environment where they can work together. Modal specifications are a language theoretic account of a fragment of the modal mu-calculus logic with a rich composition algebra which meets certain methodological requirements but which does not allow the environment and the component to be distinguished. The present paper contributes a more thorough unification of the two theories by correcting a first attempt in this direction by Larsen et al., drawing a complete picture of the modal interface algebra, and pushing the comparison between interface automata, modal automata and modal interfaces even further.

6.3.2. A Stochastic Interface Theory

Notions of specification, implementation, satisfaction, and refinement, together with operators supporting stepwise design, constitute a specification theory. In [16], we construct such a theory for Markov Chains (MCs) employing a new abstraction of a Constraint MC. Constraint MCs permit rich constraints on probability distributions and thus generalize prior abstractions such as Interval MCs. Linear (polynomial) constraints suffice for closure under conjunction (respectively parallel composition). This is the first specification theory for MCs with such closure properties. We discuss its relation to simpler operators for known languages such as probabilistic process algebra. Despite the generality, all operators and relations are computable.

6.3.3. Contract-Based Compositional Analysis of Stochastic Systems

A contract allows to distinguish hypotheses made on a system (the guarantees) from those made on its environment (the assumptions). In [17], we focus on models of Assume/Guarantee contracts for (stochastic) systems. We consider contracts capable of capturing reliability and availability properties of such systems. We also show that classical notions of Satisfaction and Refinement can be checked by effective methods thanks to a reduction to classical verification problems. Finally, theorems supporting compositional reasoning and enabling the scalable analysis of complex systems are also studied.
6.3.4. Modal event-clock specifications for timed component-based design

On the one hand, modal specifications are classic, convenient, and expressive mathematical objects to represent interfaces of component-based systems. On the other hand, time is a crucial aspect of systems for practical applications, e.g. in the area of embedded systems. And yet, only few results exist on the design of timed component-based systems. In [13], we propose a timed extension of modal specifications, together with fundamental operations (conjunction, product, and quotient) that enable reasoning in a compositional way about timed system. The specifications are given as modal event-clock automata, where clock resets are easy to handle. We develop an entire theory that promotes efficient incremental design techniques.

6.4. Scheduling and Supervisory Control

Participants: Eric Badouel, Benoît Caillaud, Philippe Darondeau.

6.4.1. Model Identification and Synthesis of Discrete-Event Systems

Book chapter [28] focuses on two important and tightly related problems, namely the identification and synthesis of discrete-event systems. Particular attention is devoted to two main formalisms in this area, i.e., finite state automata and Petri nets. The goal of this chapter is to provide a collection of references in this framework, and discuss the main research areas where such problems have been investigated. Due to the extensive literature, only some of the results are discussed in a certain detail, such as the basic ideas related to the theory of regions and the synthesis of labeled Petri nets, while other results are simply mentioned and the reader is addressed to the specific contributions for more details.

6.4.2. Assembling Sessions

Sessions are a central paradigm in Web services to implement decentralized transactions with multiple participants. Sessions enable the cooperation of workflows while at the same time avoiding the mixing of workflows from distinct transactions. Languages such as BPEL, ORC, AXML that implement Web Services usually realize sessions by attaching unique identifiers to transactions. The expressive power of these languages makes the properties of the implemented services undecidable. In [25], we propose a new formalism for modelling web services. Our model is session-based, but avoids using session identifiers. The model can be translated to a dialect of Petri nets that allows the verification of important properties of web services.

6.4.3. Towards Distributed Control of Discrete Event Systems

To initiate a discussion on the modeling requirements for distributed control of discrete-event systems, a partially-automated region based methodology is presented in [26]. The methodology is illustrated via a well-known example from distributed computing: the dining philosophers.

6.4.4. Communicating Decentralized Control

Frameworks that incorporate communication into decentralized supervisory control theory address the following problem: find locations in the evolution of the plant behavior where some supervisors send information so that a supervisor that was unable to make the correct control decision prior to receiving external information, is now capable of making the correct control decision. We propose in [19] a solutions to this problem and identify an earliest and a latest placement where such communication results in the synthesis of a correct control solution. In addition to a first and last communication opportunity, there may be a selection of intermediate possibilities where communication would produce the correct control solution. We present a computable procedure to identify a broader range of suitable communication locations.

6.4.5. Residuation of tropical series: rationality issues

In [20], the decidability of existence, rationality of delay controllers and robust delay controllers are investigated for systems with time weights in the tropical and interval semirings. Depending on the (max,+) or (min,+) rationality of the series specifying the controlled system and the control objective, cases are identified where the controller series defined by residuation is rational, and when it is positive (i.e., when delay control is feasible). When the control objective is specified by a tolerance, i.e. by two bounding rational series, a nice case is identified in which the controller series is of the same rational type as the system specification series.
6.5. Games, Logic and System Synthesis

Participants: Bastien Maubert, Sophie Pinchinat.

6.5.1. Opacity Issues in Games with Imperfect Information

In [27], we study the class of games with opacity condition, which are two-player games with imperfect information in which one of the players only has imperfect information, and where the winning condition relies on the information he has along the play. Those games are relevant for security aspects of computing systems: a play is opaque whenever the player who has imperfect information never "knows" for sure that the current position is one of the distinguished "secret" positions. We study the problems of deciding the existence of a winning strategy for each player, and we call them the opacity-violate problem and the opacity-guarantee problem. Focusing on the player with perfect information is new in the field of games with imperfect-information because when considering classical winning conditions it amounts to solving the underlying perfect-information game. We establish the EXPTIME-completeness of both above-mentioned problems, showing that our winning condition brings a gap of complexity for the player with perfect information, and we exhibit the relevant opacity-verify problem, which noticeably generalizes approaches considered in the literature for opacity analysis in discrete-event systems. In the case of blindfold games, this problem relates to the two initial ones, yielding the determinacy of blindfold games with opacity condition and the PSPACE-completeness of the three problems.

6.5.2. Hardness of preorder checking for basic formalisms

We investigate in [15] the complexity of preorder checking when the specification is a flat finite-state system whereas the implementation is either a non-flat finite-state system or a standard timed automaton. In both cases, we show that simulation checking is Exptime-hard, and for the case of a non-flat implementation, the result holds even if there is no synchronization between the parallel components and their alphabets of actions are pairwise disjoint. Moreover, we show that the considered problems become Pspace-complete when the specification is assumed to be deterministic. Additionally, we establish that comparing a synchronous non-flat system with no hiding and a flat system is Pspace-hard for any relation between trace containment and bisimulation equivalence.
6. New Results

6.1. Parallelism and convergence in Krylov methods

Participants: Édouard Canot, Jocelyne Erhel, Désiré Nuentsa Wakam, Bernard Philippe.

This work is done in the context of the Cinemas2 and the Libraero contracts, 7.2 and 8.1.3. It is also done in collaboration with the joint INRIA/NCSA laboratory on petascale computing.

A Ph-D thesis was defended this year [12].

6.1.1. Some properties of Krylov methods

Participant: Jocelyne Erhel.

A survey was presented at a conference and published in a book chapter [37] [24].

Solving a linear system is at the heart of many scientific and engineering applications. Generally, this operations is the most time and memory consuming part of the simulation. This paper focuses on some properties of Krylov iterative methods. Iterative methods of Krylov type require less memory than direct methods, but the number of iterations increases rapidly with the size of the system. The convergence rate and the accuracy of the results depend on the condition number which can blow up at large scale. Therefore, it is essential to combine these methods with a preconditioner; the idea is to solve another system, close to the original one, but which is easier to solve; also, on parallel computers, it must be scalable. In Krylov iterative methods, the matrix is not transformed but the kernel operation is the matrix-vector product; thus it is possible to use matrix-free versions without storing the matrix. However, preconditioning will sometimes require the matrix. Krylov methods are described in many books. In this survey, we choose the framework of polynomial and projection methods. We first give general properties. Then, we study specific methods for the three different types of matrices: the case of SPD matrices is analyzed first, followed by the case of symmetric indefinite matrices. The general case of nonsymmetric matrices is studied with the description of several Krylov methods. Finally, some practical issues, preconditioning and parallelism are discussed.

6.1.2. Generation of Krylov subspace bases

Participant: Bernard Philippe.

This work was done in collaboration with L. Reichel, from University of Kent, USA.

It has been published in a journal [19].

Many problems in scientific computing involving a large sparse square matrix A are solved by Krylov subspace methods. This includes methods for the solution of large linear systems of equations with A, for the computation of a few eigenvalues and associated eigenvectors of A, and for the approximation of nonlinear matrix functions of A. When the matrix A is non-Hermitian, the Arnoldi process commonly is used to compute an orthonormal basis for a Krylov subspace associated with A. The Arnoldi process often is implemented with the aid of the modified Gram–Schmidt method. It is well known that the latter constitutes a bottleneck in parallel computing environments, and to some extent also on sequential computers. Several approaches to circumvent orthogonalization by the modified Gram–Schmidt method have been described in the literature, including the generation of Krylov subspace bases with the aid of suitably chosen Chebyshev or Newton polynomials. We review these schemes and describe new ones. Numerical examples are presented.

6.1.3. Parallel preconditioned GMRES with Multiplicative Schwarz

Participants: Édouard Canot, Jocelyne Erhel, Désiré Nuentsa Wakam, Bernard Philippe.

This work was published in a journal [18].
This paper presents a robust hybrid solver for linear systems that combines a Krylov subspace method as accelerator with a Schwarz-based preconditioner. This preconditioner uses an explicit formulation associated to one iteration of the multiplicative Schwarz method. The Newton-basis GMRES, which aim at expressing a good data parallelism between subdomains is used as accelerator. In the first part of this paper, we present the pipeline parallelism that is obtained when the multiplicative Schwarz preconditioner is used to build the Krylov basis for the GMRES method. This is referred as the first level of parallelism. In the second part, we introduce a second level of parallelism inside the subdomains. For Schwarz-based preconditioners, the number of subdomains is kept small to provide a robust solver. Therefore, the linear systems associated to subdomains are solved efficiently with this approach. Numerical experiments are performed on several problems to demonstrate the benefits of using these two levels of parallelism in the solver, mainly in terms of numerical robustness and global efficiency.

6.1.4. Adaptive deflation in preconditioned GMRES algorithm using a combined preconditioning

Participants: Jocelyne Erhel, Désiré Nuentsa Wakam, Bernard Philippe.

This work has been presented at a conference and a workshop [35], [27] and submitted to the proceedings of DD20 [45]. The software module DGMRES is integrated in the Petsc distribution.

Many scientific libraries are currently based on the GMRES method as a Krylov subspace iterative method for solving large linear systems. The restarted formulation known as GMRES($m$) has been extensively studied and several approaches have been proposed to reduce the negative effects due to the restarting procedure. A common effect in GMRES($m$) is a slow convergence rate or a stagnation in the iterative process. In this situation, it is less attractive as a general solver in industrial applications. In this work, we propose an adaptive deflation strategy which retains useful information at the time of restart to avoid stagnation in GMRES($m$) and improve its convergence rate. We give a parallel implementation in the PETSc package. The provided numerical results show that this approach can be effectively used in the hybrid direct/iterative methods to solve large-scale systems.

6.1.5. Adaptive deflation in preconditioned GMRES algorithm using an augmented subspace

Participants: Jocelyne Erhel, Désiré Nuentsa Wakam, Bernard Philippe.

This work has been presented at a conference [31] and submitted to the journal ETNA [46].

The GMRES iterative method is widely used as Krylov subspace accelerator for solving sparse linear systems when the coefficient matrix is nonsymmetric and indefinite. The Newton basis implementation has been proposed on distributed memory computers as an alternative to the classical approach with the Arnoldi process. The aim of our work here is to introduce a modification based on deflation techniques. This approach builds an augmented subspace in an adaptive way to accelerate the convergence of the restarted formulation. In our numerical experiments, we show the benefits of using this implementation with hybrid direct/iterative methods to solve large linear systems.

6.1.6. Using deflated preconditioned GMRES for industrial CFD problems

Participant: Désiré Nuentsa Wakam.

This work has been submitted to the journal Computers and Fluids [47].

This paper deals with the solution of large and sparse linear systems arising from design optimization in Computational Fluid Dynamics. From the algebraic decomposition of the input matrix, a hybrid robust direct/iterative solver is often defined with a Krylov subspace method as accelerator, a domain decomposition method as preconditioner and a direct method as subdomain solver. The goal of this paper is to reduce the memory requirements and indirectly the computational cost at different steps of this scheme. To this end, we use a grid-point induced block approach for the data storage and the partitioning part, a Krylov subspace method based on the restarted GMRES accelerated by deflation, a preconditioner formulated with the restricted additive Schwarz method and an aerodynamic/turbulent fields split at the subdomain level. Numerical results are presented with industrial test cases to show the benefits of these choices.
6.2. Parallel numerical algorithms

6.2.1. High Performance Scientific Computing

Participant: Bernard Philippe.

This work was done in collaboration with several authors, from US, Greece, etc. A book will appear on this subject in 2012 [39] and a chapter of this book is devoted to a historical perspective [38].

This comprehensive text/reference, inspired by the visionary work of Prof. Ahmed H. Sameh, represents the state of the art in parallel numerical algorithms, applications, architectures, and system software. Articles in this collection address solutions to various challenges arising from concurrency, scale, energy efficiency, and programmability. These solutions are discussed in the context of diverse applications, ranging from scientific simulations to large-scale data analysis and mining.

As exascale computing is looming on the horizon while multicore and GPU’s are routinely used, we survey the achievements of Ahmed H. Sameh, a pioneer in parallel matrix algorithms [38]. Studying his contributions since the days of Illiac IV as well as the work that he directed and inspired in the building of the Cedar multiprocessor and his recent research, unfolds a useful historical perspective in the field of parallel scientific computing.

6.2.2. Updating the Diagonalization of a Symmetric Matrix

Participant: Bernard Philippe.

This work is done in the context of the DIAMS project.

Two methods are compared: Jacobi method and first order correction of the spectral projectors [25],[26].

6.2.3. Counting eigenvalues in domains of the complex field

Participant: Bernard Philippe.

This work is done in collaboration with E. Kamgnia, from the University of Yaounde 1, Cameroon, in the context of the MOMAPLI project at LIRIMA.

It has been submitted to a journal [43].

A procedure for counting the number of eigenvalues of a matrix in a region surrounded by a closed curve is presented. It is based on the application of the residual theorem. The quadrature is performed by evaluating the principal argument of the logarithm of a function. A strategy is proposed for selecting a path length that insures that the same branch of the logarithm is followed during the integration. Numerical tests are reported for matrices obtained from conventional matrix test sets.

6.2.4. Rescaling for time integration

Participant: Jocelyne Erhel.

This work is done in collaboration with N. Makhoul and N. Nassif, from the American University of Beirut, Lebanon.

It is published in a journal [17].
This paper considers the mathematical framework of a sliced-time computation method for explosive solutions to systems of ordinary differential equations: \( Y(t) \in \mathbb{R}^k : \frac{dY}{dt} = F(Y), 0 < t, Y(0) = Y_0, \) that have finite or infinite explosion time. The method used generates automatically a sequence of non uniform slices \([T_{n-1}, T_n]| n \geq 1\) determined by an end-of-slice condition that controls the growth of the solution within each slice. It also uses rescaling of the variables, whereas: \( t = T_{n-1} + \beta_n s \) and \( Y(t) = Y(T_{n-1}) + D_n Z_n(s) \), \( D_n \mathbb{R}^{k \times k} \) and \( \beta_n \) being respectively an invertible diagonal matrix and a rescaling time factor. Thus, the original system is transformed into a sequence of slices-dependent initial-value shooting problems:

\[
\frac{dZ_n}{ds} = G_n(Z_n), 0 < s \leq s_n, Z_n(0) = 0.
\]

A suitable selection of \( \beta_n \) and \( D_n \) leads the rescaled systems to verify a concept of uniform similarity, allowing to disable the extreme stiffness of the original ODE problem.

Then, on each time slice, the uniformly rescaled systems are locally solved using a 4th order explicit Runge-Kutta scheme, within a computational tolerance of \( \epsilon_{\text{loc}} \). After sequentially implementing the local solver on a total of \( N \) slices, a global tolerance \( \epsilon_{\text{glob}} \) would result in approximating the solution \( Y(t) \) of the original system.

The proper definition of Uniform Similarity leads to deriving, under a stability assumption, a relationship between \( \epsilon_{\text{loc}}, \epsilon_{\text{glob}} \) and \( N \). Numerical experiments are conducted for infinite and finite times explosive discrete reaction diffusion problems. These experiments validate the theoretical results and attest for the efficiency of the method in terms of stability and high accuracy.

6.3. Numerical models and simulations applied to physics

6.3.1. Heat and mass transfer in soil and prehistoric fires

Participant: Édouard Canot.

This work is done in the context of the Arphymat project, in collaboration with Archeosciences, IPR and Lebanese International University (LIU), Lebanon.

This work is published in a journal [16].

This paper is devoted to the simulation of water forced evaporation in a porous saturated medium in a 3D-axisymmetric domain by resolution of partial differential algebraic equations (PDAE) that are encountered in different engineering applications. The goal of this paper is an attempt to present effective realizations, in order to determine the minimal duration of burning for prehistoric occupations. This multidisciplinary work includes scientists in Mathematics, Physics and Archaeology. The model proposed here couples the heat conduction in a water saturated soil with the water steam flow in the medium. We propose an efficient and robust global numerical method, based on a method of lines and differential algebraic equations (DAE) solvers, combined with a Newton method using a powerful sparse linear solver. After a brief overview of classes for numerical techniques applied for moving boundary problems, the Apparent Heat Capacity method (AHC) is used, and in order to validate our codes, a comparison with experiments is done.

Recent work concerns the optimal choice of the temperature interval across which the phase change occurs in the apparent capacity method, because we have to make a compromise between the smoothness of the solution and its accuracy.

6.3.2. Rheology of granular systems flowing out of silo

Participant: Édouard Canot.

This work is done in the framework of a project funded by the Region Bretagne. A PhD thesis (Merline Djouwe-Tankeo), coadvised with Patrick Richard, who is from the Physics Institute at the University of Rennes (IPR), started in February 2009 and will be defended in January 2012.

It has been presented at a conference [36] and a paper is submitted.
We first studied the granular flows by the "discrete elements" method in silo geometries. By changing the micro-mechanical properties of the grains (restitution and friction), we showed that they had a significant influence on the flow discharge. Although models such as "discrete elements" provide access to all the individual properties of the grains, they have one major drawback: the computation time is very important that prohibits the modeling of geophysical and industrial situations. To overcome this problem, we used the "continuous medium" approach, which consider that the granular medium studied follows a rheology recently proposed in the literature. After discussing the numerical implementation, we have studied this rheology for steady and fully developed flows with a semi-analytical method in two configurations: a shear cell and a channel. This allowed us to highlight the differences between a granular medium and a Newtonian fluid.

6.4. Models and simulations for transport in porous media

6.4.1. Transport in highly heterogeneous porous medium

Participants: Jocelyne Erhel, Géraldine Pichot, Nadir Soualem.

This work is done in collaboration with A. Beaudoin, from University of Poitiers (Pprime) and J.-R. de Dreuzy, from Geosciences Rennes. It is done in the context of the Micas project (8.1.2).

It has been presented at a conference and a paper is in preparation [28].

We study the transport of an inert species in a 2D heterogeneous porous medium via a Random Walk Particle Tracking (RWPT) method. The main objective is to derive the macroscopic properties of the transport by the means of Monte-Carlo simulations in large domains. Conditions to reach asymptotic macro-dispersion coefficients are given. We also present our on-going research about the RWPT method in presence of discontinuities within the domain.

6.4.2. Transport in discontinuous porous medium

Participants: Jocelyne Erhel, Géraldine Pichot.

This work is done in collaboration with A. Lejay, from Inria Nancy. It is done in the context of the Micas project (8.1.2).

It is published in the proceedings of a conference and submitted in a journal [30], [44].

We study a diffusion process in a 1D discontinuous medium using a random walk approach. Our main contribution is to encompass two existing numerical methods in the unified framework of the Skew Brownian Motion. This theoretical approach allows to detail and justify the derived algorithms. Numerical simulations are performed on two test cases to show that the algorithms can deal with the discontinuity in the diffusion coefficient.

6.4.3. Reactive transport

Participants: Édouard Canot, Jocelyne Erhel, Souhila Sabit, Nadir Soualem.

This work is done in the context of the MOMAS GNR (8.1.1) and the contract with Andra (7.1).

It has been presented at a workshop and a paper is in preparation [33]. The software GRT3D (see section 5.6) is described in a report [48].

We have developed a method coupling transport and chemistry, based on a method of lines such that spatial discretization leads to a semi-discrete system of algebraic differential equations (DAE system). The main advantage is to use a complex DAE solver, which controls simultaneously the timestep and the convergence of Newton nonlinear iterations [53]. Analysis done with several numerical experiments showed that most of CPU time is spent in solving the linear systems of Newton iterations. We have reduced this computational time by reducing the size of the system; numerical experiments with large 2D domains show the efficiency.
6.5. Models and simulations for flow in fractured media

This work is done in collaboration with J.-R. de Dreuzy, from the department of Geosciences at the University of Rennes 1 (who is on leave until 2013 at UPC, Barcelona, Spain). It is done in the context of the Micas project (8.1.2).

A Ph-D thesis was defended this year [13].

6.5.1. Domain decomposition method for flow in 3D networks of fractures

Participants: Jocelyne Erhel, Baptiste Poirriez.

This work was presented at a conference and published in the proceedings of another conference [29], [32]. A paper is in preparation.

This paper aims at solving efficiently the linear system arising from flow computations in Discrete Fracture Networks (DFN). We define a partition of fractures into connected sets and apply a Schur domain decomposition method. Conjugate Gradient is preconditioned by Neumann-Neumann and deflation. Preliminary results with one network show the ability of our method to reduce both the number of iterations and the computational time.

6.5.2. Mortar method for flow in 3D networks of fractures

Participants: Jocelyne Erhel, Géraldine Pichot.

This work is published in a journal [20].

The simulation of flow in fractured media requires handling both a large number of fractures and a complex interconnecting network of these fractures. Networks considered in this paper are 3D domains made up of 2D fractures intersecting each other and randomly generated. Due to the stochastic generation of fractures, intersections can be highly intricate. The numerical method must generate a mesh and define a discrete problem for any Discrete Fracture Network (DFN). A first approach [51] is to generate a conforming mesh and to apply a mixed hybrid finite element method. However the resulting linear system becomes very large when the network contains many fractures. Hence a second approach [52] is to generate a non conforming mesh, using an independent mesh generation for each fracture. Then a Mortar technique applied to the mixed hybrid finite element method deals with the non-matching grids. When intersections do not cross nor overlap, pairwise Mortar relations for each intersection are efficient [52]. But for most of random networks, discretized intersections involve more than two fractures. In this paper, we design a new method generalizing the previous one and applicable for stochastic networks. The main idea is to combine pairwise Mortar relations with additional relations for the overlapping part. This method still ensures the continuity of fluxes and heads and still yields a symmetric positive definite linear system. Numerical experiments show the efficiency of the method applied to complex stochastic fracture networks. We also study numerical convergence when reducing the mesh step. This method makes it easy to perform mesh optimization and appears as a very promising tool to simulate flow in multiscale fracture networks.

6.6. Uncertainty quantification in hydrogeology

This work is done in collaboration with A. Debussche, from ENS-Cachan-Rennes and Ipso INRIA team. It is done in the context of the Micas project (8.1.2).

A PhD thesis was defended this year [11].

6.6.1. Strong and weak error estimates for elliptic partial differential equations with random coefficients

Participant: Julia Charrier.

This work has been presented at a workshop and is published in a journal [23], [14].
We consider the problem of numerically approximating the solution of an elliptic partial differential equation with random coefficients and homogeneous Dirichlet boundary conditions. We focus on the case of a lognormal coefficient, we have then to deal with the lack of uniform coercivity and uniform boundedness with respect to the randomness. This model is frequently used in hydrogeology. We approximate this coefficient by a finite dimensional noise using a truncated Karhunen-Loève expansion. We give then estimates of the corresponding error on the solution, both a strong error estimate and a weak error estimate, that is to say an estimate of the error committed on the law of the solution. We obtain a weak rate of convergence which is twice the strong one. Besides this, we give a complete error estimate for the stochastic collocation method in this case, where neither coercivity nor boundedness are stochastically uniform. To conclude, we apply these results of strong and weak convergence to two classical cases of covariance kernel choices: the case of an exponential covariance kernel on a box and the case of an analytic covariance kernel, yielding explicit weak and strong convergence rates.

6.6.2. Numerical analysis of a multilevel Monte Carlo method for elliptic PDEs with random coefficients
Participant: Julia Charrier.

This work has been presented at a conference and is submitted in a journal [42], [22].

We consider a finite element approximation of elliptic partial differential equations with random coefficients. Such equations arise, for example, in uncertainty quantification in subsurface flow modelling. Models for random coefficients frequently used in these applications, such as log-normal random fields with exponential covariance, have only very limited spatial regularity, and lead to variational problems that lack uniform coercivity and boundedness with respect to the random parameter. In our analysis we overcome these challenges by a careful treatment of the model problem almost surely in the random parameter, which then enables us to prove uniform bounds on the finite element error in standard Bochner spaces. These new bounds can then be used to perform a rigorous analysis of the multilevel Monte Carlo method for these elliptic problems that lack full regularity and uniform coercivity and boundedness. To conclude, we give some numerical results that confirm the new bounds.

6.6.3. Numerical analysis of the advection-diffusion of a solute in random media
Participant: Julia Charrier.

This work is submitted in a journal [41].

We consider the problem of numerically approximating the solution of the coupling of the flow equation in a random porous medium, with the advection-diffusion equation. More precisely, we present and analyse a numerical method to compute the mean value of the spread of a solute introduced at the initial time, and the mean value of the macro-dispersion, defined at the temporal derivative of the spread. We propose a Monte-Carlo method to deal with the uncertainty, i.e. with the randomness of the permeability field. The flow equation is solved using finite element. The advection-diffusion equation is seen as a Fokker-Planck equation, and its solution is approximated thanks to a probabilistic particular method. The spread is indeed the expected value of a function of the solution of the corresponding stochastic differential equation, and is computed using an Euler scheme for the stochastic differential equation and a Monte-Carlo method. Error estimates on the mean spread and on the mean dispersion are established, under various assumptions, in particular on the permeability random field.

6.6.4. Model reduction for a 1D stochastic elliptic PDE
Participants: Jocelyne Erhel, Mestapha Oumouni.

This work is done in collaboration with Z. Mghazli, from the university of Kenitra, Morocco, in the context of the Co-Advise and Hydromed projects (8.2.1, 8.3.4).

This work has been presented at a conference and published in a journal [15] [34].
In this paper, we present an efficient method to approximate the expectation of the response of a one-dimensional elliptic problem with stochastic inputs. In conventional methods, the computational effort and cost of the approximation of the response can be dramatic. Our method presented here is based on the Karhunen–Loève (K-L) expansion of the inverse of the diffusion parameter, allowing us to build a base of random variables in reduced numbers, from which we construct a projected solution. We show that the expectation of this projected solution is a good approximation, and give an a priori error estimate. A numerical example is presented to show the efficiency of this approach.

6.6.5. Inverse problems in hydrogeology

Participant: Sinda Khalfallah.

This work is done in collaboration with A. ben Abda, from LAMSIN, Tunisia, in the context of the Hydromed and Co-Advise projects (8.2.1, 8.3.4). It is also done in collaboration with B. T. Johansson, from University of Birmingham, GB.

This work has been submitted to a journal [40].

This work is an initial study of a numerical method for identifying multiple leak zones in saturated unsteady flow. Using the conventional saturated groundwater flow equation, the leak identification problem is modelled as a Cauchy problem for the heat equation and the aim is to find the regions on the boundary of the solution domain where the solution vanishes, since leak zones corresponds to null pressure values. To reconstruct the solution to the Cauchy problem in a stable way, we modify and employ an iterative regularizing method proposed recently. In this method, one solves mixed well-posed problems (obtained by changing the boundary conditions) for the heat operator as well as for its adjoint, to get a sequence of approximations to the original Cauchy problem. The mixed problems are solved using a Finite element method (FEM), and the numerical results obtained show that the leak zones can be accurately identified also when there is noise in the data.
6. New Results

6.1. Real Solving Polynomial Systems

In [20], we describe an algorithm (VQE) for a variant of the real quantifier elimination problem (QE). The variant problem requires the input to satisfy a certain extra condition, and allows the output to be almost equivalent to the input. The motivation/rationale for studying such a variant QE problem is that many quantified formulas arising in applications do satisfy the extra conditions. Furthermore, in most applications, it is sufficient that the output formula is almost equivalent to the input formula. The main idea underlying the algorithm is to substitute the repeated projection step of CAD by a single projection without carrying out a parametric existential decision over the reals. We find that the algorithm can tackle important and challenging problems, such as numerical stability analysis of the widely-used MacCormack’s scheme. The problem has been practically out of reach for standard QE algorithms in spite of many attempts to tackle it. However the current implementation of VQE can solve it in about 12 hours. This paper extends the results reported at the conference ISSAC 2009.

We also focused on the interaction of real solving polynomial system with global optimization. Let \( f \in \mathbb{Q}[X_1, ..., X_n] \) of degree \( D \). Algorithms for solving the unconstrained global optimization problem \( f^\mathbb{R} = \inf_{x \in \mathbb{R}^n} f(x) \) are of first importance since this problem appears frequently in numerous applications in engineering sciences. This can be tackled by either designing appropriate quantifier elimination algorithms or by certifying lower bounds on \( f^\mathbb{R} \) by means of sums of squares decompositions but there is no efficient algorithm for deciding if \( f^\mathbb{R} \) is a minimum. The paper [41] is dedicated to this important problem. We design an algorithm that decides if \( f^\mathbb{R} \) is reached over \( \mathbb{R}^n \) and computes a point \( x^\mathbb{R} \in \mathbb{R}^n \) such that \( f(x^\mathbb{R}) = f^\mathbb{R} \) if such a point exists. If \( L \) is the length of a straight-line program evaluating \( f \), a probabilistic version of the algorithm runs in time \( \tilde{O}(n^2(L + n^2)(D(D - 1)^{n-1})) \). Experiments show its practical efficiency.

Global optimization problems can also be tackled by computing algebraic certificates of positivity through sums of squares decompositions. Let \( f_1, \ldots, f_p \) and \( f \) be polynomials in \( \mathbb{Q}[X_1, \ldots, X_n] \) and let \( V = V(f_1, \ldots, f_p) \subset \mathbb{C}^n \) be the algebraic variety defined by \( f_1 = \cdots = f_p = 0 \) whose dimension is denoted by \( d \). Assume in the sequel that the ideal \( \langle f_1, \ldots, f_p \rangle \) is radical and equidimensional and that \( V \) is smooth. In [18], up to a generic linear change of variables, we construct families of polynomials \( M_0, \ldots, M_d \) in \( \mathbb{Q}[X_1, \ldots, X_n] \) such that \( f(x) \geq 0 \) for all \( x \in V \cap \mathbb{R}^n \) if and only if \( f \) can written as a sum of squares of polynomials in \( \mathbb{R}[X_1, \ldots, X_n] \) modulo \( \langle M_i \rangle \) for \( 0 \leq i \leq d \). Such an algebraic certificate of positivity is simpler than the more general Positivstellensatz in Real Algebra. It can be used to certify lower bounds on \( f^\mathbb{R} = \inf_{x \in V \cap \mathbb{R}^n} f(x) \). Also, computing a numerical approximation of such certificates of positivity can be reformulated as a semidefinite program which can be solved efficiently. We provide numerical experiments showing the effectiveness of our approach.

In [25], we consider the problem of constructing roadmaps of real algebraic sets. This problem was introduced by Canny to answer connectivity questions and solve motion planning problems. Given \( s \) polynomial equations with rational coefficients, of degree \( D \) in \( n \) variables, Canny’s algorithm has a Monte Carlo cost of \( s^d \log(s)D^{O(n^2)} \) operations in \( \mathbb{Q} \); a deterministic version runs in time \( s^d \log(s)D^{O(n^2)} \). A subsequent improvement was due to Basu, Pollack and Roy, with an algorithm of deterministic cost \( s^{d+1}D^{O(n^2)} \) for the more general problem of computing roadmaps of a semi-algebraic set \( (d \leq n \text{ is the dimension of an associated object}) \). We give a probabilistic algorithm of complexity \( (nD)^{O(n^{1.5})} \) for the problem of computing a roadmap of a closed and bounded hypersurface \( V \) of degree \( D \) in \( n \) variables, with a finite number of singular points. Even under these extra assumptions, no previous algorithm featured a cost better than \( D^{O(n^2)} \).
6.2. Zero dimensional Solve

Let $I \subset \mathbb{K}[x_1, \ldots, x_n]$ be a 0-dimensional ideal of degree $D$ where $\mathbb{K}$ is a field. It is well-known that obtaining efficient algorithms for change of ordering of Gröbner bases of $I$ is crucial in polynomial system solving. Through the algorithm FGLM, this task is classically tackled by linear algebra operations in $\mathbb{K}[x_1, \ldots, x_n]/I$.

With recent progress on Gröbner bases computations, this step turns out to be the bottleneck of the whole solving process.

In [38], we present an efficient algorithm that takes advantage of the sparsity structure of multiplication matrices appearing during the change of ordering. This sparsity structure arises even when the input polynomial system defining $I$ is dense. As a by-product, we obtain an implementation which is able to manipulate 0-dimensional ideals over a prime field of degree greater than 30000. It outperforms the Magma/Singular/FGb implementations of FGLM.

In [38], we investigate the particular but important shape position case. The obtained algorithm performs the change of ordering within a complexity $O(D(N_1 + n \log (D)))$, where $N_1$ is the number of nonzero entries of a multiplication matrix (the density of the matrix). This almost matches the complexity of computing the minimal polynomial of one multiplication matrix. Then, we address the general case and give corresponding complexity results. Our algorithm is dynamic in the sense that it selects automatically which strategy to use depending on the input. Its key ingredients are the Wiedemann algorithm to handle 1-dimensional linear recurrence (for the shape position case), and the Berlekamp–Massey–Sakata algorithm from Coding Theory to handle multi-dimensional linearly recurring sequences in the general case.

6.3. Solving structured systems

Solving multihomogeneous systems, as a wide range of structured algebraic systems occurring frequently in practical problems, is of first importance. Experimentally, solving these systems with Gröbner bases algorithms seems to be easier than solving homogeneous systems of the same degree. Nevertheless, the reasons of this behaviour are not clear. In [16], we focus on bilinear systems (i.e. bihomogeneous systems where all equations have bidegree $(1,1)$). Our goal is to provide a theoretical explanation of the aforementioned experimental behaviour and to propose new techniques to speed up the Gröbner basis computations by using the multihomogeneous structure of those systems. The contributions are theoretical and practical.

First, we adapt the classical $F_5$ criterion to avoid reductions to zero which occur when the input is a set of bilinear polynomials. We also prove an explicit form of the Hilbert series of bihomogeneous ideals generated by generic bilinear polynomials and give a new upper bound on the degree of regularity of generic affine bilinear systems. This leads to new complexity bounds for solving bilinear systems. We propose also a variant of the $F_5$ Algorithm dedicated to multihomogeneous systems which exploits a structural property of the Macaulay matrix which occurs on such inputs. Experimental results show that this variant requires less time and memory than the classical homogeneous $F_5$ Algorithm. Lastly, we investigate the complexity of computing a Gröbner basis for the grevlex ordering of a generic 0-dimensional affine bilinear system over $\mathbb{K}[x_1, \ldots, x_n, y_1, \ldots, y_m]$. In particular, we show that this complexity is upper bounded by $O\left(\left(\frac{n_x + n_y + \min(n_x + 1, n_y + 1)}{\min(n_x + 1, n_y + 1)}\right)^N\right)$, which is polynomial in $n_x + n_y$ (i.e. the number of unknowns) when $\min(n_x, n_y)$ is constant.

6.4. Structured Systems and Applications to Cryptanalysis

The Goppa Code Distinguishing (GCD) problem consists in distinguishing the matrix of a Goppa code from a random matrix. Up to now, it is widely believed that the GCD problem is a hard decisional problem. In [36], we present the first technique allowing to distinguish alternant and Goppa codes over any field. Our technique can solve the GCD problem in polynomial-time provided that the codes have rates sufficiently large. The key ingredient is an algebraic characterization of the key-recovery problem which reduces to the solving of a system of bi-homogeneous polynomial equations. The idea is to consider the dimension of the solution space of a linearized system deduced from the algebraic system describing the key-recovery. It turns
out that experimentally this dimension depends on the type of code. Explicit formulas derived from extensive experimentations for the value of the dimension are provided for “generic” random, alternant, and Goppa code over any alphabet. Finally, we give explanations of these formulas in the case of random codes, alternant codes over any field and binary Goppa codes.

6.5. Algebraic Cryptanalysis

The Isomorphism of Polynomials (IP) is one of the most fundamental problems in multivariate public key cryptography (MPKC). In In [23], we introduce a new framework to study the counting problem associated to IP. Namely, we present tools of finite geometry allowing to investigate the counting problem associated to IP. Precisely, we focus on enumerating or estimating the number of isomorphism equivalence classes of homogeneous quadratic polynomial systems. These problems are equivalent to finding the scale of the key space of a multivariate cryptosystem and the total number of different multivariate cryptographic schemes respectively, which might impact the security and the potential capability of MPKC. We also consider their applications in the analysis of a specific multivariate public key cryptosystem. Our results not only answer how many cryptographic schemes can be derived from monomials and how big the key space is for a fixed scheme, but also show that quite many HFE cryptosystems are equivalent to a Matsumoto-Imai scheme.

In [34], we present a practical cryptanalysis of the Identification Scheme proposed by Patarin at Crypto 1996. This scheme relies on the hardness of the Isomorphism of Polynomial with One Secret (IP1S), and enjoys shorter key than many other schemes based on the hardness of a combinatorial problem (as opposed to number theoretic problems). We present two new deterministic algorithms to attack the IP1S problem, and we rigorously analyze their complexity and success probability. We show that they can solve a constant fraction of all the instances of degree two in polynomial time.

In [33], we investigate the security of a generalization of HFE (multivariate and odd-characteristic variants). We propose an improved version of the basic Kipnis-Shamir key recovery attack against HFE. We then generalize the Kipnis-Shamir attack to Multi-HFE. The attack reduces to solve a MinRank problem directly on the public key. This leads to an improvement of a factor corresponding to the square of the degree of the extension field. We used recent results on MinRank to show that our attack is polynomial in the degree of the extension field. It appears that multi-HFE is less secure than original HFE for equal-sized keys. Finally, adaptations of our attack overcome several variants (i.e. minus modifier and embedding). As a proof of concept, we have practically broken the most conservative parameters given by Chen, Chen, Ding, Werner and Yang in 9 days for 256 bits security. All in all, our results give a more precise picture on the (in)security of several variants of HFE proposed these last years.

In [31], we initiate the formal treatment of cryptographic constructions (“Polly Cracker”) based on the hardness of computing remainders modulo an ideal. We start by formalising and studying the relation between the ideal remainder problem and the problem of computing a Gröbner basis. We show both positive and negative results. On the negative side, we define a symmetric Polly Cracker encryption scheme and prove that this scheme only achieves bounded CPA security under the hardness of the IR problem. Furthermore, we show that a large class of algebraic transformations cannot convert this scheme to a fully secure Polly Cracker-style scheme. On the positive side, we formalise noisy variants of the ideal related problems. These problems can be seen as natural generalisations of the LWE problem and the approximate GCD problem over polynomial rings. After formalising and justifying the hardness of the noisy assumptions we show that noisy encoding of messages results in a fully IND-CPA secure somewhat homomorphic encryption scheme. Together with a standard symmetric-to-asymmetric transformation for additively homomorphic schemes, we provide a positive answer to the long standing open problem of constructing a secure Polly Cracker-style cryptosystem reducible to the hardness of solving a random system of equations. Indeed, our results go beyond that by also providing a new family of somewhat homomorphic encryption schemes based on new, but natural, hard problems. Our results also imply that Regev’s LWE-based public-key encryption scheme is (somewhat) multiplicatively homomorphic for appropriate choices of parameters.
6.6. Computer Algebra and Algorithmic Number Theory

The Elliptic Curve Discrete Logarithm Problem (ECDLP) has become the most attractive alternative to factoring for public key cryptography. Whereas subexponential factoring algorithms exist, solving the ECDLP in general can only be done in exponential time. Provided that a certain heuristic assumption holds, we present in [39] an index calculus algorithm solving ECDLP over any binary field $\mathbb{F}_q$ in time $O(2^{e n^{2/3} \log n})$, where $e$ is a small constant. Our algorithm follows the index calculus method that was first introduced by Semaev and later developed by Gaudry and Diem. In particular, the main step consists in decomposing points of the curve with respect to an appropriately chosen factor basis. This part can be nicely reformulated as a purely algebraic problem consisting in finding solutions to a multivariate polynomial $f(x_1, \ldots, x_m) = 0$ such that all the variables $x_i$ belong to some vector subspace of $\mathbb{F}_q/\mathbb{F}_p$. We solve this problem by means of Gröbner basis techniques and analyse its complexity using the multihomogeneous structure of the equations. Even, if this paper is essentially theoretical and is not aiming for practical attacks, the new ideas developed here could be used to have practical attacks in the future. This of course represents a challenging open problem.
5. New Results

5.1. Languages and Foundations: Process algebra

**Participants:** Damien Pous, Alan Schmitt, Jean-Bernard Stefani, Claudio Mezzina, Cinzia di Giusto.

The goal of this work is to study process algebraic foundations for component-based distributed programming. Most of this work takes place in the context of the ANR PiCoq project.

To develop composable abstractions for programming dependable systems, we investigate concurrent reversible models of computation, where arbitrary executions can be reversed, step by step, in a causally consistent way. This year we have continued the study of the reversible higher-order pi-calculus and obtained a new encoding of it in the higher-order pi-calculus which improves on the result we published in Concur 2010 by proving the faithfulness of the encoding with a much finer equivalence relation. We also developed a reversible variant of the higher-order pi-calculus where reversibility can be controlled by means of an explicit rollback primitive [37]. We have proved that this rollback primitive is sound and complete in that it provides a causally consistent and complete reversal of concurrent computations, and we have developed a low-level semantics for this primitive, closer to an actual distributed implementation, which we have proved equivalent to the high-level one. All these results are presented in detail in Claudio Mezzina’s forthcoming PhD thesis, and have been developed in cooperation with the INRIA Focus team at the University of Bologna.

An interesting and expressive component model for embedded systems is the BIP component model [58], developed by J. Sifakis’ team at the Verimag Laboratory, which features hierarchical software architectures, explicit constructs for specifying component compositions (glues), and multipoint synchronization under priority constraints. We have begun a process calculus analysis of BIP, with a view to combine the reactive features of BIP with the dynamic reconfiguration features of Fractal. Our first result takes the form of new process calculus, called CAB, which we have proved to be a conservative extension of BIP. CAB also enabled us to study the intrinsic expressivity of the BIP model and to prove that priority constraints are essential to BIP expressivity [34].

We have made significant progress on the formalization in the Coq proof assistant of a core higher-order π-calculus, called HOcore [20]. We have in particular adapted a canonical locally nameless representation of binding to handle alpha-conversion in our formalization. Several major theorems of HOcore, in particular the fact that IO-bisimulation is correct in relation to barbed congruence and is decidable. This work has been submitted for publication.

A longer version of our work on untyping theorems and cyclic linear logic has been accepted for publication in LMCS [24], and a book chapter on up-to techniques for bisimulations, written with Davide Sangiorgi from the INRIA Focus team in Bologna, has been published by Cambdridge University Press [46].

Together with Filippo Bonchi (LIP, ENS Lyon), we have worked on a new algorithm for checking the language equivalence of non-deterministic finite automata (NFA). This algorithm improves on the standard Hopcroft and Karp’ algorithm, by using up-to techniques. The first empirical tests look really promising [47].

Together with Tom Hirschowitz (LAMA, U. de Chambéry), we have worked on a categorical model of CCS, where innocent strategies are pre-sheaves. This work has been presented at the ICE workshop [36], and a long version has been submitted to SACS.

5.2. Languages and Foundations: Proof tactics

**Participants:** Damien Pous, Thomas Braibant.
The goal of this work is to develop proof-assistant-based tools for verifying distributed systems and distributed abstract machines. In particular, we aim to support the derivation of fully formal proofs of correctness for abstract machines supporting the component-based languages and programming models we develop.

We have presented our work about tools for rewriting modulo AC in Coq at CPP’11 [32]. An extended version of our work on Kleene algebra (ATBR, first published at ITP’10), was accepted for publication in LMCS [19]. Also on the Coq side, we have developed a library for verifying hardware circuits, which was also presented at CPP’11 [31].

5.3. Control for adaptive systems: Discrete control for adaptive and reconfigurable systems

**Participants:** Eric Rutten, Noël de Palma, Olivier Gruber, Fabienne Boyer, Tayeb Bouhadiba, Xin An.

The goal of this work is to apply control techniques based on the behavioral model of reactive automata and the algorithmic techniques of discrete controller synthesis. We adopt the synchronous approach to reactive systems, and use an associated effective controller synthesis tool, Sigali, developed at INRIA Rennes. Both are integrated into a programming language, called BZR, and its compiler, as an extension of the Heptagon language. We thus have a complete tool-supported method from control modeling down to concrete execution, considering different execution models, and targeting either software or hardware. We explore control theory for computer science, as an original alternative to computer science for control (as more usually in embedded systems), and to classical discrete control systems (as more usually applied to manufacturing). We are exploring several target application domains, where we expect to find commonalities in the control problems, and variations in the definitions of configurations, and in the criteria motivating adaptation.

We have obtained this year the following results:

- At the programming language level, we are continuing the development of a modelling and controller generation language called BZR, which involves DCS in its compilation. BZR is designed and developed in cooperation with the Pop Art and VerTecs (INRIA Rennes) teams [40].
- We have developed a technique for designing reconfiguration controllers in the Fractal component-based framework, where discrete control loops automatically enforce safety properties on the interactions between components, concerning, e.g., mutual exclusions, forbidden or imposed sequences [29] [48].
- We have integrated BZR with Orccad, a programming environment for real-time control systems, in cooperation with the NeCS and SED teams at INRIA Grenoble [28].
- We are investigating administration loops in virtual machine-based distributed systems [44], and the coordination of such loops, especially in relation with green computing problems. We are starting a new ANR project called Ctrl-Green on this topic in 2012.
- We work on the formal modelling and control of dynamic reconfiguration in FPGA circuits, in cooperation with the DaRT team (INRIA Lille) [43] and the Lab-STIC laboratory in Lorient [42], building upon earlier work related to the MARTE framework.
- In cooperation with GIPSA-Lab and ENSI Tunis, we have adapted the discrete controller synthesis technique to the control of decentralized systems that are composed of several subsystems spread across remote sites [17].
- In cooperation with Orange labs and GIPSA-Lab we are beginning to explore the application of discrete event systems and supervisory control to the domain of Machine to Machine and Internet of Things, with the objective to manage energy aspects; this will start with the CIFRE PhD (U. Grenoble) of Mengxuan Zhao (co-advised with H. Alla, G. Privat).

5.4. System configuration and deployment

**Participants:** Loris Bouzonnet, Fabienne Boyer, Willy Malvault, Noël de Palma, Vivien Quéma, Jean-Bernard Stefani.
The goal of this work is to study system configuration and software deployment issues in large distributed systems.

System configuration and software deployment in a distributed environment can be greatly aided by the use of a uniform component model to support software assembly, software configuration and deployment, as well as runtime system configuration. We have developed a specialization of the Fractal component model that provides a reference model for heterogeneous software assembly and configuration. In particular, we have shown how this reference model can be used to assemble and configure software architectures built from heterogeneous software packages (e.g. OSGI bundles for Java packages, Debian or RPM packages for Linux modules and applications). The definition of this model, a description of its implementation and its evaluation are documented in Loris Bouzonnet’s PhD thesis [13].

As an alternative to current public cloud infrastructures, which rely on large data centers, we have started the study of a cloud infrastructure based on a peer-to-peer (P2P) overlay network built on gossip-based protocols. More precisely, we have studied how to implement a distributed resource allocation service in a P2P environment maintained by a gossip-based peer-sampling protocol [81]. The resulting system, called Salute, provides for the allocation of application-specific overlays out of an underlying P2P network. By combining several P2P services (including peer-sampling, topology maintenance, and node synchronization), and by partitioning available nodes into free nodes (available for the allocation of new application overlays) and reserve nodes (nodes dedicated to the maintenance of allocated overlays), Salute provides a churn-resistant, completely decentralized cloud infrastructure. In addition, we have shown that Salute can provide its allocation service while maintaining fairness and avoiding starvation. The Salute architecture has been validated through simulations using network traces from different real-world P2P environments. The Salute architecture, algorithms and their validation are documented in Willy Malvault’s PhD thesis [14].

In a cloud computing context the complexity of deploying and configuring non-trivial software architectures is exacerbated. In line with our previous work on architecture-based distributed system management, we have proposed a novel algorithm for configuring component-based distributed applications deployed within several virtual machines in an IaaS environment. The algorithm is completely decentralized, relies on a message queuing middleware and exploits the software architecture descriptions of the applications to deploy and configure, written in an extension of the Fractal Architecture Description Language. A first version of this algorithm, that does not take into account potential failures during the configuration process, has been formally specified in collaboration with Gwen Salaün from the INRIA Vasy team in Grenoble, and presented at IEEE Cloud 2011 [35].

5.5. System support: System support for multicore machines

Participants: Vivien Quémé, Renaud Lachaize, Fabien Gaud, Baptiste Lepers, Sylvain Genevès, Fabien Mottet.

Multicore machines with Non-Uniform Memory Accesses (NUMA) are becoming commodity platforms. Efficiently exploiting their resources remains an open research problem. Most of the body of existing work focuses on increasing locality between computations and memory or I/O resources. This is achieved by allocating data items preferably in local memory nodes, by moving computations close to I/O devices or by moving already allocated memory pages close to the applications which use them most. In all these works, researchers always assume that all processors have equal memory performance. Nevertheless, this assumption is not always valid. In 2011, we have studied the performance achieved by a 16-core NUMA exhibiting an irregular connectivity between processors. Some processors are directly connected to all other processors and access memory nodes with a low latency. Other processors have a lower degree of connectivity and need more hops to access some memory nodes and access memory with a higher latency.

Current operating systems are not aware of such performance characteristics. We have shown that the completion time of applications taken from the PARSEC benchmark suite can vary by up to 15% depending on the processor they are scheduled on. We have thus proposed a new OS scheduler that takes this asymmetry into account in order to make efficient decisions. This scheduler relies on a new metric, called MAPI (number
of main Memory Accesses Per retired Instruction), to predict the impact of processor interconnect asymmetry on the performance of applications. We have empirically evaluated the relevance of this metric on applications taken from the PARSEC benchmark suite. We have shown that this metric helps estimating the performance gap between running an application on a "well-interconnected" processor and on a "weakly-interconnected" one. Using this metric, the scheduler we proposed makes efficient decisions. More precisely, we have observed that the scheduler always performed within 3% of the best possible scheduling decision. This work is currently under submission.

5.6. System support: Protocols for resilient systems

Participants: Vivien Quéma, Alessio Pace.

We have worked on replication protocols for P2P systems. In particular, we have worked on replication in so called Distributed Hash-Tables (DHTs). DHTs provide a simple high-level put/get abstraction that can be used to build efficient distributed storage systems. DHTs gained wide popularity in the last decade, fostering a large amount of interest in the academia, and inspiring the design of key/value distributed storage systems deployed in production.

DHTs provide a way to deterministically map objects to nodes and allow efficiently retrieving objects in a distributed fashion. Nodes and objects are logically arranged in a large numeric key-space, according to a given variant of consistent hashing. Typically, the node in charge of an object is the one whose position immediately follows the object in the key-space.

To guarantee that objects are reliably stored, DHTs rely on replication. A replication protocol is in charge of ensuring that, at any time, each object is replicated on a sufficiently large number of replicas. Several replication strategies have been proposed in the last years. The most efficient ones use predictions about the availability of nodes to reduce the number of object migrations that need to be performed: objects are preferably stored on highly available nodes.

We have proposed an alternative replication strategy. Rather than exploiting highly available nodes, we have designed a protocol that leverages nodes that exhibit regularity in their connection pattern. Roughly speaking, the strategy consists in replicating each object on a set of nodes that is built in such a way that, with high probability, at any time, there are always at least k nodes in the set that are available. We have evaluated this new replication strategy using traces of two real-world systems: eDonkey and Skype. Our evaluation showed that our regularity-based replication strategy induces a systematically lower network usage than existing state of the art replication strategies. This work has been published at the International Symposium on Reliable Distributed Systems, in October 2011.

5.7. System support: End-to-end caching

Participants: Sara Bouchenak, Damian Serrano.

Cloud Computing is a paradigm for enabling remote, on-demand access to a virtually infinite set of configurable computing resources. This model aims to provide hardware and software services to customers, while minimizing human efforts in terms of service installation, configuration and maintenance, for both cloud provider and cloud customer. A cloud may have the form of an Infrastructure as a Service (IaaS), a Platform as a Service (PaaS) or a Software as a Service (SaaS). Clouds pose significant challenges to the full elasticity of clouds, their scalability and their dependability in large scale data management and large scale computing resources. Caching is a means for high performance and scalability of distributed systems. Although caching solutions have been successfully studied for individual systems such as database systems or web servers, if collectively applied, these solutions violate the coherence of cached data. We precisely studied this issue in e-Caching, a novel end-to-end caching system.

The contribution of this work is twofold: guaranteeing the coherence of cached data at multiple locations of a distributed system, while improving the overall performance of the system. In collaboration with Marta Patino and Ricardo Jimenez from Universidad Politecnica de Madrid, we proposed a novel distributed caching protocol, implemented it and evaluated it with real online services. The experiments showed that e-Caching was successfully able to improve service performance by two orders of magnitude.
This work has been presented at CFSE, the French Chapter of ACM-SIGOPS in May 2011. An extended version has been submitted for publication in a journal.

5.8. System support: Performance and dependability benchmarking

Participants: Amit Sangroya, Dàmian Serrano, Sara Bouchenak [correspondant].

MapReduce has become a popular programming model and runtime environment for developing and executing distributed data-intensive and compute-intensive applications. It offers developers a means to transparently handle data partitioning, replication, task scheduling and fault tolerance on a cluster of commodity computers. MapReduce allows a wide range of applications such as log analysis, data mining, Web search engines, scientific computing, bioinformatics, decision support and business intelligence.

There has been a large amount of work on MapReduce towards improving its performance and reliability. Several efforts have explored task scheduling policies in MapReduce, cost-based optimization techniques, replication and partitioning policies. There has also been a considerable interest in extending MapReduce with other fault tolerance models, or with techniques from database systems. However, there has been very little in the way of empiric evaluation for the comparison of the different systems. Most evaluations of these systems have relied on microbenchmarks based on simple MapReduce programs. While microbenchmarks may be useful in targeting specific system features, they are not representative of full distributed applications, and they do not provide multi-user realistic workloads. Furthermore, as far as we know, no studies have investigated dependability benchmarking of MapReduce.

Thus, we provide MapReduce Benchmarking (MRB), a novel MapReduce benchmark suite to enable a thorough analysis of a wide range of features of MapReduce systems. MRB has the following features. First, it enables the empirical evaluation of the performance and dependability of MapReduce systems. This provides a means to analyze the effectiveness of scalability and fault tolerance, two key features of MapReduce. Second, it covers a variety of application domains, workload and faultload characteristics, ranging from compute-oriented to data-oriented applications, batch applications to online real-time applications. While MapReduce frameworks were originally limited to offline batch processing, recent works are exploring the extension of MapReduce beyond batch processing. Moreover, in order to stress MapReduce dependability and performance, the benchmark suite enables different fault injection rates, workloads and concurrency levels. Finally, the benchmark suite is portable and easy to use on a wide range of platforms, covering different MapReduce frameworks and cloud infrastructures. This work has been submitted for publication.

5.9. System support: Self-adaptive Internet services

Participant: Sara Bouchenak.

Although distributed services provide a means for supporting scalable Internet applications, their ad-hoc provisioning and configuration pose a difficult tradeoff between service performance and availability. This is made harder as Internet service workloads tend to be heterogeneous, and vary over time in amount of concurrent clients and in mixture of client interactions. This work proposes an approach for building self-adaptive Internet services through utility-aware capacity planning and provisioning. First, an analytic model is presented to predict Internet service performance, availability and cost. Second, a utility function is defined and a utility-aware capacity planning method is proposed to calculate the optimal service configuration which guarantees SLA performance and availability objectives while minimizing functioning costs. Third, an adaptive control method is proposed to automatically apply the optimal configuration to the Internet service. Finally, the proposed model, capacity planning and control methods are implemented and applied to an online bookstore. Experimental evaluations show that the service successfully self-adapts to both workload mix and workload amount variations, and present significant benefits in terms of performance and availability, with a saving of resources underlying the Internet service.

This work is part of the MyCloud ANR project. It has been described in a chapter of the book titled Performance and Dependability in Service Computing, 2011. There has been an industrial transfer of the MOKA software prototype.
5.10. Self-Configuration of distributed system in the Cloud

Participants: Fabienne Boyer, Noël de Palma.

Cloud computing environments fall under three main kinds of offers according to the resources they provide. The Infrastructure as a Service (IaaS) level enables the access to virtualized hardware resources (processing, storage and network). The Software as a Service (SaaS) layer aims at providing the end-users with software applications. The intermediary layer, called Platform as a Service (PaaS), offers a set of tools and runtime environments that allow managing the applications life-cycle. This life-cycle includes the phases related to the design, the development, the deployment of applications, and generally speaking all their management stages (workload, fault tolerance, security). This article focuses on the deployment of distributed applications in virtualized environments such as cloud computing. Such deployments require to generate the virtual images that will be instantiated as virtual machines, thus ensuring the execution of the application on an IaaS platform. Each image embeds technical elements (operating system, middleware pieces) and functional ones (data and applicative software entities). Once it has been instantiated, each virtual machine is subjected to a stage of dynamic settings, which finalizes the global configuration of the distributed application.

On the whole, the deployment solutions currently available do not take into account these different configuration parameters, which are mostly managed by dedicated scripts. Moreover these solutions are not able to automate the images generation, their instantiation as virtual machines and their configuration independently from the kind of distributed application to be deployed. For instance, Google App Engine solution only deals with Web services organized into precisely defined tiers. In our opinion, the absence of general solutions results essentially from a lack of formalism for describing the distributed application architecture with its configuration constraints in a virtualized infrastructure such as cloud computing. Our work focused on a general solution, for Virtual Applications Management Platform, that automates the deployment of any distributed applications in the cloud. The suggested approach is architectural, meaning that it is based upon an explicit representation of the applications’ distributed architecture. We offer, on the one hand, a formalism for describing an application as a set of interconnected virtual machines and, on the other hand, an engine for interpreting this formalism and automating the application deployment on an IaaS platform. Specifically, we study three contributions:

- A formalism that offers a global view of the application to be deployed in terms of components with the associated configuration- and interconnection constraints and with their distribution within virtual machines. This formalism extends OVF language, dedicated to virtual machines description, with an architecture description language (ADL) that allows describing a distributed application software architecture;

- A deployment engine, i.e. a runtime support able to deploy automatically an application described with this formalism. This engine is based on a decentralized protocol for self-configuring the instantiated virtual machines. In our opinion it can ease the scalability of the dynamic configuration stage;

- A performance evaluation of the proposed solution on an industrial IaaS platform.

We published in this context two journal articles (TPDS [26] and TAAS [18]) and three conference papers (Cloud11 [35], UCC11 [39] and SAC12).

5.11. Virtual Machine

Participants: Olivier Gruber, Fabienne Boyer, Damien Pous, Ludovic Demontes, Clément Deschamps.

A core aspect of the Synergy virtual machine is its ability to reconfigure component-based applications at execution time. We have focused on the reconfiguration protocol with the intent of verifying and proving its robustness.
In a first step, we have formalized and verified that any correct and complex reconfiguration through our reconfiguration protocol can be processed as a sequence of elementary reconfiguration operations and always results in a component assembly that is architecturally consistent. This aspect has been verified using model-checking techniques. This work has been done in collaboration with Gwen Salaün from the VASY team (Inria Rhône-Alpes). It lead to a publication in the Formal Method (FM’11) conference [30].

In a second step, we have considered software failures that may occur during a reconfiguration. Although the protocol is trusted code, it invokes components to reconfigure them, thereby executing unsafe code that may fail. This work with Damien Pous produced a high-level formalisation of our reconfiguration protocol and a completely certified modelisation of these algorithms in Coq [50]. This work resulted in a submitted publication.

Finally, we have also investigated the control of complex reconfiguration through using discrete synchronous control techniques with Eric Rutten and Gwenael Delaval [44].
6. New Results

Processes have received a lot of attention in the last decade and proposed workflow solutions for office automation. The topic is subject today to a lot of interests carried by the expansion of business on the Web. However it is required need to satisfy new application requirements and execution contexts. We are interested in different aspects of process engineering: the management of change in business process; modeling and implementing Quality of Services properties (time, security, constraints...); composing existing process fragments of different nature and models; decentralizing a global process for a distributed execution with organizational constraints; process governance. Most of these aspects are considered within the frame of Web services and/or peer to peer architectures, and we are also interested in proposing new models of process for new applications domains.

6.1.1. Optimized decentralization and synchronization of cross-organizational business processes

Participants: Claude Godart, Walid Fdhila.

Globalization and the increase of competitive pressures created the need for agility in business processes, including the ability to outsource, offshore, or otherwise distribute its once-centralized business processes or parts thereof. While hampered thus far by limited infrastructure capabilities, the increase in bandwidth and connectivity and decrease in communication cost have removed these limits. An organization that aims for such fragmentation of its business processes needs to be able to separate the process into different parts. Therefore, there is a growing need for the ability to fragment one’s business processes in an agile manner, and be able to distribute and wire these fragments so that their combined execution recreates the function of the original process. Additionally, this needs to be done in a networked environment, which is where Service Oriented Architecture plays a vital role.

Our work is focused on solving some of the core challenges resulting from the need to dynamically restructure enterprise interactions. Restructuring such interactions corresponds to the fragmentation of intra and inter enterprise business process models. It describes how to identify, create, and execute process fragments without loosing the operational semantics of the original process models. It also proposes methods to optimize the fragmentation process in terms of QoS properties and communication overhead [21], [10]. Moreover, it presents a framework to model web service choreographies in Event Calculus formal language.

Walid Fdhila has successfully defended his thesis on October, 7th [1].

6.1.2. A Declarative Approach to Web Services Computing

Participants: Olivier Perrin, Ehtesham Zahoor, Claude Godart.

Web services composition and monitoring are still highly active and widely studied research directions. Little work however has been done in integrating these two dimensions using an unified framework and formalism. Classical approaches introduce an additional layer for handling the composition monitoring and thus do not provide the important execution time violations feedback to the composition process. This year, we proposed the DISC framework which aims to provide a highly declarative event-oriented model to accommodate various aspects such as composition design and exceptions, data relationships and constraints, business calculations and decisions, compliance regulations, security or temporal requirements. Then, the same model is used for combining the control of the composition definition, its execution and the composition monitoring. We proposed a service oriented architecture with a flexible logic, including complex event patterns and choreographies, business oriented rules, and dynamic control of compositions. Advantages of this unified framework are the higher level of abstraction to design, execute, and reason upon a composition, the flexibility
of the approach, and the ability to easily include non-functional requirements such as temporal or security
issues and we implement the DISC framework using the Discrete Event Calculus reasoner. Ehtesham Zahoor
defended his thesis in November [3], and had presented the DISC framework at ICWS 2011 [20].

We also continued the previous work initiated within the Associate Team INRIA VanaWeb about the
provisioning of Web services composition using constraints solvers. The approach consists in instantiating
this abstract representation of a composite Web service by selecting the most appropriate concrete Web
services. This instantiation is based on constraint programming techniques which allow matching Web services
according to a given request. The proposal performs this instantiation in a distributed manner, i.e., the solvers
for each service type are solving some constraints at one level, and they are forwarding the rest of the request
(modified by the local solution) to the next services. When a service cannot provision part of the composition,
a distributed backtrack mechanism enables to change previous solutions (i.e., provisions). A major interest of
this approach is to preserve privacy: solutions are not sent to the whole composition, services know only the
services to which they are connected, and parts of the request that are already solved are removed from the
next requests.

6.1.3. Alignment between Business Process and Service Architecture
Participants: François Charoy, Karim Dahman, Claude Godart.

In the continuation of work done previously on change management during process execution, we are
conducting work on the governance of change at the business level and on its implications at the architecture
and infrastructure level of an information system. Last year was devoted to the definition of the transformation
rules that allowed to go from a business model to an IT model, i.e. a transformation between model based
on different paradigms. During this year, a great deal of effort has been done in order to extend our work on
Business to IT alignment management. Our goal is still to maintain this alignment at the lowest possible cost
when the business process are changing [9]. Further than that we are trying to describe and validated an
engineering method to help designer to maintain this alignment [8].

6.1.4. Distributed Processes with Security Constraints
Participants: Olivier Perrin, Aymen Baouab, Claude Godart.

Distributed processes governance is a very important challenge. In the past, we proposed various approaches
for dealing with distribution, particularly for computing a set of sub-processes that can be distributed and that
are equivalent to a given process. However, we did not deal with non-functional requirements as the focus
was only on control and data flows. In this work, we try to deal not only with functional requirements, but
also with non-functional requirements, in particular the security aspects. With Aymen Baouab, we already
proposed an event-based approach that is able to verify that choreographies are valid with respect to given
constraints (security constraints for instance) [7].

6.1.5. A Crisis Management Process Model
Participants: François Charoy, Joern Franke.

As said before, crisis management has been a very fruitful domain to investigate new approaches in the domain
of high value, human driven activity coordination in a multi organisational setting. Our work benefits from a
large amount of use cases and detailed accounts of previous dramatic events to analyze requirements and
confront our proposals. 2011 has been devoted to terminate the evaluation and the validation of the model that
we have defined during the previous years. It has also been devoted to complete the work done in the previous
years on the inter organisational dimension of the coordination management [11]. The entire contribution on
crisis management, i.e. the model, the system and the evaluation are described in Joern Franke PhD document [2]

In order to try to leverage this work in a more information system oriented way, we have started some
collaboration to confront our view on coordination with existing reference model for humanitarian operations[12]. We are currently looking for alternative financing vehicle in order to continue this work.
6.2. Distributed Collaborative Systems

Starting with Web2.0 era, the web became easily writable and changeable, and nowadays, it is getting more real-time. Rather than requiring that users or their software check a source periodically for updates, real-time web is a paradigm based on the principle of pushing information to users as soon as it is available. We are faced with an explosion of real-time social software (Twitter, Facebook, etc.). Even if many social software are currently available, most of them rely on collaborative systems with a centralized architecture or authority and consequently suffer of intrinsic problems of centralization: lack of fault tolerance, poor scalability, costly infrastructure, problems of privacy.

Distributed collaborative systems (DCS) ease and coordinate collaboration among multiple users who jointly fulfill common tasks over computer networks without the need of a central architecture or authority.

We continued our work on migrating DCS to pure peer-to-peer architectures. This year we focussed on the real-time aspect of the collaboration. We evaluated replication mechanisms suitable for real-time collaboration over peer-to-peer architectures.

Moreover, peer-to-peer collaborative systems need revisiting traditional security models that prevent users from accessing to data and granted rights are checked before access is allowed. These access control mechanisms are too strict and they do not scale well in a peer-to-peer architecture. We make the assumption that an effective collaboration should rely on a flexible optimistic security model based on trust. This year we proposed a new collaboration model based on contracts where we rely on an optimistic security model. Rather than adopting an a priori strict enforcement of security rules, in this optimistic solution, access is given first to data without control but with restrictions that are verified a posteriori.

6.2.1. Evaluation of algorithms for Peer-to-Peer Real-time collaboration

Participants: Mehdi Ahmed-Nacer, Claudia Ignat, Gérald Oster, Hyun-Gul Roh, Pascal Urso.

Nowadays, real-time collaborative editing systems such as Etherpad or Google Docs became very popular. The operational transformation (OT) approach is a traditional optimistic replication mechanism that was used for real-time collaboration. Recently, Commutative Replicated Data Types (CRDTs) were introduced as a new class of replication mechanisms whose concurrent operations are designed to be natively commutative. CRDTs, such as WOOT, Logoot, Treedoc, and RGAs, are expected to be substitutes of replication mechanisms in collaborative editing systems.

We investigated the suitability of CRDTs for real-time collaborative editing [6]. To reflect the tendency of decentralized collaboration, which can resist censorship, tolerate failures, and let users have control over documents, we collect editing logs from real-time peer-to-peer collaborations. We provided a theoretical evaluation as well as an experimental one by replaying the editing logs on various CRDTs and OT algorithms implemented in the same environment. We found out that CRDT algorithms initially designed for peer-to-peer asynchronous collaboration are suitable for real-time collaboration. Moreover, they outperform some representative operational transformation approaches that were well established for real-time collaboration in terms of generation time, remote integration time and space complexity.

6.2.2. Contract-based collaboration

Participants: Claudia Ignat, Hien Thi Thu Truong.

In the push-pull-clone collaborative editing model widely used in distributed version control systems users replicate shared data, modify it and redistribute modified versions of this data without the need of a central authority. However, in this model no usage restriction mechanism is proposed to control what users can do with the data after it has been released to them. We extended the push-pull-clone model with contracts that express usage restrictions and that are checked a posteriori by users when they receive the modified data [18], [25]. We proposed a merging algorithm that deals not only with modifications on data but also with contracts. A
log-auditing protocol [19] was used to detect users who do not respect contracts after they received data and to adjust user trust levels. The associated trust values can be computed by using any existing decentralised trust model. Our proposed contract-based model has been implemented and evaluated by using PeerSim simulator.

6.3. Interoperability and Enterprise Modeling

Participants: Nacer Boudjlida [contact], Khalid Benali.

In the continuation of our previous work on semantic-based and model-based solutions for interoperability, we applied and experienced a variety of semantic annotation types (structural, terminological and behavioral) in the frame of dynamic web services discovery and for competence management systems. In addition, we explored semantic graphs as a formal framework for competence description and management. Further, in order to ease semantic interoperability of heterogeneous competence management systems, we are defining a generic representation model that could serve as a shared ontology for these types of systems.
5. New Results

5.1. Symmetric cryptosystems

Participants: Céline Blondeau, Christina Boura, Baudoin Collard, Anne Canteaut, Pascale Charpin, Stéphane Jacob, Gohar Kyureghyan.

From outside, it might appear that symmetric techniques become obsolete after the invention of public-key cryptography in the mid 1970's. However, they are still widely used because they are the only ones that can achieve some major features as high-speed or low-cost encryption, fast authentication, and efficient hashing. Today, we find symmetric algorithms in GSM mobile phones, in credit cards, in WLAN connections. Symmetric cryptology is a very active research area which is stimulated by a pressing industrial demand for low-cost implementations (in terms of power consumption, gate complexity...). These extremely restricting implementation requirements are crucial when designing secure symmetric primitives and they might be at the origin of some weaknesses. Actually, these constraints seem quite incompatible with the rather complex mathematical tools needed for constructing a provably secure system.

The specificity of our research work is that it considers all aspects of the field, from the practical ones (new attacks, concrete specifications of new systems) to the most theoretical ones (study of the algebraic structure of underlying mathematical objects, definition of optimal objects). But, our purpose is to study these aspects not separately but as several sides of the same domain. Our approach mainly relies on the idea that, in order to guarantee a provable resistance to the known attacks and to achieve extremely good performance, a symmetric cipher must use very particular building blocks, whose algebraic structures may introduce unintended weaknesses. Our research work captures this conflict for all families of symmetric ciphers. It includes new attacks and the search for new building blocks which ensure both a high resistance to the known attacks and a low implementation cost. This work, which combines cryptanalysis and the theoretical study of discrete mathematical objects, is essential to progress in the formal analysis of the security of symmetric systems.

In this context, the very important challenges are the designs of low-cost ciphers and of secure hash functions. Most teams in the research community are actually working on the design and on the analysis (cryptanalysis and optimization of the performance) of such primitives.

5.1.1. Hash functions.

Following the recent attacks against almost all existing hash functions (MD5, SHA-0, SHA-1...), we have initiated a research work in this area, especially within the Saphir-2 ANR project and with several PhD theses. Our work on hash functions is two-fold: we have designed two new hash functions, named FSB and Shabal, which have been submitted to the SHA-3 competition, and we have investigated the security of several hash functions, including the previous standards (SHA-0, SHA-1...) and some other SHA-3 candidates.

Recent results:

- study of the algebraic properties of the recent hash function proposals, including the SHA-3 candidates Keccak and Luffa. This work includes a theoretical study of the algebraic degree of iterated functions composed of parallel applications of a smaller function [24].
- Upper bounds on the degree of an iterated permutation from the degree of the inverse of the inner transformation; this result has been applied both to hash functions and to block ciphers [31], [44].

5.1.2. Stream ciphers.

Our research work on stream ciphers is a long-term work which has been developed within the 4-year ANR RAPIDE project. It includes an important cryptanalytic effort on stream ciphers.
Recent results:
- Evaluation of the bias of parity-check relations in the context of cryptanalysis of combination generators with constituent devices which generate period sequences [13].
- Cryptanalysis of the recent stream cipher proposal Armadillo [21].

5.1.3. Block ciphers.
Even if the security of the current block cipher standard, AES, is not threatened when it is used in a classical context, there is still a need for the design of improved attacks, and for the determination of design criteria which guarantee that the existing attacks do not apply. This notably requires a deep understanding of all previously proposed attacks.

Recent results:
- Differential cryptanalysis with multiple differentials, multiple differential cryptanalysis on the lightweight block cipher Present [23].
- Use of tools from error correcting theory in linear cryptanalysis [36].
- Determination of the data complexity (i.e., of the required number of plaintexts-ciphertexts) and of the success probability of all statistical attacks against block ciphers [12].

5.1.4. Cryptographic properties and construction of appropriate building blocks.
The construction of building blocks which guarantee a high resistance to the known attacks is a major topic within our project-team, for stream ciphers, block ciphers and hash functions. The use of such optimal objects actually leads to some mathematical structures which may be the origin of new attacks. This work involves fundamental aspects related to discrete mathematics, cryptanalysis and implementation aspects. Actually, characterizing the structures of the building blocks which are optimal regarding to some attacks is very important for finding appropriate constructions and also for determining whether the underlying structure induces some weaknesses or not.

For these reasons, we have investigated several families of filtering functions and of S-boxes which are well-suited for their cryptographic properties or for their implementation characteristics. For instance, bent functions, which are the Boolean functions which achieve the highest possible nonlinearity, have been extensively studied in order to provide some elements for a classification, or to adapt these functions to practical cryptographic constructions. We have also been interested in functions with a low differential uniformity (e.g., APN functions), which are the S-boxes ensuring an (almost) optimal resistance to differential cryptanalysis.

Recent results:
- Study of the properties of the family of power functions with exponents $2^t - 1$. This family notably includes the cube function $x^3$ and the inverse function over a finite field with characteristic 2. In this work, the whole Walsh spectrum of $x^7$ is determined [11].
- Construction and study of the properties of new families of permutation polynomials over the field with $2^m$ elements; study of permutations with a linear structure: [14].
- Study of the algebraic properties (e.g. the algebraic degree) of the inverses of APN power permutations [47].

5.2. Code-based cryptography
Participants: Matthieu Finiasz, Grégory Landais, Rafael Misoczki, Ayoub Otmani, Nicolas Sendrier, Jean-Pierre Tillich.
Most popular public-key cryptographic schemes rely either on the factorization problem (RSA, Rabin), or on the discrete logarithm problem (Diffie-Hellman, El Gamal, DSA). These systems have evolved and today instead of the classical groups \((\mathbb{Z}/n\mathbb{Z})\) we may use groups on elliptic curves. They allow a shorter block and key size for the same level of security. An intensive effort of the research community has been and is still being conducted to investigate the main aspects of these systems: implementation, theoretical and practical security. It must be noted that these systems all rely on algorithmic number theory. As they are used in most, if not all, applications of public-key cryptography today (and it will probably remain so in the near future), cryptographic applications are thus vulnerable to a single breakthrough in algorithmics or in hardware (a quantum computer can break all those scheme).

Diversity is a way to dilute that risk, and it is the duty of the cryptographic research community to prepare and propose alternatives to the number theoretic based systems. The most serious tracks today are lattice-based cryptography (NTRU,...), multivariate cryptography (HFE,...) and code-based cryptography (McEliece encryption scheme,...). All these alternatives are referred to as post-quantum cryptosystems, since they rely on difficult algorithmic problems which would not be solved by the coming-up of the quantum computer.

The code-based primitives have been investigated in details within the project-team. The first cryptosystem based on error-correcting codes was a public-key encryption scheme proposed by McEliece in 1978; a dual variant was proposed in 1986 by Niederreiter. We proposed the first (and only) digital signature scheme in 2001. Those systems enjoy very interesting features (fast encryption/decryption, short signature, good security reduction) but also have their drawbacks (large public key, encryption overhead, expensive signature generation). Some of the main issues in this field are

- security analysis, implementation and practicality of existing solutions,
- reducing the key size, e.g., by using rank metric instead of Hamming metric, or by using particular families of codes,
- address new functionalities, like hashing or symmetric encryption.

**Recent results:**

- A distinguishing attack on high rate Goppa codes [25]. This results does not lead to an attack on any code based cryptosystem, but, in some particular cases, it invalidates the security reduction. It was conjectured that there was no such distinguishers.
- A new class of codes for McEliece type cryptosystems offering more versatility [22]
- A generic attack on one-time signature based on codes (KKS type) [27].
- A improvement of generic decoding techniques when addressing multiple targets [28].

### 5.3. Error-correcting codes and applications

**Participants:** Mamdouh Abbara, Matthieu Finiasz, Vincent Herbert, Denise Maurice, Nicolas Sendrier, Jean-Pierre Tillich.

Decoding algorithms are extensively used for cryptanalyses. For instance, a classical cryptanalysis of the stream ciphers which rely on linear feedback shift register filtered by a Boolean function models the attacked cipher as the result of the transmission of a linear function through a very highly noisy channel. Then, removing the noise amounts to decoding a certain linear code. This code is highly structured, and one of the most efficient methods to decode it exploits the fact that it has low density parity-check equations, and thus can be decoded as a low-density parity-check code, with iterative algorithms. Furthermore, the problem of finding good approximations of ciphers amounts to a decoding problem of the first order Reed-Muller code. Local decoding is then used in this context, and enables various attacks, such as correlation attacks or linear cryptanalysis.

Besides the cryptographic applications of decoding algorithms, we also investigate two new application domains for decoding algorithms: reverse engineering of communication systems, and quantum error correcting codes for which we have shown that some of them can be decoded successfully with iterative decoding algorithms.
5.3.1. **Algebraic error-correcting codes.**

Finding lower bounds on the minimum distance of cyclic codes is an old and difficult problem. Cyclic codes with three zeroes correct at most three errors, that is have minimum distance at most 7. It is an interesting question to determine which cyclic codes with three zeroes have minimum distance 7. Vincent Herbert revisit this problem by using an algorithm due to Shaub. Some classification questions are addressed about three error correcting cyclic codes and some new results involving intensive computer search have been obtained [10], [26].

5.3.2. **Quantum codes.**

The knowledge we have acquired in iterative decoding techniques has also led to study whether or not the very same techniques could also be used to decode quantum codes. Part of the old ACI project “RQ” in which we were involved and the new ANR project “COCQ” are about this topic. It is worth noticing that protecting quantum information from external noise is an issue of paramount importance for building a quantum computer. It also worthwhile to notice that all quantum error-correcting code schemes proposed up to now suffer from the very same problem that the first (classical) error-correcting codes had: there are constructions of good quantum codes, but for the best of them it is not known how to decode them in polynomial time. Our approach for overcoming this problem has been to study whether or not the family of turbo-codes and LDPC codes (and the associated iterative decoding algorithms) have a quantum counterpart.

**Recent results:**

- a construction of a family of quantum turbo-codes with excellent error reducing performance under iterative decoding and this even for very noisy channels [29];
- a proof that this family has unbounded minimum distance [20].

5.3.3. **Reverse engineering of communication systems.**

To evaluate the quality of a cryptographic algorithm, it is usually assumed that its specifications are public, as, in accordance with Kerckhoffs principle\(^2\), it would be dangerous to rely, even partially, on the fact that the adversary does not know those specifications. However, this fundamental rule does not mean that the specifications are known to the attacker. In practice, before mounting a cryptanalysis, it is necessary to strip off the data. This reverse engineering process is often subtle, even when the data formatting is not concealed on purpose. A typical case is interception; some raw data, not necessarily encrypted, is observed out of a noisy channel. To access the information, the whole communication system has first to be disassembled and every constituent reconstructed. Our activity within this domain, whose first aim is to establish the scientific and technical foundations of a discipline which does not exist yet at an academic level, has been supported by some industrial contracts driven by the DGA.

---

\(^2\) Kerckhoffs stated that principle in a paper entitled *La Cryptographie militaire*, published in 1883.
6. New Results

6.1. Indistinguishability Proofs

Participants: Rohit Chadha, Vincent Cheval, Ştefan Ciobăcă, Hubert Comon-Lundh, Stéphanie Delaune, Steve Kremer.

Most existing results in verification of security protocols focus on trace properties such as secrecy or authentication. There are however several security properties that cannot be defined (or cannot be naturally defined) as trace properties and require the notion of indistinguishably. Typical examples are anonymity, privacy related properties or statements closer to security properties used in cryptography.

In the framework of the applied pi-calculus \[54\], as in similar languages based on equational logics, indistinguishability corresponds to a relation called trace equivalence. Roughly, two processes are trace equivalent when an observer cannot see any difference between the two processes.

Under some conditions, trace equivalence can be reduced to the problem of deciding symbolic equivalence, an equivalence relation introduced by M. Baudet \[55\]. However, the procedure proposed by Mathieu Baudet for deciding symbolic equivalence is complex and cannot be implemented in its current state. Moreover, this method can only deal with simple processes with trivial else branches and is restricted to the class of subterm-convergent equational theories. Unfortunately, this makes it unsuitable for some case studies of interest to the SECSI team, among which the FOO electronic voting protocol, and the electronic passport protocols.

In order to provide tool support to decide trace equivalence, Rohit Chadha, Ştefan Ciobăcă, and Steve Kremer propose a procedure that can handle a large set of cryptographic primitives. The procedure has been implemented in a prototype tool and has been effectively tested on examples (e.g., the FOO e-voting protocol). This paper is currently under submission.

Vincent Cheval, Hubert Comon-Lundh and Stéphanie Delaune have designed another procedure that allows one to check trace equivalence for a general class of processes \[31\]. In their class, they can model conditionals (with non-trivial else branches), private channels, and non-deterministic choice. The private authentication protocol and the various versions of the electronic passport protocol fall into their class.

6.2. Anonymous Credentials

Participants: Stéphanie Delaune, Malika Izabachène, Graham Steel.

Anonymous credentials plays an important role in non-interactive anonymous authentication: they allow a user to obtain certificates from organization and subsequently prove their possession in such a way that transactions of a same user remain unlinkable. In collaboration with Benoit Libert and Damien Vergnaud, Malika Izabachène present an anonymous credential scheme \[39\] in which a user can prove possession of appropriate attributes in an non-interactive fashion, by showing that these attributes satisfy a certain predicate (different type of predicates are handled).

Following this line of research on anonymous protocols, Stéphanie Delaune, Malika Izabachène and Graham Steel formalize unlinkability in the pi-calculus framework. They are exploring several scenarios in order to capture many adversarial strategies, especially in the context of low-cost devices, in which sensitive data are stored and identifier means are exchanged through public channels.

6.3. Security APIs

Participants: Stéphanie Delaune, Steve Kremer, Robert Künnemann, Graham Steel, Yusuke Kawamoto, Joe-Kai Tsay.
Security APIs allow untrusted code to access sensitive resources in a secure way. The idea is to design an interface between a trusted component, such as a smart card or cryptographic security module, and the untrusted outside world such that no matter what sequence of commands in the interface are called, and no matter what the parameters, certain good properties will continue to hold, e.g. the secret long term keys on the smartcard are never revealed. Designing such interfaces is very tricky, and several vulnerabilities in APIs in common use have come to light in recent years.

The members of the SECSI team have been studying the application of formal security analysis techniques to APIs, for the last few years. These APIs include industrial standards such as PKCS#11 and the Trusted Platform Module (TPM).

In [37], Delaune, Kremer and Steel present a Horn-clause-based framework for analyzing security protocols that use platform configuration registers (PCRs), which are registers for maintaining state inside the Trusted Platform Module (TPM). In their model, the PCR state space is unbounded, and experience shows that a naïve analysis using verification tools such as ProVerif or SPASS does not terminate. To address this, the authors extract a set of instances of the Horn clauses of the model, for which ProVerif does terminate on the chosen examples. The authors prove the soundness of this extraction process: no attacks are lost, that is, any query derivable in the more general set of clauses is also derivable from the extracted instances. The effectiveness of this framework is demonstrated in two case studies: a simplified version of Microsoft Bitlocker, and a digital envelope protocol that allows a user to choose whether to perform a decryption, or to verifiably renounce the ability to perform the decryption.

One of the reasons for the existence of security flaws that the members of the SECSI team identified when studying security APIs is the absence of definitions stating the expected security properties.

In [40], Kremer, Steel and Warinschi propose a much-needed formal definition of security for cryptographic key management APIs. The advantages of this definition are that it is general, intuitive, and applicable to security proofs in both symbolic and computational models of cryptography. This definition relies on an idealized API which allows only the most essential functions for generating, exporting and importing keys, and takes into account dynamic corruption of keys. Based on this the authors can define the security of more expressive APIs which support richer functionality. They illustrate their approach by showing the security of APIs both in symbolic and computational models.

More recently, Kremer, Künnemann and Steel go even a step further in that direction and present the first key-management functionality in Canetti’s Universal Composability (UC) framework. It allows one to enforce a wide range of security policy and is highly extensible. The authors illustrate its use by proving an implementation of a Security API secure with respect to arbitrary key-usage operations and explore a proof technique that allows to store cryptographic keys externally, a novelty in the UC framework. This work is currently submitted.

In other recent work, in collaboration with Riccardo Focardi at the University of Venice, Kawamoto, Steel and Tsay have investigated the error behaviour of functions in the PKCS#11 API of various cryptographic devices including security tokens, electronic ID cards and Hardware Security Modules (HSMs). In certain circumstances attackers can take advantage of errors reported to make cryptanalytic attacks on functions in the API. Taking the example of the command used to import and encrypted key onto the device, they have discovered a number of so-called ‘error oracle attacks’ based on variations of well-known padding attacks due to Bleichenbacher and Vaudenay. This work has also recently been submitted. A number of vulnerability reports have been sent to manufacturers and national agencies.

6.4. Mobile Ad-Hoc Networks

Participants: Mathilde Arnaud, Morten Dahl, Stéphanie Delaune, Graham Steel.

Mobile ad hoc networks consist of mobile wireless devices which autonomously organize their communication infrastructure: each node provides the function of a router and relays packets on paths to other nodes. Finding these paths in an a priori unknown and constantly changing network topology is a crucial functionality of any ad hoc network. Specific protocols, called routing protocols, are designed to ensure this functionality known as...
route discovery. Secure routing protocols use cryptographic mechanisms in order to prevent a malicious node from compromising the discovered route and they often perform some recursive tests on received messages.

Mathilde Arnaud, Véronique Cortier and Stéphanie Delaune provide NPTIME decision procedures for protocols with recursive tests and for a bounded number of sessions [26]. They also revisit constraint system solving, providing a complete symbolic representation of the attacker knowledge.

In the context of vehicular ad-hoc networks, to improve road safety, a vehicle-to-vehicle communication platform is currently being developed by consortia of car manufacturers and legislators.

In [35], Morten Dahl, Stéphanie Delaune and Graham Steel propose a framework for formal analysis of privacy in location based services such as anonymous electronic toll collection. They give a formal definition of privacy, and apply it to the VPriv scheme for vehicular services. They analyse the resulting model using the ProVerif tool, concluding that the privacy property holds only if certain conditions are met by the implementation. Their analysis includes some novel features such as the formal modelling of privacy for a protocol that relies on interactive zero-knowledge proofs of knowledge and list permutations.

6.5. Composition Results

Participants: Céline Chevalier, Stéphanie Delaune, Steve Kremer.

Céline Chevalier, Stéphanie Delaune, and Steve Kremer investigate the composition of protocols that share a common weak secret [32]. This situation arises when users employ the same password on different services. More precisely they study whether resistance against guessing attacks composes when a same password is used. More precisely, they present a transformation which maps a password protocol that is secure for a single protocol session (a decidable problem) to a protocol that is secure for an unbounded number of sessions. Their result provides an effective strategy to design secure password protocols: (i) design a protocol intended to be secure for one protocol session; (ii) apply the transformation and obtain a protocol which is secure for an unbounded number of sessions. This technique also applies to compose different password protocols allowing one to obtain both inter-protocol and inter-session composition.

6.6. Protecting Hypervisors from Denial of Service Attacks

Participant: Hedi Benzina.

Hedi Benzina showed that hypervisors can be protected from some denial of service attacks by allowing administrators to write security policies in a simple language [41]. He implemented the RuleGen tool, which translates these policies into Orchids signatures.

6.7. Soundness Results: Some Limitations

Participant: Hubert Comon-Lundh.

Soundness results aim at bridging the gap between computational and symbolic security; they show that some symbolic model, in which messages are terms and the attacker is a formal process, faithfully abstracts the computational model, in which messages are bitstrings and the attacker is any probabilistic polynomial time Turing machine. Such results allow one to derive strong security guarantees, while reasoning at an abstract level. They have been developed for several cryptographic primitives (e.g. symmetric and asymmetric encryption, signatures, hash) and security properties.

These results however suffer from some severe limitations, as Hubert Comon-Lundh and Véronique Cortier demonstrate [34], focusing on symmetric encryption.

6.8. Model-Checking Reactive Probabilistic Systems

Participant: Rohit Chadha.
Rohit Chadha along with A. Prasad Sistla and Mahesh Viswanathan continued their study on reactive probabilistic systems modeled as Probabilistic Büchi Automata (PBA) in [30]. Reactive probabilistic systems are probabilistic non-deterministic systems in which the nondeterminism is resolved by a external environment which is oblivious of the “current” state of the system. This paper investigates the power of PBA when the threshold probability of acceptance is non-extremal, i.e., is a value strictly between 0 and 1. Many practical randomized algorithms are designed to work under non-extremal threshold probabilities and thus it is important to study power of PBAs for such cases. The paper presents a number of surprising expressiveness and decidability results for PBAs when the threshold probability is non-extremal. Some of these results sharply contrast with the results for extremal threshold probabilities. The paper also presents results for Hierarchical PBAs and for an interesting subclass of them called simple PBAs.

Rohit Chadha along with V. Korthikranthi, M. Viswanathan, G. Agha and Y. Kwon also study reactive probabilistic systems in [28]. In [28], reactive probabilistic systems are viewed as transformers of probability distributions, giving rise to a labeled transition system over the probability distributions over the states of the system. Thus, a reactive probabilistic system can be seen as defining a set of executions where each execution is a sequence of probability distributions. Reasoning about sequences of distributions allows one to express properties not expressible in standard probabilistic logics like PCTL; examples include expressing bounds on transient rewards and expected values of random variables, as well as comparing the probability of being in one set of states at a given time with another set of states. With respect to such a semantics, the model-checking problem is undecidable. In this paper, the authors identify a special class of systems called semi-regular Markov Decision Processes that have a unique non-empty, compact, invariant set of distributions, for which they show that checking any $\omega$-regular property is decidable. Their decidability result also implies that for semi-regular probabilistic finite automata with isolated cut-points, the emptiness problem is decidable.

6.9. Continuous Random Variables

**Participant:** Jean Goubault-Larrecq.

Continuing work on probabilistic and non-deterministic choice in a domain-theoretic setting, Jean Goubault-Larrecq and Daniele Varacca (PPS, University Paris 7) proposed a new monad for probabilistic choice, that of continuous random variables [38]. The usual Jones-Plotkin monad of continuous valuations, although simple enough, suffers from the defect that no category of continuous domains is known that would be both Cartesian-closed (i.e., would allow one to interpret functions) and stable under the Jones-Plotkin monad.

Jean Goubault-Larrecq and Daniele Varacca managed to show that a related monad, that of continuous random variables, inspired from the notion of a random variable in probability theory, did not suffer from this defect: the category of bc-domains is indeed both Cartesian-closed and stable under this monad. Moreover, the authors showed that using one or the other monad gave semantics to higher-order probabilistic programs that were indistinguishable at ground types. Finally, they used this to solve an open problem by Escardò, namely that observational equivalence of probabilistic higher-order programs is recursively enumerable.

6.10. Choquet-Kendall-Matheron Theorems

**Participant:** Jean Goubault-Larrecq.

One of the results obtained by Jean-Goubault-Larrecq in his theory of semantics for mixed non-deterministic and probabilistic choice [60] is that there is a one-to-one correspondence between continuous credibilities over some (state) space $X$ and certain compact subsets of the space of all continuous valuations over $X$, under mild assumptions on $X$. Similar theorems were produced by Choquet in the 1950s, refined by Kendall, then by Matheron in the 1970s, with applications in random set theory, among others.

Klaus Keimel and Jean Goubault-Larrecq produced an extremely simple proof of this fact [22], based on a simple special case of Groemer’s integral theorem. This proof also produces a much more general result than what was known earlier, as it does not assume that $X$ is second-countable or Hausdorff, and only local compactness.
A domain-theoretic view is that this is a representation theorem for mixed demonic choice and probabilistic choice; the angelic and erratic cases are also covered by Goubault-Larrecq and Keimel. These results had been presented at Dagstuhl Seminar 10232, June 2010.

6.11. Full Abstraction for Call-by-Value Programs with Choice

**Participant:** Jean Goubault-Larrecq.

Consider a programming language, with both an operational semantics, stating how one can implement a machine for this language, and a denotational semantics, which states what programs compute (not how). A classical question in programming language semantics is whether equality of denotations (from denotational semantics) coincides with contextual equivalence (from operational semantics). This is called *full abstraction.*

This question was first formulated for PCF by G. Plotkin in 1977, who showed that PCF was not fully abstract, although PCF plus a form of parallel or was. PCF is a simply-typed higher-order language, which one could see as a simple variant of the ML language without mutable state.

Jean Goubault-Larrecq examined the question for variants of PCF with various forms of non-deterministic and probabilistic choice. The latter are modeled denotationally by using his theory of previsions [61]. The most startling result is that the call-by-value variant of PCF with only angelic non-determinism is fully abstract, without the need for parallel or. Jean Goubault-Larrecq also showed that call-by-value PCF with angelic non-determinism and probabilistic choice is not fully abstract, but that this language plus so-called statistical test primitives is fully abstract. These results were presented at the Domains X Workshop, Swansea, Wales, UK, September 2011.
SELECT Project-Team

6. New Results

6.1. Model selection in Regression and Classification

Participants: Gilles Celeux, Mohammed El Anbari, Clément Levrard, Robin Genuer, Erwan Le Pennec, Lucie Montuelle, Pascal Massart, Caroline Meynet, Jean-Michel Poggi.

Erwan Le Pennec continues his work with Serge Cohen (IPANEMA Soleil) on hyperspectral image segmentation based on a spatialized Gaussian Mixture Model. They derive, and implement within MIXMOD, an efficient minimization algorithm combining EM algorithm, dynamic programming and model selection[37]. They have applied this technique to analyze ancient material[9]. This scheme is supported by a theoretical work on conditional density estimation[40]. In the framework of her PhD, Lucie Montuelle has studied some extension to this model to spatially varying logistic weights.

In collaboration with Marie-Laure Martin-Magniette (URGV et UMR AgroParisTech/INRA MIA 518) and Cathy Maugis (INSA Toulouse) has extended their variable selection procedure for model-based clustering and supervised classification to deal with high dimensional data sets with a backward selection procedure which is more efficient that the previous forward selection procedure in this context. [17]. Moreover they have shown the advantage of the model-based approach over a geometrical approach to select variable for clustering [13]. These variable selection procedures are in particular used for genomics applications which is the result of a collaboration with researchers of of URGV (Evry Genopole).

Caroline Meynet provided an $\ell_1$-oracle inequality satisfied by the Lasso estimator with the Kullback-Leibler loss in the framework of a finite mixture of Gaussian regressions model for high-dimensional heterogeneous data where the number of covariates may be much larger than the sample size. In particular, she has given a condition on the regularization parameter of the Lasso to obtain such an oracle inequality. This oracle inequality extends the $\ell_1$-oracle inequality established by Massart and Meynet [16] in the homogeneous Gaussian linear regression case. It is deduced from a finite mixture Gaussian regression model selection theorem for $\ell_1$-penalized maximum likelihood conditional density estimation, which is inspired from Vapnik’s method of structural risk minimization and from the theory on model selection for maximum likelihood estimators developed by Massart.

From an practical point of view, Caroline Meynet has introduced a procedure to select variables in model-based clustering in a high-dimensional context. In order to tackle with the problem of high-dimension, she has proposed to first use the Lasso in order to select different sets of variables and then estimate the density by a standard EM algorithm by reducing the inference to the linear space of the selected variables by the Lasso. Numerical experiments show that this method can outperform direct estimation by the Lasso.

In collaboration with Professor Abdallah Mkhadri (University of Marrakesh, Marocco), Gilles Celeux supervised the thesis of Mohammed El Anbari which concern regularisation methods in linear regression. In collaboration with Professor Abdallah Mkhadri (University of Marrakesh, Marocco), Mohammed El Anbari proposed a method to simultaneously select variables and favor a grouping effect where strongly correlated predictors tend to be in or out of the model together. Numerical experiments showed that their method can be preferred to Elastic-Net when the number of variables is less or equal to the sample size and remain competitive otherwise. Moreover, they have proposed AdaGril an extension of the the adaptive Elastic Net which incorporates information redundancy among correlated variables for model selection and estimation. Under weak conditions, They have established an oracle property of AdaGril. Numerical experiments show in some cases of AdaGril outperforms its competitors.

In collaboration with Jean-Michel Marin (Université de Montpellier) and Christian P. Robert (CEREMADE, Université Paris Dauphine) Gilles Celeux and Mohammed El Anbari highlight the interest of Bayesian regularization methods, using hierarchical non informative priors, compared with standard regularization methods in a poorly informative context through numerical experiments [47].
Clément Levrard worked on the obtention of fast rates of convergence for vector quantization. Using theoretical analogies between quantization seen as an unsupervised learning problem and the one of supervised learning by empirical contrast minimization, he has obtained a logarithmic improvement on the previously obtained bound. He has been furthermore able to define intelligible "margin type" condition under which fast rates can be obtained.

Since September 2008, Pascal Massart is the cosupervisor with Frédéric Chazal (GEOMETRICA) of the thesis of Claire Caillerie (GEOMETRICA). The project intends to explore and to develop new researches at the crossing of information geometry, computational geometry and statistics.

6.2. Statistical learning methodology and theory

Participants: Gilles Celeux, Christine Keribin, Erwan Le Pennec, Pascal Massart, Lucie Montuelle, Jean-Michel Poggi.

Unsupervised segmentation is an issue similar to unsupervised classification with an added spatial aspect. Functional data is acquired on points in a spatial domain and the goal is to segment the domain in homogeneous domains. The range of applications includes hyperspectral images in conservation sciences, fMRI data and all spatialized functional data. Erwan Le Pennec and Lucie Montuelle are focusing on the questions of the way to handle the spatial component from both the theoretical and the practical point of views as well as the choice of the number of clusters. Furthermore, as functional data require heavy computation, they are required to propose numerically efficient algorithms.

Gilles Celeux, Christine Keribin and the Ph.D. student Vincent Brault continue their work on the Latent Block Model. They have proposed an efficient algorithm coupling a Stochastic version of the EM algorithm including a Gibbs sampling step and the Variational EM algorithm. This SEM-VEM algorithm is insensitive to its initial position. On the other hand they got a closed formed expression of the Integrated Completed Likelihood for binary tables which allows for a reliable model selection criterion avoiding asymptotic approximation. Moreover, Christine Keribin derived sufficient conditions ensuring the identifiability of the Latent Block Model.

6.3. Reliability and Computer Experiments

Participants: Yves Auffray, Gilles Celeux, Rémi Fouchereau, Shuai Fu, Pascal Massart.

In the computer experiments field, the goal is to approximate an expensive black box function from a limited number of evaluations. The choice of these evaluations i.e. the choice of a design of (computer) experiments is a major issue.

This year Yves Auffray and Pierre Barbillon, in collaboration with Jean-Michel Marin (Université de Montpellier) have considered estimating the probability of rare events in the context of computer experiments. These rare events depend on the output of a physical model with random input variables. Since the model is only known through an expensive black box function, a crude Monte Carlo estimator does not perform well. Two strategies have been developed to cope with this difficulty: a Bayesian estimate and an importance sampling method. Both methods rely on Kriging metamodeling. They are able to achieve sharp upper confidence bounds on the rare event probability. These methods have been applied to a toy example and a real case study which consists of finding an upper bound of the probability that the trajectory of an airborne load collides the aircraft that has released it.

Following the previous work of the first year, Shuai Fu, under the direction of Gilles Celeux, focus on the design of experiments and its validation, which has become the main issues of the thesis. It leads both to theoretical and computational developments. An original DAC criterion has been proposed and leads to a Bayesian procedure of DAC-test to measure the quality of a design. For improving the design of experiments, an adaptive kriging procedure well adapted to the specific problem has been proposed. However, the algorithms require a too important computation time which should be reduced in future work.
In the framework of a CIFRE convention with Snecma-SAFRAN Rémy Fouchereau has started a thesis on the modeling of fatigue damage for Inco718 supervised by Gilles Celeux. Inco718 is a Zinc-based alloy. To determine its minimum lifetime, a lot of stress tests are made. The lloay lifetimes are reported as function of the stress. The aim of this work is to analyse the resulting curves. A mixture model with a lognormal component and a sum of two lognormals components is considered. Since the sum of two or more lognormal distribution is not closed form. Inference on this model needs Monte Carlo integration within the EM algorithm. Despite some unstability for small sample sizes, this model show encouraging and easily interpretable results.

6.4. Statistical analysis of genomic data
Participants: Gilles Celeux, Andrea Rau.

Andrea Rau and Gilles Celeux, in collaboration with Marie-Laure Martin-Magniette (URGV and UMR AgroParisTech/INRA MIA 518) and Cathy Maugis-Rabusseau (IMT/INSA Toulouse) have developed a method to cluster digital gene expression observations from high-throughput (HTS) data using Poisson mixture models [44]. The proposed model has the advantage of accounting for the particularities of HTS data and providing straightforward procedures for parameter estimation and model selection. A series of simulation experiments was done to compare the performance of the proposed model to that of previously proposed clustering methods for similar sequence-based data, and the performance of the proposed approach was examined on two real high-throughput sequencing data sets. The R package HTSCluster used to implement the proposed Poisson mixture model has been made freely available on CRAN.

6.5. Curves classification, denoising and forecasting
Participant: Jean-Michel Poggi.

In collaboration with Farouk Mhamdi and Meriem Jaidane (ENIT, Tunis, Tunisia), Jean-Michel Poggi proposed, in [18], a method for trend extraction from seasonal time series through the Empirical Mode Decomposition (EMD). Experimental comparison of trend extraction based on EMD, X11, X12 and Hodrick Prescott filter are conducted. First results show the eligibility of the blind EMD trend extraction method. Tunisian real peak load is also used to illustrate the extraction of the intrinsic trend.

In collaboration with Mina Aminghafari (Amirkabir University, Teheran), Jean-Michel Poggi made uses of wavelets in a statistical forecasting purpose for time series. Recent approaches involve wavelet decompositions in order to handle non stationary time series. They study and extended an approach proposed by Renaud et al., to estimate the prediction equation by direct regression of the process on the Haar non-decimated wavelet coefficients depending on its past values. The new variants are used first for stationary data and after for stationary data contaminated by a deterministic trend [3].

Jean-Michel Poggi was the supervisor (with A. Antoniadis) of the PhD Thesis of Jairo Cugliari-Duhalde which takes place in a CIFRE convention with EDF. It is strongly related to the use of wavelets together with curves clustering in order to perform accurate load consumption forecasting. The thesis develops methodological and applied aspects linked to the electrical context as well as theoretical ones by introducing exogeneous variables in the context of nonparametric forecasting time series (see [27] and [45]).

6.6. Neuroimaging, Statistical analysis of fMRI data
Participants: Gilles Celeux, Christine Keribin.

This research takes place as part of a collaboration with Neurospin on brain functional Magnetic Resonance Imaging (fMRI) data. (http://www.math.u-psud.fr/select/reunions/neurospin/Welcome.html). This year it concerned essentially regularisation in a supervised clustering methodology that includes spatial information in the prediction framework, and yields clustered weighted maps.
6. New Results

6.1. Coordination Parsing

Participants: Bruno Guillaume, Guy Perrier.

In the development of the French grammar, FRIGRAM, Joseph Le Roux and Guy Perrier have tackled the difficult problem of modelling and parsing coordination [39]. They have enriched FRIGRAM with a module expressing different syntactic constructions with coordination. An important drawback of this approach is the number of elementary constructions that have to introduced to obtain a reasonable coverage of the phenomenon.

In the continuation of his Master thesis, Valmi Dufour-Lussier with Bruno Guillaume and Guy Perrier worked on a different approach. They propose to process coordination at the parsing level as a linguistic performance issue, outside the grammar, rather than as a matter of competence [15]. They apply a specific algorithm to combine coordinated syntactic structures that were partially parsed using a coordination-less grammar, resulting in a directed acyclic parse graph in which constituent sharing appears sharply. They have experimented the algorithm within the framework of Tree-Adjoining Grammars (although it can be adapted to other formalisms) on a small subset of the Penn Treebank \(^2\). They have shown that it is able to handle many types of coordinative constructions, including left and right node raising, argument clusters, and verb gapping.

6.2. Graph Rewriting

Participants: Bruno Guillaume, Mathieu Morey, Guy Perrier.

Guillaume Bonfante (from CARTE team), Bruno Guillaume, Mathieu Morey and Guy Perrier have improved their graph rewriting calculus, experimenting it in two directions. Taking an asynchronous perspective on the syntax-semantics interface, they have designed a modular graph rewriting system to produce underspecified semantic representations from a syntactic dependency graph [14]. They experimentally validated this approach on a set of sentences extracted from the French Treebank annotated with syntactic dependencies [27]. The results open the way for the production of underspecified semantic dependency structures from corpora annotated with syntactic dependencies and, more generally, for a broader use of modular rewriting systems for computational linguistics.

In a second application, they show how to enrich a syntactic dependency annotation of the French Treebank, using graph rewriting, in order to compute its semantic representation [13]. The rewriting system is composed of grammatical and lexical rules structured in modules. The lexical rules use a control information extracted from Dicovalence, a lexicon of French verbs \(^3\).

6.3. ACG Type System

Participants: Philippe de Groote, Sylvain Pogodalla, Florent Pompigne.

In order to extend the flexibility and the expressiveness of the the ACG framework, [57] proposed a type-system extension. However, the formal properties of the system have to be proved. In his PhD work, Florent Pompigne is proposing alternate \(\eta\)-rules and commutative conversions in order to get the desirable properties. This work, currently in progress, relates to former proposals for a linear calculus with dependent types [28] and a calculus for extensionality with variants [40].

\(^2\) http://www.cis.upenn.edu/~treebank/
\(^3\) http://bach.arts.kuleuven.be/dicovalence/
6.4. Logic and Grammars

Participant: Maxime Amblard.

Maxime Amblard has presented an extension of Minimalist Categorial Grammars (MCG) to encode Chomsky’s phases in [11]. These grammars are based on Partially Commutative Logic (PCL) and encode properties of Minimalist Grammars (MG) of Stabler. The first implementation of MCG were using both non-commutative properties (to respect the linear word order in an utterance) and commutative ones (to model features of different constituents). Here, we propose to adding Chomsky’s phases with the non-commutative tensor product of the logic.

6.5. Discourse dynamics

Participants: Maxime Amblard, Sai Qian.

Sai Qian and Maxime Amblard has presented a framework which constructs an event-style discourse semantics, [17]. The discourse dynamics are encoded in continuation semantics [54] and various rhetorical relations are embedded in the resulting interpretation of the framework. They assume that discourse and sentence are distinct semantic objects, that play different roles in meaning evaluation. Moreover, two sets of composition functions, for handling different discourse relations, are introduced.

6.6. Modeling pathological discourse

Participant: Maxime Amblard.

Maxime Amblard starts a conjoint work with a psychologist Michel Musiol (IntePsy) and a philosopher Manuel Rebuschi (Archives Poincaré) about developing a formal analysis of pathological conversations involving schizophrenic speakers [18]. Such conversations give rise to manifest incongruities or ruptures that can be seen as mere contradictions by any “normal” speaker. Our construal relies both on semantic and pragmatic features of conversation. After an overview on the making of the corpus, we propose a SDRT-inspired account of pathological conversations, and we apply it to two relevant excerpts. We conclude with a short discussion about the localization of incoherencies by schizophrenics, either in semantics or in pragmatics, and its importance for our understanding of thought disorders.
6. New Results

6.1. Introduction

The new results are organized in the following sections:

1. decision under uncertainty,
2. foundations of machine learning,
3. supervised learning,
4. signal processing (sensor networks),
5. other results.

6.2. Decision Under Uncertainty

6.2.1. Reinforcement learning and approximate dynamic programming

In the domain of reinforcement learning and approximate dynamic programming, we identify two main lines of research.

6.2.1.1. Links between Approximate Dynamic Programming and Statistical Learning Theory

The main objective here is to use tools from statistical learning theory to derive finite-sample performance bounds for RL and ADP algorithms. The goal is to derive bounds on the performance of the policies induced by these algorithms in terms of the number of simulation data and the capacity and approximation power of the considered function and policy spaces. The results of this study allow us to have a better understanding of the functionality of these algorithms and help us to design them more efficiently. The main contributions to this research line in 2011 are:

- **Classification-based Policy Iteration with a Critic** [25], [51]. In collaboration with Bruno Scherrer (INRIA Nancy - Grand Est, Team MAIA) we extended last year work on classification-based policy iteration by adding a value function approximation component (critic) to rollout classification-based policy iteration (RCPI) algorithms. The idea is to use a critic to approximate the return after we truncate the rollout trajectories. This allows us to control the bias and variance of the rollout estimates of the action-value function. Therefore, the introduction of a critic can improve the accuracy of the rollout estimates, and as a result, enhance the performance of the RCPI algorithm. We presented a new RCPI algorithm, called direct policy iteration with critic (DPI-Critic), and provided its finite-sample analysis when the critic is based on the LSTD method. We also empirically evaluated the performance of DPI-Critic and compared it with DPI and LSPI in two benchmark reinforcement learning problems.

- **Finite-Sample Analysis of Least-Squares Policy Iteration** [10], [45]. We extended last year work on the finite-sample analysis of least-squares temporal-difference (LSTD) to the least-squares policy iteration (LSPI) algorithm. In particular, we analyzed how the error at each policy evaluation step is propagated through the iterations of a policy iteration method, and derive a performance bound for the LSPI algorithm.
• **Speedy Q-Learning** [16], [48]. We introduce a new convergent variant of Q-learning, called speedy Q-learning, to address the problem of slow convergence in the standard form of the Q-learning algorithm. We prove a PAC bound on the performance of SQL, which shows that for an MDP with \( n \) state-action pairs and the discount factor \( \gamma \) only \( T = O(\log(n)/(\epsilon^2(1-\gamma)^4)) \) steps are required for the SQL algorithm to converge to an \( \epsilon \)-optimal action-value function with high probability. This bound has a better dependency on \( 1/\epsilon \) and \( 1/(1-\gamma) \), and thus, is tighter than the best available result for Q-learning. Our bound is also superior to the existing results for both model-free and model-based instances of batch Q-value iteration that are considered to be more efficient than the incremental methods like Q-learning.

• **Selecting the State-Representation in Reinforcement Learning** [34]. The problem of selecting the right state-representation in a reinforcement learning problem is considered. Several models (functions mapping past observations to a finite set) of the observations are given, and it is known that for at least one of these models the resulting state dynamics are indeed Markovian. Without knowing neither which of the models is the correct one, nor what are the probabilistic characteristics of the resulting MDP, it is required to obtain as much reward as the optimal policy for the correct model (or for the best of the correct models, if there are several). We propose an algorithm that achieves that, with a regret of order \( T^{2/3} \) where \( T \) is the horizon time.

• **Transfer from Multiple MDPs** [32]. Transfer reinforcement learning (RL) methods leverage on the experience collected on a set of source tasks to speed-up RL algorithms. A simple and effective approach is to transfer samples from source tasks and include them in the training set used to solve a target task. In this paper, we investigate the theoretical properties of this transfer method and we introduce novel algorithms adapting the transfer process on the basis of the similarity between source and target tasks. Finally, we report illustrative experimental results in a continuous chain problem.

6.2.1.2. **RL in High-dimensional Spaces**

The main objective here is to devise, analyze, implement, and experiment with RL algorithms whose sample and computational complexities do not grow rapidly with the dimension of the state space. We have tackled this problem from two different angles:

• **Exploiting the Regularities of the Problem** [57], [8], [27]. In order to solve RL in high dimensions, we should exploit all the regularities of the problem in hand. **Smoothness** is the most common regularity. We continued our collaboration with Amir massoud Farahmand and Csaba Szepesvári at the university of Alberta, Canada, and Shie Mannor at Technion, Israel, on using regularization methods for automatic model selection for value function approximation in RL. We have devised and analyzed the first \( \ell_2 \)-regularized RL algorithms by adding \( \ell_2 \)-regularization to three well-known ADP algorithms: fitted Q-iteration, modified Bellman residual minimization, and least-squares temporal-difference learning [57], [8]. The designed algorithms work in both linear and reproducing kernel Hilbert spaces. **Sparsity** is another form of regularity that clearly plays a central role in the emerging theory of learning in high dimensions. We have worked on using \( \ell_1 \)-regularization in approximate dynamic programming and RL, which may also serve as a method for feature selection in value function approximation. We have derived finite-sample performance bounds for an algorithm resulting from adding \( \ell_1 \)-penalty to the widely-used \textit{least-squares temporal-difference learning} (LSTD) algorithm [27].

• **Random Projections** [28], [52]. We have looked into recent directions popularized in compressive sensing concerning the preservation of properties, such as norm or inner-product, of high dimensional objects when projected on possibly much lower dimensional random subspaces. We have studied the popular LSTD algorithm when a space of low dimension is generated with a random projection from the high-dimensional space, and derived performance bounds for the resulting algorithm [28], [52].

6.2.2. **Planning and exploration vs. exploitation trade-off**

In the domain of planning and exploration-exploitation algorithms, we identify two main lines of research.
6.2.2.1. Multi-arm Bandit, Online Learning and Optimization

- **Active Learning in Multi-Armed Bandit Problems** [18], [49], [24], [50]. This can be seen as an online allocation problem with several options and is closely related to the problem of optimal experimental design in statistics. The objective here is to allocate a fixed budget to a finite (or possibly infinite) number of options (arms) in order to achieve the best accuracy in estimating the quality of each option. In addition to having application in a number of different fields such as online advertisement and personalizing treatment, this problem is of specific importance in RL in which generating training data is usually expensive. In this framework, we have studied the following two problems: 1) estimating the mean values of all the arms uniformly well in a multi-armed bandit setting [18], [49], and 2) identifying the best arm in each of the bandits in a multi-bandit multi-armed setting [24], [50]. For each problem, we have developed algorithms with theoretical guarantees.

- **Finite Time Analysis of Stratified Sampling for Monte Carlo** [20]. We consider the problem of stratified sampling for Monte-Carlo integration. We model this problem in a multi-armed bandit setting, where the arms represent the strata (an interval in the input domain), and the goal is to estimate a weighted average of the mean values of the arms. We propose a strategy that samples the arms according to an upper bound on their standard deviations and compare its estimation quality to an ideal allocation that would know the standard deviations of the strata. We provide two regret analyses: a distribution-dependent bound $O(n^{-3/2})$ that depends on a measure of the disparity of the strata, and a distribution-free bound $O(n^{-4/3})$ that does not.

- **Optimistic Optimization of a Deterministic Function without the Knowledge of its Smoothness** [36]. We consider a global optimization problem of a deterministic function $f$ in a semi-metric space, given a finite budget of $n$ evaluations. The function $f$ is assumed to be locally smooth (around one of its global maxima) with respect to a semi-metric. We describe two algorithms based on optimistic exploration that use a hierarchical partitioning of the space at all scales. A first contribution is an algorithm, DOO, that requires the knowledge of $\Theta$. We report a finite-sample performance bound in terms of a measure of the quantity of near-optimal states. We then define a second algorithm, SOO, which does not require the knowledge of the semi-metric under which $f$ is smooth, and whose performance is almost as good as DOO optimally-fitted.

- **Finite-Time Analysis of Multi-armed Bandits Problems with Kullback-Leibler Divergences** [35]. We consider a Kullback-Leibler-based algorithm for the stochastic multi-armed bandit problem in the case of distributions with finite supports (not necessarily known beforehand), whose asymptotic regret matches the lower bound of Burnetas and Katehakis (1996). Our contribution is to provide a finite-time analysis of this algorithm; we get bounds whose main terms are smaller than the ones of previously known algorithms with finite-time analyses (like UCB-type algorithms).

- **Adaptive bandits: Towards the best history-dependent strategy** [33]. We consider multi-armed bandit games with possibly adaptive opponents. We introduce models $\Theta$ of constraints based on equivalence classes on the common history (information shared by the player and the opponent) which define two learning scenarios: (1) The opponent is constrained, i.e. he provides rewards that are stochastic functions of equivalence classes defined by some model. The regret is measured with respect to (w.r.t.) the best history-dependent strategy. (2) The opponent is arbitrary and we measure the regret w.r.t. the best strategy among all mappings from classes to actions (i.e. the best history-class-based strategy) for the best model. This allows to model opponents (case 1) or strategies (case 2) which handles finite memory, periodicity, standard stochastic bandits and other situations. When only one model is considered, we derive tractable algorithms achieving a tight regret (at time $T$) bounded by $O(\sqrt{TAC})$, where $C$ is the number of classes. Now, when many models are available, all known algorithms achieving a nice regret $O(\sqrt{T})$ are unfortunately not tractable and scale poorly with the number of models. Our contribution here is to provide tractable algorithms with regret bounded by $T^{2/3}C^{1/3} \log (|\Theta|)^{1/2}$. 

- **Pure Exploration in Finitely-Armed and Continuous-Armed Bandits** [5]. We consider the framework of stochastic multi-armed bandit problems and study the possibilities and limitations of forecasters that perform an on-line exploration of the arms. These forecasters are assessed in terms of their simple regret, a regret notion that captures the fact that exploration is only constrained by the number of available rounds (not necessarily known in advance), in contrast to the case when the cumulative regret is considered and when exploitation needs to be performed at the same time. We believe that this performance criterion is suited to situations when the cost of pulling an arm is expressed in terms of resources rather than rewards. We discuss the links between the simple and the cumulative regret. One of the main results in the case of a finite number of arms is a general lower bound on the simple regret of a forecaster in terms of its cumulative regret: the smaller the latter, the larger the former. Keeping this result in mind, we then exhibit upper bounds on the simple regret of some forecasters. The paper ends with a study devoted to continuous-armed bandit problems; we show that the simple regret can be minimized with respect to a family of probability distributions if and only if the cumulative regret can be minimized for it. Based on this equivalence, we are able to prove that the separable metric spaces are exactly the metric spaces on which these regrets can be minimized with respect to the family of all probability distributions with continuous mean-payoff functions.

- **X-Armed Bandits** [6]. We consider a generalization of stochastic bandits where the set of arms, X, is allowed to be a generic measurable space and the mean-payoff function is locally Lipschitz with respect to a dissimilarity function that is known to the decision maker. Under this condition we construct an arm selection policy, called HOO (hierarchical optimistic optimization), with improved regret bounds compared to previous results for a large class of problems. In particular, our results imply that if X is the unit hypercube in a Euclidean space and the mean-payoff function has a finite number of global maxima around which the behavior of the function is locally continuous with a known smoothness degree, then the expected regret of HOO is bounded up to a logarithmic factor by \( \sqrt{n} \), that is, the rate of growth of the regret is independent of the dimension of the space. We also prove the minimax optimality of our algorithm when the dissimilarity is a metric. Our basic strategy has quadratic computational complexity as a function of the number of time steps and does not rely on the doubling trick. We also introduce a modified strategy, which relies on the doubling trick but runs in linearithmic time. Both results are improvements with respect to previous approaches.

- **Learning with Stochastic Inputs and Adversarial Outputs** [11]. Most of the research in online learning is focused either on the problem of adversarial classification (i.e., both inputs and labels are arbitrarily chosen by an adversary) or on the traditional supervised learning problem in which samples are independent and identically distributed according to a stationary probability distribution. Nonetheless, in a number of domains the relationship between inputs and outputs may be adversarial, whereas input instances are i.i.d. from a stationary distribution (e.g., user preferences). This scenario can be formalized as a learning problem with stochastic inputs and adversarial outputs. In this paper, we introduce this novel stochastic-adversarial learning setting and we analyze its learnability. In particular, we show that in binary classification, given a hypothesis space \( H \) with finite VC-dimension, it is possible to design an algorithm which incrementally builds a suitable finite set of hypotheses from \( H \) used as input for an exponentially weighted forecaster and achieves a cumulative regret of order \( nV\sqrt{\log n} \) with overwhelming probability. This result shows that whenever inputs are i.i.d., it is possible to solve any binary classification problem using a finite VC-dimension hypothesis space with a sub-linear regret independently from the way labels are generated (either stochastic or adversarial). We also discuss extensions to multi-label classification, regression, learning from experts and bandit settings with stochastic side information, and application to games.

- **ICML Exploration-Exploitation Challenge** [65], [63]. Olivier Nicol and Jérémie Mary won the ICML challenge on Exploration and Exploitation 2 organized by Cambridge on dataset provided by Adobe. The winning approach is based on ideas close to bayesian networks and Thomson sampling as Ad Predictor from Microsoft. These kind of succes emphases the need for better theoretical analysis of theses frameworks. The challenge was also a good occasion to think about the best way
Optimization, Learning and Statistical Methods - New Results - Project-Team SEQUEL

to evaluate online politics (this part also attracts interest from Orange Labs). A publication to JLMR is submitted.

6.2.2.2. Planning

- **Optimistic Planning for Sparsely Stochastic Systems** [17]. We propose an online planning algorithm for finite action, sparsely stochastic Markov decision processes, in which the random state transitions can only end up in a small number of possible next states. The algorithm builds a planning tree by iteratively expanding states, where each expansion exploits sparsity to add all possible successor states. Each state to expand is actively chosen to improve the knowledge about action quality, and this allows the algorithm to return a good action after a strictly limited number of expansions. More specifically, the active selection method is optimistic in that it chooses the most promising states first, so the novel algorithm is called optimistic planning for sparsely stochastic systems. We note that the new algorithm can also be seen as model-predictive (receding-horizon) control. The algorithm obtains promising numerical results, including the successful online control of a simulated HIV infection with stochastic drug effectiveness.

- **Optimistic Planning in Markov decision processes** [46]. We review a class of online planning algorithms for deterministic and stochastic optimal control problems, modeled as Markov decision processes. At each discrete time step, these algorithms maximize the predicted value of planning policies from the current state, and apply the first action of the best policy found. An overall receding-horizon algorithm results, which can also be seen as a type of model-predictive control. The space of planning policies is explored optimistically, focusing on areas with largest upper bounds on the value or upper confidence bounds, in the stochastic case. The resulting optimistic planning framework integrates several types of optimism previously used in planning, optimization, and reinforcement learning, in order to obtain several intuitive algorithms with good performance guarantees. We describe in detail three recent such algorithms, outline the theoretical guarantees on their performance, and illustrate their behavior in a numerical example.

6.2.3. Applications

6.2.3.1. Management of ad campaigns on the web

More work has been dedicated to the topic aiming at optimizing ad campaigns on the web under real-time constraints, in a dynamic environment [9].

6.3. Foundations of Machine Learning

Participants: Daniil Ryabko, Azadeh Khaleghi, Romaric Gaudel.

6.3.1. Sequence prediction in the most general form

The problem of sequence prediction consists in forecasting, on each step of time $n$, the probabilities of the next outcome of the observed sequence of data $x_1, x_2, \ldots, x_n, \ldots$. In the most general formulation of the problem, we assume that we are given a set $\mathcal{C}$ of probability measures (on the space of infinite sequences). We can then assume that the sequence is generated by an unknown measure $\mu$ that belongs to $\mathcal{C}$, or that the measure $\mu$ is arbitrary, but we compare the performance of our predictor to that of the best predictor in $\mathcal{C}$.

6.3.1.1. Relation between the realizable and non-realizable cases of the sequence prediction problem

The realizable case of the sequence prediction problem is when the measure $\mu$ belongs to an arbitrary but known class $\mathcal{C}$ of process measures. The non-realizable case is when $\mu$ is completely arbitrary, but the prediction performance is measured with respect to a given set $\mathcal{C}$ of process measures. We are interested in the relations between these problems and between their solutions, as well as in characterizing the cases when a solution exists, and finding these solutions. In this work [13] we show that if the quality of prediction is measured by total variation distance, then these problems coincide, while if it is measured by expected average KL-divergence, then they are different. For some of the formalizations we also show that when a solution exists, it can be obtained as a Bayes mixture over a countable subset of $\mathcal{C}$. As an illustration to the
general results obtained, we show that a solution to the non-realizable case of the sequence prediction problem exists for the set of all finite-memory processes, but does not exist for the set of all stationary processes.

6.3.2. Statistical inference

We continue to obtain new results using the theoretical framework developed recently for studying time series generated by stationary ergodic time series. This year, new results obtained include a topological characterizing of composite hypotheses for which consistent tests exist, as well as new results on clustering.

6.3.2.1. A criterion for the existence of consistent tests

The most general result that we have obtained [14] on hypothesis testing provides a complete characterization (necessary and sufficient conditions) for the existence of a consistent test for membership to an arbitrary family $H_0$ of stationary ergodic discrete-valued processes, against $H_1$ which is the complement of $H_0$ to this class of processes. The criterion is that $H_0$ has to be closed in the topology of distributional distance, and closed under taking ergodic decompositions of its elements.

6.3.3. Clustering

6.3.3.1. Online clustering of time series

An asymptotically consistent algorithm has been proposed for the problem of online clustering of time series. There is a growing body of time series samples, each of which grows with time. On each time step, it is required to group these time series into $k$ clusters. It is known that each of the time series is generated by one out of known stationary ergodic distributions. An algorithm is proposed that, for each fixed portion of samples, eventually (with probability 1) puts into the same group those and only those samples that were generated by the same distribution. Empirical performance of the algorithm is evaluated on synthetic and real data.

6.3.3.2. Clustering of ranked data

We introduced [47] a novel approach to clustering rank data on a set of possibly large cardinality $n \in \mathbb{N}^*$, relying upon Fourier representation of functions defined on the symmetric group $\mathfrak{S}_n$. In the proposed setup, covering a wide variety of practical situations, rank data are viewed as distributions on $\mathfrak{S}_n$. Cluster analysis aims at segmenting data into homogeneous subgroups, hopefully very dissimilar in a certain sense. Whereas considering dissimilarity measures/distances between distributions on the non commutative group $\mathfrak{S}_n$, in a coordinate manner by viewing it as embedded in the set $[0, 1]^n$ for instance, hardly yields interpretable results and leads to face obvious computational issues, evaluating the closeness of groups of permutations in the Fourier domain may be much easier in contrast. Indeed, in a wide variety of situations, a few well-chosen Fourier (matrix) coefficients may permit to approximate efficiently two distributions on $\mathfrak{S}_n$ as well as their degree of dissimilarity, while describing global properties in an interpretable fashion. Following in the footsteps of recent advances in automatic feature selection in the context of unsupervised learning, we propose to cast the task of clustering rankings in terms of optimization of a criterion that can be expressed in the Fourier domain in a simple manner.

6.4. Supervised learning

6.4.1. Regression and classification

- **Sparse Recovery with Brownian Sensing [19].**

  We consider the problem of recovering the parameter $\alpha$ of a sparse function $f$ (i.e. the number of non-zero entries of $\alpha$ is small compared to the number $K$ of features) given noisy evaluations of $f$ at a set of well-chosen sampling points. We introduce an additional randomization process, called Brownian sensing, based on the computation of stochastic integrals, which produces a Gaussian sensing matrix, for which good recovery properties are proven, independently on the number of
sampling points \( N \), even when the features are arbitrarily non-orthogonal. Under the assumption that \( f \) is Hölder continuous with exponent at least \( 1/2 \) we provide an estimate of the parameter with quadratic error \( O(||\eta||/N) \), where \( \eta \) is the observation noise. The method uses a set of sampling points uniformly distributed along a one-dimensional curve selected according to the features. We report numerical experiments illustrating our method.

- **Operator-valued Kernels for Nonlinear FDA** [31], [38], [30], [53] Following the extension of RKHS to functional setting [74], we further developed this work in [38] for functional supervised classification.

  We introduced a set of rigorously defined operator-valued kernels that can be valuably applied to nonparametric operator learning when input and output data are continuous smooth functions, and we have showed their use for solving the problem of minimizing a \( L^2 \)-regularized functional in the case of functional outputs without the need to discretize covariate and target functions [53].

  The framework developed can also be applied when the input data are both discrete and continuous [30].

  Our fully functional approach has been successfully applied to the problems of speech inversion [31] and sound recognition [38], showing that the proposed framework is particularly relevant for audio signal processing applications where attributes are really functions and dependent of each other.

  This work is done in collaboration with Francis Bach (INRIA, Sierra), Alain Rakotomamonjy and Stéphane Canu (LITIS, Rouen).

- **Datum-wise representation** [44], [54]. We consider supervised classification. We introduce the concept of datum-wise representation for supervised classification [44]. While traditional approaches yield a “best” representation at the data space level, that is, the same representation is used for all the data, we proposed the idea, as well as an algorithm, that yields the “best” representation for each data. Among other appealing properties, this leads to sparse representation of each data, and an averaged sparser representation of each data in the data space. Along a classifier, the learning algorithm produces a “representer”, that is a function that yields a representation given a data.

  We further improved this approach to encompass various settings which are traditionally kept as different (cost-sensitive classification and different structured sparsity) [54].

- **Iso-regularization descent** [1]. Manuel Loth has defended his PhD dissertation [1] where he has provided a detailed presentation and analysis of his algorithm to solve the LASSO. This algorithm is very efficient. It is an active set algorithm that solves the LASSO by considering it a convex problem with linear constraints.

- **Learning with few examples** [41], [64]. Christophe Salperwyck has studied the performance of various classifiers when few examples are available. This is an important point in incremental learning, and few studies have been devoted to this particular setting. Performance we are accustomed to when the examples are quite numerous are severely disturbed in this setting. For more details, please see [41], [64].

- **Incremental discretization** [40]. In incremental learning, discretization should be adaptive in order to cope with the values of the attributes that are observed. This issue is currently under study by Christophe Salperwyck [40].

### 6.5. Sensors Networks: Tracking, Localization and Communication

**Participants:** Emmanuel Delande, Emmanuel Duflos, Pierre Chainais, Philippe Vanheeghe.
6.5.1. The sensor management problem

The aim of this work is to manage a set of sensors to track vehicles or groups of people in land applications. Our work focuses on sensor management in the frame of the random finite sets where the Probability Hypothesis Density (PHD) is a well-known method for single-sensor multi-target tracking problems in a Bayesian framework, but the extension to the multi-sensor case seems to remain a challenge. We have proposed an extension of Mahler’s work to the multi-sensor case by providing an expression of the true PHD multi-sensor data update equation. Then, based on the configuration of the sensors fields of view (FOVs), a joint partitioning of both the sensors and the state space provides an equivalent yet more practical expression of the data update equation, allowing a more effective implementation in specific FOV configurations ([70]). This work is done in collaboration with Thales Communications. The multi-sensor / multi-target filtering problem by using PHD filtering methods are topics developed in the PhD thesis of Emmanuel Delande. This PhD thesis entitled “Multi-sensor PHD filtering with application to sensor management” will be defended in December 2011. In addition to the different questions described above, see also [22] and [23]. Then, a new approach using operational objectives, related to the type of application, for sensor manager is proposed.

6.5.2. Statistical signal processing: application to civil engineering

We have obtained a PICS (International Project for Scientific Cooperation) from the CNRS in 2008 for 3 years to work in cooperation with the Department of Civil and Environmental Engineering of the University of Waterloo (Canada). During this cooperation we have developed a belief functions based method to track the building materials on a construction site. ([71]). Based on this cooperation, during 2011 a new common research project with the same department of the University of Waterloo has been built, and is actually submitted for funding. The topic of this project is the using of nonparametric Bayesian models in the area of Non-destructive Testing.

6.5.3. Accurate Localization using Satellites in Urban Canyons

Today, Global Navigation Satellite Systems (GNSS) have penetrated the transport field through applications such as monitoring of containers. These applications do not necessarily request a high availability, integrity and accuracy of the positioning system. For safety applications (as complete guidance of autonomous vehicles), performances require to be more stringent. For, sensors may deliver very erroneous measurements because of such hard external conditions which reduce significantly the possibilities to receive direct signals. The consequences of environmental obstructions are unavailability of the service and reception of reflected signals that degrades in particular the accuracy of the positioning. Indeed, NLOS (Non Line Of Sight) signals, i.e. signals received after reflections on the surrounding obstacles, frequently occur in dense environments and degrade localization accuracy because of the delays observed on the propagation time measurement creating additional error on pseudorange estimation. In the previous years we have proposed new algorithms to improve the localization precision. This algorithm are based on two principles : a jump multimodel approach and a joint state - noise density estimation. We have focused this year on an approach using Dirichlet Process Mixture to track the noise density in urban canyon while estimating the position of the vehicle. Algorithm have been validated on real data collected in a French town : Belfort. Nicolas Viandier has defended his PhD on this subject on June 2011. ([76], [75], [84], [85], [4]). These results will be presented to the Workshop Non Parametric Bayes at the NIPS Conference en Decembre 2011 ([62]) and to the ICASSP 2011 Conference ([37]).

6.5.4. Internet of Things : Mitigation of Impulsive Noise Effects

The term “Internet of Things” has come to describe a number of technologies and research disciplines that enable the Internet to reach out into the real world of physical objects. Technologies like RFID, short-range wireless communications, real-time localization and sensor networks are now becoming increasingly common, bringing the Internet of Things into commercial use. In such applications the data sent by a thing to another may generate an impulse noise in the reception channel of objects in the neighbourhood. The noise appearing in such applications can be considered as $\alpha$-stable. In this context, we’ve tackled the problem of interference mitigation in ad hoc networks. In such context, the multiple access interference (MAI) is known to be of an
impulsive nature. Therefore, the conventional Gaussian assumption cannot be considered to model this type of interference. Contrariwise, it can be accurately modeled by stable distributions. Here, this issue is addressed within an Orthogonal Frequency Division Multiplexing (OFDM) transmission link assuming a symmetric $\alpha$-stable model for the signal distortion due to MAI. We have proposed a method for the joint estimation of the transmitted multicarrier signal and the noise parameters. Based on sequential Monte Carlo (SMC) methods, the proposed scheme allows the online estimation using a Rao-Blackwellized particle filter. These results have been presented to the International Conference on Acoustics, Speech, and Signal Processing (ICASSP 2011) [29]. We are now focusing on Bayesian non-linear filtering with non-stationary alpha stable measurement noise. We have shown that a Dirichlet Process Mixture can improve the estimation by modeling the noise by both an infinite Cauchy mixture or an infinite alpha stable mixture. These first results will be presented to the Workshop Non Parametric Bayes at the NIPS Conference in December 2011 [62].

6.5.5. Image processing and statistical image modeling

Pierre Chainais arrived in SequeL in September 2010 with the purpose of a thematic evolution toward non-parametric Bayesian approaches. This represents an important investment in very new directions on an emerging topic at the interface between machine learning and signal/image processing. Discussions have begun with Emmanuel Duflos and Philippe Vanheeghe on the use of non-parametric Bayesian approaches to blind deconvolution of noisy natural images. The main objective is to use together the typical structure and sparsity of space-scale representations of images.

Pierre Chainais has continued working on several older projects. One of them deals with the segmentation of nanotubes in microscopic imaging [12], [43]. B. Lebental at IFFSTAR works on the conception of new nano-sensors based on the use of carbon nanotubes to build a nano-membrane. P. Chainais has developed an image processing pipeline to analyse images of these nanomembranes so as to characterize their properties in a precise and objective manner. Among other properties, the histograms of orientations of the nanotubes is provided. This tool will be very useful since such nanosensors are becoming more and more common.

In solar astronomy [7], [21], we have proposed a tool for the virtual super-resolution of scale invariant textured images. The aim of this project was to provide astronomers with plausible high-resolution images to calibrate next generation spatial telescopes. In particular, our images can be used to optimize the compression algorithm to be embedded in a spatial telescope. In collaboration with M. Chevaldonné and J.-M. Favreau (Université Clermont-Ferrand I), we work a software for texture synthesis on 3D surfaces [42] based on multifractal processes. A first version of the software is under current development. More marginal is our work on the use of stochastic processes for the simulation of turbulent pressure fields in collaboration with M. Pachebat (Laboratoire de Mécanique et d’Acoustique de Marseille) and Nicolas Totaro (LVA, INSA Lyon).
6. New Results

6.1. Aggregation methods for optical flow computation

Participants: Charles Kervrann, Denis Fortun.

We address the problem of optical flow estimation, that is recovering the dense apparent motion of the pixels in a sequence of images. It is a fundamental computer vision task at the basis of a large variety of applications: object tracking, video compression, motion segmentation, movement detection, 3D reconstruction . . . Most of state-of-the art methods rely on a common global variational framework \[ 22 \], \[ 31 \]. Computing optical flow amounts to minimizing a global energy. Our experiments demonstrated that the restriction of the minimization to local regions yields significant improvements of the estimation. Motivated by this fact, we developed a novel method to take advantage of this local approach by deriving the global estimate of the flow field from an aggregation of several local estimates. Our work can thus be seen as a general semi-local framework which can be used to improve the performance of any global variational method (Figure 3 ). We evaluated the performance of our approach on real and synthetic sequences. We investigate adaptations of this methodology to time-lapse fluorescence microscopy and we have recently performed comparisons with usual correlation techniques.

6.2. Lifetime estimation of moving vesicles in FLIM microscopy

Participants: Charles Kervrann, Philippe Roudot.

Fluorescence lifetime imaging microscopy (FLIM) is a widely spread imaging technique for sensing fluorophore environment in a living biological sample (like pH, ions...). Fluorescence lifetime (i.e. the average time a fluorophore stays in excited state before relaxing to its ground state possibly emitting a photon) is particularly useful to detect the Förster resonance energy transfer (FRET) which quantifies spatial proximity between molecules. We have proposed a statistical framework that exploits the intensity model of the frequency-domain FLIM output to jointly estimate trajectories and lifetimes of tracked vesicles. The proposed tracker, inspired from template cross-correlation or gaussian fitting, combines lifetime estimation and robust M-estimation in a efficient and fast way. Estimation of movement and lifetime are decoupled and alternatively performed, while particle/spot detection is performed on the first frame (Figure 4 ). To improve the results on real image sequences depicting moving vesicles, the background (cytoplasmic auto-fluorescence) model parameters and the scale parameters involved in the M-estimation procedure are estimated in our approach.

Partner:: F. Waharte and J. Boulanger (UMR 144 CNRS PICT IBiSA Institut Curie)

6.3. Repetitive and transient event detection in fluorescence video-microscopy

Participants: Charles Kervrann, Pierre Hellier.

Progresses in imaging dynamic behaviours of molecules including fast video microscopy and the application of evanescent wave microscopy have allowed to image intracellular vesicular movements, exocytosis and endocytosis of fluorescent-tagged proteins. For an unbiased quantification of repetitive and transient events, we have proposed an approach which is versatile enough, to be applicable to diverse although complementary modes of microscopy. The proposed detection method described in \[ 21 \], \[ 11 \], \[ 16 \] can be decomposed into three main steps: i) a first pre-processing step is dedicated to the normalization of the image sequence; ii) the second step is the patch-based detection procedure to detect unusual patterns; iii) a third post-processing step allows us to cluster and count detected events in space and time. In a more recent case study, we have used this approach to analyse image sequences depicting M10 cells stably expressing Langerin-YFP and to get deeper insights in the recycling pathway and dynamics of this molecule.
Figure 3. Average Angular Error (AAE) of vector flows obtained with the global variational method and three aggregation methods applied to three image sequences of the Middlebury (http://vision.middlebury.edu/flow/) database: row #1: first frame of the sequence; row #2: global variational method; row #3: mean aggregation; row #4: confidence-based weighted average; row #5: graph cut aggregation.
6.4. Atlas creation of fluorescence microscopy images

Participant: Pierre Hellier.

In this work, we consider the analysis of fluorescence images over time to account for two artifacts: fluorescence decreasing over time and geometric misalignment. A single exponential function is most commonly used to represent measured fluorescence decay profiles due to photobleaching. Accordingly, homologous points need to be geometrically aligned over time. Unfortunately the living cell exhibits slow motion over time. We have considered the iterative estimation of both geometrical alignment and intensity correction by the creation of a 3D atlas.

6.5. Averaging of 3D volumes and denoising for the analysis of cryo-electron tomograms

Participant: Charles Kervrann.

Trichocysts are large vesicles secreted by the ciliated protozoa, Paramecium. They are characterized by the presence of large three-dimensional crystals of proteins. Under chemical or physical stimuli, or facing a predator, trichocysts undergo an exocytosis, right after fusion of their membrane with the unicellular organism plasma membrane. The crystalline mesh changes its conformation from a condensed to an extended shape in a few milliseconds. Nowadays, cryo-electron tomography (cryo-ET) allows one to visualize those crystals and so, to analyse their three-dimensional organization. However, two main impediments remain with this method. Samples are very sensitive to electron radiation involving the spreading out of the electron dose on the whole tilt series, causing the emergence of background noise in the images. Moreover, a lack of data occurs during image acquisition, called the “missing wedge”, due to uncovered angles at the moment of the acquisition of the tilt series. After tomogram reconstruction of four trichocysts, we have tested usual denoising methods (anisotropic diffusion, Fourier coefficient thresholding) and an unpublished patch-based denoising method.
inspired from the nD-safir software \(^1\). The denoising methods improved the alignment of different crystal sub-volumes. The sub-volume averaging allowed us to fill in partially the “missing wedge” and then, to obtain a more faithful three-dimensional crystal reconstruction \(^1\), \(^2\). 

**Partners:** E. Pollet, A. Guesdon and D. Chrétien (UMR 6026 CNRS University of Rennes 1)

### 6.6. Analysis of spatio-temporal dynamics of cytoplasmic actin under geometrical confinement

**Participant:** Charles Kervrann.

The generation, cell-cycle regulation and maintenance of such cellular functions are often correlated with symmetry breaking and spatiotemporal reorganization of F-actin assembly. In this study, we analyzed the spatiotemporal evolution of actin filaments using Xenopus meiotic extracts artificially confined within a geometry mimicking the cell boundary. It turns out the confinement of the cytoplasm generates symmetry breaking in the spatial organization of actin filaments. Combination of quantitative image analysis and biochemical perturbations show that both spatial localization of F-actin nucleators and actin turnover play a decisive role in generating symmetry breaking. In this project, we proposed to combine an optical flow-based tracker (Kanade-Lucas-Tomasi tracker \(^4\), \(^5\)) to a photobleaching correction method in order to extract quantitative spatiotemporal characteristics of the actin dynamics.

**Partners:** Z. Gueroui (BioPhysics team, UMR 8640 Ecole Normale Superieure, Paris) and M. Pinot (UMR 144 CNRS Institut Curie, Paris)

### 6.7. Analysis of lateral organization of ordered domains at the plasma membrane surface

**Participant:** Charles Kervrann.

Modifications of plasma membrane physical properties are also known to be involved in the perception and response to environmental modifications such as temperature, mechanical and osmotic stress in various organisms. We have analysed a recently designed probe, di-4-ANEPPDHQ, that can change its fluorescent properties depending on whether it is residing in ordered or disordered phases of the tobacco cell plasma membranes. We performed a spatial analysis (covariograms, Markov Random Fields) of small (<200 nm) ordered domains observed in multispectral confocal microscopy. We focused on binary images, assumed to be realizations of a MRF-Ising model, depicting the spatial organization of ordered domains. Maximum pseudo-likelihood methods were investigated to estimate parameters able to describe the spatial properties of ordered domains. We analyzed the modifications of the whole plasma membrane fluidity, and the distribution of ordered domains occurring in the few minutes following addition of the elicitor of defense reaction cryptogein to tobacco cells.

**Partners:** P. Gerbeau-Pissot, F. Simon-Plas (UMR 1088 PME INRA, Dijon) and K. Kiêu (MIA Unit INRA, Jouy-en-Josas)
6. New Results

6.1. Local Component Analysis

**Participants:** Francis Bach, Nicolas Le Roux.

Kernel density estimation, a.k.a. Parzen windows, is a popular density estimation method, which can be used for outlier detection or clustering. With multivariate data, its performance is heavily reliant on the metric used within the kernel. Most earlier work has focused on learning only the bandwidth of the kernel (i.e., a scalar multiplicative factor). In this paper, we propose to learn a full Euclidean metric through an expectation-minimization (EM) procedure, which can be seen as an unsupervised counterpart to neighbourhood component analysis (NCA). In order to avoid overfitting with a fully nonparametric density estimator in high dimensions, we also consider a semi-parametric Gaussian-Parzen density model, where some of the variables are modelled through a jointly Gaussian density, while others are modelled through Parzen windows. For these two models, EM leads to simple closed-form updates based on matrix inversions and eigenvalue decompositions. We show empirically that our method leads to density estimators with higher test-likelihoods than natural competing methods, and that the metrics may be used within most unsupervised learning techniques that rely on such metrics, such as spectral clustering or manifold learning methods. Finally, we present a stochastic approximation scheme which allows for the use of this method in a large-scale setting [30].

6.2. Weakly Supervised Learning of Foreground-Background Segmentation using Masked RBMs

**Participant:** Nicolas Le Roux.

Collaboration with: Nicolas Heess (School of Informatics, University of Edinburgh) and John Winn (Machine Learning and Perception, Microsoft research Cambridge).

We propose an extension of the Restricted Boltzmann Machine (RBM) that allows the joint shape and appearance of foreground objects in cluttered images to be modeled independently of the background. We present a learning scheme that learns this representation directly from cluttered images with only very weak supervision. The model generates plausible samples and performs foreground-background segmentation. We demonstrate that representing foreground objects independently of the background can be beneficial in recognition tasks [15].

6.3. Clusterpath: an algorithm for clustering using convex fusion penalties

**Participants:** Toby Hocking, Francis Bach, Armand Joulin.

We present a new clustering algorithm by proposing a convex relaxation of hierarchical clustering, which results in a family of objective functions with a natural geometric interpretation. We give efficient algorithms for calculating the continuous regularization path of solutions, and discuss relative advantages of the parameters. Our method experimentally gives state-of-the-art results similar to spectral clustering for non-convex clusters, and has the added benefit of learning a tree structure from the data [16].

6.4. Convex and Network Flow Optimization for Structured Sparsity

**Participants:** Rodolphe Jenatton, Guillaume Obozinski, Francis Bach.

Collaboration with: Julien Mairal (Department of Statistics, University of California, Berkeley).
In [5], we consider a class of learning problems regularized by a structured sparsity-inducing norm defined as the sum of $\ell_2$- or $\ell_\infty$-norms over groups of variables. Whereas much effort has been put in developing fast optimization techniques when the groups are disjoint or embedded in a hierarchy, we address here the case of general overlapping groups. To this end, we present two different strategies: On the one hand, we show that the proximal operator associated with a sum of $\ell_\infty$-norms can be computed exactly in polynomial time by solving a quadratic min-cost flow problem, allowing the use of accelerated proximal gradient methods. On the other hand, we use proximal splitting techniques, and address an equivalent formulation with non-overlapping groups, but in higher dimension and with additional constraints. We propose efficient and scalable algorithms exploiting these two strategies, which are significantly faster than alternative approaches. We illustrate these methods with several problems such as CUR matrix factorization, multi-task learning of tree-structured dictionaries, background subtraction in video sequences, image denoising with wavelets, and topographic dictionary learning of natural image patches.

### 6.5. Multi-scale Mining of fMRI data with Hierarchical Structured Sparsity

**Participants:** Rodolphe Jenatton, Guillaume Obozinski, Francis Bach.

Collaboration with: Alexandre Gramfort, Vincent Michel, Evelyn Eger and Bertrand Thirion (Laboratoire de Neuroimagerie Assistée par Ordinateur (LNAO), CEA: DSV/I2BM/NEUROSPIN, PARIETAL (INRIA Saclay - Ile de France) and Neuroimagerie cognitive, INSERM: U992 – Université Paris Sud – CEA).

Inverse inference, or “brain reading”, is a recent paradigm for analyzing functional magnetic resonance imaging (fMRI) data, based on pattern recognition and statistical learning. By predicting some cognitive variables related to brain activation maps, this approach aims at decoding brain activity. Inverse inference takes into account the multivariate information between voxels and is currently the only way to assess how precisely some cognitive information is encoded by the activity of neural populations within the whole brain. However, it relies on a prediction function that is plagued by the curse of dimensionality, since there are far more features than samples, i.e., more voxels than fMRI volumes. To address this problem, different methods have been proposed, such as, among others, univariate feature selection, feature agglomeration and regularization techniques. In this paper, we consider a sparse hierarchical structured regularization. Specifically, the penalization we use is constructed from a tree that is obtained by spatially-constrained agglomerative clustering. This approach encodes the spatial structure of the data at different scales into the regularization, which makes the overall prediction procedure more robust to inter-subject variability. The regularization used induces the selection of spatially coherent predictive brain regions simultaneously at different scales. We test our algorithm on real data acquired to study the mental representation of objects, and we show that the proposed algorithm non only delineates meaningful brain regions but yields as well better prediction accuracy than reference methods [24], [17].

### 6.6. Convergence Rates of Inexact Proximal-Gradient Methods for Convex Optimization

**Participants:** Mark Schmidt, Nicolas Le Roux, Francis Bach.

In [21], we consider the problem of optimizing the sum of a smooth convex function and a non-smooth convex function using proximal-gradient methods, where an error is present in the calculation of the gradient of the smooth term or in the proximity operator with respect to the non-smooth term. We show that both the basic proximal-gradient method and the accelerated proximal-gradient method achieve the same convergence rate as in the error-free case, provided that the errors decrease at appropriate rates. Using these rates, we perform as well as or better than a carefully chosen fixed error level on a set of structured sparsity problems.

### 6.7. Generalized Fast Approximate Energy Minimization via Graph Cuts: Alpha-Expansion Beta-Shrink Moves

**Participant:** Mark Schmidt.
Collaboration with: Karteek Alahari (Willow project-team, INRIA Paris-Rocquencourt).

In [20], we present alpha-expansion beta-shrink moves, a simple generalization of the widely-used alpha-beta swap and alpha-expansion algorithms for approximate energy minimization. We show that in a certain sense, these moves dominate both alpha-beta-swap and alpha-expansion moves, but unlike previous generalizations the new moves require no additional assumptions and are still solvable in polynomial-time. We show promising experimental results with the new moves, which we believe could be used in any context where alpha-expansions are currently employed.

6.8. Hybrid Deterministic-Stochastic Methods for Data Fitting

Participant: Mark Schmidt.

Collaboration with: Michael P. Friedlander (University of British Columbia).

Many structured data-fitting applications require the solution of an optimization problem involving a sum over a potentially large number of measurements. Incremental gradient algorithms offer inexpensive iterations by sampling only subsets of the terms in the sum. These methods can make great progress initially, but often slow as they approach a solution. In contrast, full gradient methods achieve steady convergence at the expense of evaluating the full objective and gradient on each iteration. We explore hybrid methods that exhibit the benefits of both approaches. Rate of convergence analysis shows that by controlling the size of the subsets in an incremental gradient algorithm, it is possible to maintain the steady convergence rates of full gradient methods. We detail a practical quasi-Newton implementation based on this approach, and numerical experiments illustrate its potential benefits [29].

6.9. Multi-task regression using minimal penalties

Participants: Matthieu Solnon, Sylvain Arlot, Francis Bach.

In [33] we study the kernel multiple ridge regression framework, which we refer to as multi-task regression, using penalization techniques. The theoretical analysis of this problem shows that the key element appearing for an optimal calibration is the covariance matrix of the noise between the different tasks. We present a new algorithm to estimate this covariance matrix, based on the concept of minimal penalty, which was previously used in the single-task regression framework to estimate the variance of the noise. We show, in a non-asymptotic setting and under mild assumptions on the target function, that this estimator converges towards the covariance matrix. Then plugging this estimator into the corresponding ideal penalty leads to an oracle inequality. We illustrate the behavior of our algorithm on synthetic examples.

6.10. Ask the locals: multi-way local pooling for image recognition

Participants: Nicolas Le Roux, Francis Bach.

Collaboration with: Y-Lan Boureau and Jean Ponce (Willow project-team, INRIA Paris-Rocquencourt) and Yann LeCun (Courant Institute of Mathematical Science (CIMS), New York University).

Invariant representations in object recognition systems are generally obtained by pooling feature vectors over spatially local neighborhoods. But pooling is not local in the feature vector space, so that widely dissimilar features may be pooled together if they are in nearby locations. Recent approaches rely on sophisticated encoding methods and more specialized codebooks (or dictionaries), e.g., learned on subsets of descriptors which are close in feature space, to circumvent this problem. In this work, we argue that a common trait found in much recent work in image recognition or retrieval is that it leverages locality in feature space on top of purely spatial locality. We propose to apply this idea in its simplest form to an object recognition system based on the spatial pyramid framework, to increase the performance of small dictionaries with very little added engineering. State-of-the-art results on several object recognition benchmarks show the promise of this approach [12].
6.11. **Trace Lasso: a trace norm regularization for correlated designs**  
**Participants:** Edouard Grave, Guillaume Obozinski, Francis Bach.  

Using the $\ell_1$-norm to regularize the estimation of the parameter vector of a linear model leads to an unstable estimator when covariates are highly correlated. In this paper, we introduce a new penalty function which takes into account the correlation of the design matrix to stabilize the estimation. This norm, called the trace Lasso, uses the trace norm of the selected covariates, which is a convex surrogate of their rank, as the criterion of model complexity. We analyze the properties of our norm, describe an optimization algorithm based on reweighted least-squares, and illustrate the behavior of this norm on synthetic data, showing that it is more adapted to strong correlations than competing methods such as the elastic net [14].

6.12. **Shaping level sets through submodular functions**  
**Participant:** Francis Bach.  

The concept of parsimony is central in many scientific domains. In the context of statistics, signal processing or machine learning, it may take several forms. Classically, in a variable or feature selection problem, a sparse solution with many zeros is sought so that the model is either more interpretable, cheaper to use, or simply matches available prior knowledge. In this work, we instead consider sparsity-inducing regularization terms that will lead to solutions with many equal values. A classical example is the total variation in one or two dimensions, which leads to piecewise constant solutions and can be applied to various image labelling problems, or change point detection tasks. In this work [9], we follow our earlier approach which consisted in designing sparsity-inducing norms based on non-decreasing submodular functions, as a convex approximation to imposing a specific prior on the supports of the predictors. Here, we show that a similar parallel holds for some other class of submodular functions, namely non-negative setfunctions which are equal to zero for the full and empty set. Our main instance of such functions are symmetric submodular functions and we show that the Lovász extension may be seen as the convex envelope of a function that depends on level sets (i.e., the set of indices whose corresponding components of the underlying predictor are greater than a given constant). By selecting specific submodular functions, we give a new interpretation to known norms, such as the total variation; we also define new norms, in particular ones that are based on order statistics with application to clustering and outlier detection, and on noisy cuts in graphs with application to change point detection in the presence of outliers.

6.13. **Itakura-Saito Nonnegative Matrix Factorization with group sparsity**  
**Participants:** Augustin Lefèvre, Francis Bach.  

Collaboration with: Cédric Févotte (Laboratoire traitement et communication de l’information (LTCI), CNRS: UMR5141 – Institut Télécom – Télécom ParisTech).  

In [18], we propose an unsupervised inference procedure for audio source separation. Components in nonnegative matrix factorization (NMF) are grouped automatically in audio sources via a penalized maximum likelihood approach. The penalty term we introduce favors sparsity at the group level, and is motivated by the assumption that the local amplitude of the sources are independent. Our algorithm extends multiplicative updates for NMF; moreover we propose a test statistic to tune hyperparameters in our model, and illustrate its adequacy on synthetic data. Results on real audio tracks show that our sparsity prior allows to identify audio sources without knowledge on their spectral properties.

6.14. **Online algorithms for nonnegative matrix factorization with the Itakura-Saito divergence**  
**Participants:** Augustin Lefèvre, Francis Bach.  

Collaboration with: Cédric Févotte (Laboratoire traitement et communication de l’information (LTCI), CNRS: UMR5141 – Institut Télécom – Télécom ParisTech).
Nonnegative matrix factorization (NMF) is now a common tool for audio source separation. When learning NMF on large audio databases, one major drawback is that the complexity in time is \( O(FKN) \) when updating the dictionary (where \((F;N)\) is the dimension of the input power spectrograms, and \(K\) the number of basis spectra), thus forbidding its application on signals longer than an hour. We provide an online algorithm with a complexity of \( O(FK) \) in time and memory for updates in the dictionary. We show on audio simulations that the online approach is faster for short audio signals and allows to analyze audio signals of several hours [31].

6.15. A Graph-matching Kernel for Object Categorization

**Participant:** Armand Joulin.

Collaboration with: Olivier Duchenne and Jean Ponce (Willow project-team, INRIA Paris-Rocquencourt).

In [13], we address the problem of category-level image classification. The underlying image model is a graph whose nodes correspond to a dense set of regions, and edges reflect the underlying grid structure of the image and act as springs to guarantee the geometric consistency of nearby regions during matching. A fast approximate algorithm for matching the graphs associated with two images is presented. This algorithm is used to construct a kernel appropriate for SVM-based image classification, and experiments with the Caltech 101, Caltech 256, and Scenes datasets demonstrate performance that matches or exceeds the state of the art for methods using a single type of features.

**Participant:** Guillaume Obozinski.

Collaboration with: Laurent Jacob (Department of Statistics, University of California at Berkeley) and Jean-Philippe Vert (INSERM U900, Mines ParisTech, Institut Curie).

We study in [25] a norm for structured sparsity which leads to sparse linear predictors whose supports are unions of predefined overlapping groups of variables. We call the obtained formulation latent group Lasso, since it is based on applying the usual group Lasso penalty on a set of latent variables. A detailed analysis of the norm and its properties is presented and we characterize conditions under which the set of groups associated with latent variables are correctly identified. We motivate and discuss the delicate choice of weights associated to each group, and illustrate this approach on simulated data and on the problem of breast cancer prognosis from gene expression data.

6.17. Sparse Image Representation with Epitomes

**Participants:** Louise Benoît, Francis Bach.

Collaboration with: Julien Mairal (Department of Statistics, University of California, Berkeley) and Jean Ponce (Willow project-team, INRIA Paris-Rocquencourt).

Sparse coding, which is the decomposition of a vector using only a few basis elements, is widely used in machine learning and image processing. The basis set, also called dictionary, is learned to adapt to specific data. This approach has proven to be very effective in many image processing tasks. Traditionally, the dictionary is an unstructured "flat" set of atoms. In this work, we study structured dictionaries which are obtained from an epitome, or a set of epitomes. The epitome is itself a small image, and the atoms are all the patches of a chosen size inside this image. This considerably reduces the number of parameters to learn and provides sparse image decompositions with shift invariance properties. We propose a new formulation and an algorithm for learning the structured dictionaries associated with epitomes, and illustrate their use in image denoising tasks. This work has resulted in a CVPR’11 publication [11].

6.18. Dictionary Learning for Deblurring and Digital Zoom

**Participant:** Florent Couzinié-Devy.
The paper [23] proposes a novel approach to image deblurring and digital zooming using sparse local models of image appearance. These models, where small image patches are represented as linear combinations of a few elements drawn from some large set (dictionary) of candidates, have proven well adapted to several image restoration tasks. A key to their success has been to learn dictionaries adapted to the reconstruction of small image patches [35]. In contrast, recent works have proposed instead to learn dictionaries which are not only adapted to data reconstruction, but also tuned for a specific task [34]. We introduce here such an approach to deblurring and digital zoom, using pairs of blurry/sharp (or low-/high-resolution) images for training, as well as an effective stochastic gradient algorithm for solving the corresponding optimization task. Although this learning problem is not convex, once the dictionaries have been learned, the sharp/high-resolution image can be recovered via convex optimization at test time. Experiments with synthetic and real data demonstrate the effectiveness of the proposed approach, leading to state-of-the-art performance for non-blind image deblurring and digital zoom.

6.19. Robust linear least squares regression

Participant: Jean-Yves Audibert.

Collaboration with: Olivier Catoni (École Normale Supérieure, CNRS and INRIA Paris-Rocquencourt, Classic project-team)

In [26], we consider the problem of robustly predicting as well as the best linear combination of d given functions in least squares regression, and variants of this problem including constraints on the parameters of the linear combination. For the ridge estimator and the ordinary least squares estimator, and their variants, we provide new risk bounds of order d/n without logarithmic factor unlike some standard results, where n is the size of the training data. We also provide a new estimator with better deviations in presence of heavy-tailed noise. It is based on truncating differences of losses in a min-max framework and satisfies a d/n risk bound both in expectation and in deviations. The key common surprising factor of these results is the absence of exponential moment condition on the output distribution while achieving exponential deviations. All risk bounds are obtained through a PAC-Bayesian analysis on truncated differences of losses. Experimental results strongly back up our truncated min-max estimator. This work is to appear in the Annals of Statistics in 2012.

6.20. Semantic hierarchies for image annotation

Participant: Jean-Yves Audibert.

Collaboration with: Anne-Marie Tousch (École des Ponts and ONERA) and Stéphane Herbin (ONERA)

In the survey [6], we argue that using structured vocabularies is capital to the success of image annotation. We analyze literature on image annotation uses and user needs, and we stress the need for automatic annotation. We briefly expose the difficulties posed to machines for this task and how it relates to controlled vocabularies. We survey contributions in the field showing how structures are introduced. First we present studies that use unstructured vocabulary, focusing on those introducing links between categories or between features. Then we review work using structured vocabularies as an input and we analyze how the structure is exploited.

6.21. Deviations of Stochastic Bandit Regret

Participant: Jean-Yves Audibert.

Collaboration with: Antoine Salomon (École des Ponts)

The work [19] studies the deviations of the regret in a stochastic multi-armed bandit problem. When the total number of plays n is known beforehand by the agent, previous works exhibit a policy such that with probability at least 1 − 1/n, the regret of the policy is of order log n. They have also shown that such a property is not shared by the popular UCB1 policy. This work first answers an open question; it extends this negative result to any anytime policy. The second contribution of this paper is to design anytime robust policies for specific multi-armed bandit problems in which some restrictions are put on the set of possible distributions of the different arms.
6.22. Minimax Policies for Combinatorial Prediction Games

Participant: Jean-Yves Audibert.

Collaboration with: Sébastien Bubeck (Centre de Recerca Matematica of Barcelona) and Gabor Lugosi (ICREA and Pompeu Fabra University)

In [8], we address the online linear optimization problem when the actions of the forecaster are represented by binary vectors. Our goal is to understand the magnitude of the minimax regret for the worst possible set of actions. We study the problem under three different assumptions for the feedback: full information, and the partial information models of the so-called “semi-bandit”, and “bandit” problems. We consider both $L_{\infty}$- and $L_2$-type of restrictions for the losses assigned by the adversary. We formulate a general strategy using Bregman projections on top of a potential-based gradient descent, which generalizes the ones studied in numerous recent works. We provide simple proofs that recover most of the previous results. We propose new upper bounds for the semi-bandit game. Moreover we derive lower bounds for all three feedback assumptions. With the only exception of the bandit game, the upper and lower bounds are tight, up to a constant factor. Finally, we answer an open question raised by W. M. Koolen, M. K. Warmuth, and J. Kivinen by showing that the exponentially weighted average forecaster is suboptimal against $L_{\infty}$ adversaries.

Participant: Francis Bach.

Collaboration with: Eric Moulines (Telecom ParisTech)

In [10], we consider the minimization of a convex objective function defined on a Hilbert space, which is only available through unbiased estimates of its gradients. This problem includes standard machine learning algorithms such as kernel logistic regression and least-squares regression, and is commonly referred to as a stochastic approximation problem in the operations research community. We provide a non-asymptotic analysis of the convergence of two well-known algorithms, stochastic gradient descent (a.k.a. Robbins-Monro algorithm) as well as a simple modification where iterates are averaged (a.k.a. Polyak-Ruppert averaging). Our analysis suggests that a learning rate proportional to the inverse of the number of iterations, while leading to the optimal convergence rate in the strongly convex case, is not robust to the lack of strong convexity or the setting of the proportionality constant. This situation is remedied when using slower decays together with averaging, robustly leading to the optimal rate of convergence. We illustrate our theoretical results with simulations on synthetic and standard datasets.
5. New Results

5.1. Statistical Physics

The analysis of multi-scale phenomena and asymptotic problems aiming at identifying the influence of microscopic scales on the macroscopic observations is a hot topic in the team. Results have been obtained concerning the derivation of effective law describing the behavior of a particle interacting with a thermal bath or a set of oscillators. This work, which combines modeling efforts, analysis and large computations, is the object of a longstanding collaboration with P. Parris (Missouri-Rolla) and is the heart of the PhD thesis of B. Aguer [37],[1]. More recently, S. De Bièvre and P. Parris have described the approach to equilibrium in such systems [11]. Transport in a related quantum mechanical model was studied in [6]. Some long time effective behavior of related models has been obtained in [58].

At the same time, M. Rousset is working on the numerical simulation of stochastically perturbed Molecular Dynamics. The main goal is to handle in the same simulation the fastest time scales (the oscillations of molecular bindings), and the slowest time scales (the so-called reaction coordinates). Recently, a monograph [60] has been published which summarized standard and state-of-the-art free energy calculations, that are used to accelerate slow variables in MD simulations. In [61] analysis of constrained dynamics is proposed, with associated numerical schemes. In [62], a new method has been proposed which drastically slows down the fast frequencies with a penalty and accelerates simulations, while conserving the statistical behavior of molecular systems.

Recently, in [64] M. Rousset has initiated some new research on variance reduction in hybrid methods, where a “fine-grained” model, typically a kinetic model, is simulated with particle/Monte-Carlo method, and the variance of the latter is reduced using the information of a “coarse-grained” model, a PDE computed with a grid method.

5.2. Hyperbolic Problems, Conservation laws and Gas Dynamics

The convergence analysis of numerical schemes for conservation laws with unstructured meshes with an original proof based on probabilistic argument is a striking result due to F. Lagoutière with F. Delarue, [56]. More generally, we refer to [59] for an overview of F. Lagoutière’s works.

J.-F. Coulombel has studied the stability of finite difference approximations of hyperbolic systems with boundary conditions. This series of works, part of which is a collaboration with A. Gloria, generalizes and simplifies previous results by Gustafsson, Kreiss, Tadmor, Wu and others. In collaboration with O. Guès and M. Williams, J.-F. Coulombel has also studied the justification of geometric optics for hyperbolic boundary value problems. The results describe the reflection of highly oscillating wave trains on a boundary. Eventually, J.-F. Coulombel has studied with S. Benzoni and N. Tzvetkov well-posedness issues for some nonlocal versions of Burgers equation.

5.3. Control in Fluid Mechanics

Results on active and passive control on the 3D Ahmed body in the 25° rear-window configuration were obtained in [4],[5],[21]. Moreover, results on the pressure wave generated by high-speed trains entering tunnels were published in [20].

5.4. Fluid/Particles Flows

We are interested in two-phase flows involving a dense and a disperse phase. These models lead to interesting mathematical questions, [38]. We develop new asymptotic preserving methods for fluid/particles flows [50]. This approach follows the scheme we developed for radiative transfer equations [51].
5.5. Plasma Physics

We obtained several results of asymptotic analysis concerning either kinetic or macroscopic models for charge transport, see [45], [44] and [52] (and we also refer to the related work [53]). Through the collaboration with Thales we proposed in [3] a method to compute numerically the boundary conditions for the Euler system derived from the BGK equation in the hydrodynamic limit. In particular this method is based on an analysis of boundary layers. In [7] we extend these techniques to the coupled Euler Poisson system.

5.6. Analysis and numerical simulation of the Schrödinger equation

The linear or nonlinear Schrödinger equation with potential is one of the basic equations of quantum mechanics and it arises in many areas of physical and technological interest, e.g. in quantum semiconductors, in electromagnetic wave propagation, and in seismic migration. The Schrödinger equation is the lowest order one-way approximation (paraxial wave equation) to the Helmholtz equation and is called Fresnel equation in optics, or standard parabolic equation in underwater acoustics. The solution of the equation is defined on an unbounded domain. If one wants to solve such a whole space evolution problem numerically, one has to restrict the computational domain by introducing artificial boundary conditions. So, the objective is to approximate the exact solution of the whole-space problem, restricted to a finite computational domain. A review article [39] was written this year to describe and compare the different current approaches of constructing and discretizing the transparent boundary conditions in one and two dimensions. However, these approaches are limited to the linear case (or nonlinear with the classical cubic nonlinearity: an article written was dedicated to this case this year [41]) and constant potentials. Therefore, in collaboration with X. Antoine (IECN Nancy and Inria Lorraine), we proposed to P. Klein to study, in her PhD thesis, the case of the Schrödinger equation with variable potentials. The study of the non-stationary one-dimensional case has already led to one publication [40] and some preliminary results in the stationary case are really promising. These cases are relevant since for example the equations appear in the Bose Einstein condensate with a quadratic potential.

This problem is obviously not limited to the Schrödinger equation and new developments are in progress on the Korteweg de Vries equation with M. Ehrhardt. This equation is more difficult to study due to its third order derivative in space.

Dispersive equations, such as the Schrödinger equation are also considered as boundary-value problems. For example, in [57], G.D. studies the long time asymptotics of the solutions of linear Schrodinger equations considered as initial-boundary value problems on the half-line and on bounded intervals when the boundary data are periodic functions of time. G.D. obtains theoretical results using a transformation method introduced by T. Fokas and provides several numerical experiments to support them.

The Diffusion Monte-Carlo method is a powerful strategy used by chemists to estimate the groundstate energy of a N-body Schrödinger Hamiltonian with high accuracy. However, the method suffers from two major limitations:

- The quantity of physical interest is more the energy variation with respect to a parameter than the energy itself.
- The case of Fermions (as electrons of atoms) relies on constraining the random walkers in some nodal pocket (which imposes skew-symmetry on the distribution of walkers) which is only approximately known (the Fixed Node Approximation).

In the article [63], Mathias Rousset proposed a new strategy for the case of Fermions to compute the energy variation with respect to a variation of the nodal pocket. The ultimate goal is to design a Monte-Carlo strategy able to optimize the Fixed Node Approximation.

5.7. Homogenization

We have three types of results regarding the homogenization theory and its applications.
The first series of results is related to nonlinear elasticity. In [2], A. Gloria has proved the convergence of a discrete model for rubber towards a nonlinear elasticity theory in collaboration with R. Alicandro and M. Cicalese. The numerical simulation of the model has been addressed within the ARC Disco by A. Gloria, P. La Tallec and M. Vidrascu (project team MACS). Comparisons with mechanical experiments are promising, and related inverse problems have been addressed in the post-doc of M. de Buhan. Two publications are in preparation. Related theoretical results in homogenization of nonlinear elasticity models have been obtained by A. Gloria and S. Neukamm (MPI Leipzig) in [15].

A second type of results concerns a quantitative theory of stochastic homogenization of discrete linear elliptic equations. A breakthrough has been obtained by A. Gloria and F. Otto (MPI Leipzig) in [16] and [17], who gave the first optimal variance estimate of the energy density of the corrector field for stochastic discrete elliptic equations. The proof makes extensive use of a spectral gap estimate and of deep elliptic regularity theory, bringing in fact the probabilistic arguments to a minimum. This analysis has enabled A. Gloria to propose efficient numerical homogenization methods, both in the discrete and continuous settings [13], [12]. In [14], A. Gloria and J. C. Mourrat has pushed the approach forward and introduced new approximation formulas for the homogenized coefficient. In [26] they have considered a more probabilistic approach and given a complete error analysis of a Monte-Carlo approximation of the homogenized coefficients in the discrete case. Work in progress concerns the generalization of the results on discrete elliptic equations to the continuous case.

The third direction of research concerns the periodic homogenization of a coupled elliptic/parabolic system arising in the modeling of nuclear waste storage. This work is in collaboration with the French agency ANDRA. A. Gloria, T. Goudon, and S. Krell have made a complete theoretical analysis of the problem, derived effective equations, and devised an efficient method to solve the effective problem numerically, based on the reduced basis approach. A publication is in preparation. This subject will be continued with the arrival of Z. Habibi.

5.8. Radiative Transfert

The interest of the team in developing efficient numerical methods preserving the asymptotic behavior of kinetic equations modelling the radiative transfer phenomena in the diffusive regime has recently brought two new innovative schemes. On the one hand, the moment closure equations proposed in [43] involve non local terms that lead to the formulation of specific numerical approximations. On the other hand, a new scheme [19] based on the projective integration procedure due to Gear and Kevrekidis was proved very efficient theoretically and numerically.

The team has also obtained a rigorous justification of the formation of so-called Zeldovich spikes in radiative shock profiles [32]. As long as the amplitude of the wave is sufficiently large, the temperature profile displays an overshoot. Such phenomenon does not occur for small amplitude waves, nor for viscous shock profiles.

5.9. Complex fluid flows

A numerical treatment [18] of phase transitions arising in the modelling of the behavior of polymers near glass transition by a non linear diffusion equation was conducted in the continuation of the theoretical results by Evans and Portilheiro and Mascia, Terracina and Tesei.

5.10. A posteriori error estimators for finite element methods

First, the generalization of [55] in the case of the full convection-reaction-diffusion case lead to robust estimators, for which the dependence of the constant in the data are explicitly given [8]. Then, we succeeded in obtaining some “asymptotic exact estimators” for the Reissner-Mindlin system in order to provide an accurate bound of the error, while keeping a reasonable computational cost [10], [24]. Finally, we obtained some residual-based a posteriori error estimators for the Maxwell system in its vectorial and scalar potential formulation [9], [23].
5. New Results

5.1. Modeling, observation and control: systems modeled by ordinary differential equations

5.1.1. Nonlinear system identification

Participants: Pierre-Alexandre Bliman, Michel Sorine, Qinghua Zhang.

Our current researches on nonlinear system identification are mainly in the framework of the joint Franco-Chinese ANR-NSFC EBONSI project (See Section 6.5), started in March 2011 for three years, in collaboration with the Laboratory of Industrial Process Monitoring and Optimization of Peking University and with Centre de Recherche en Automatique de Nancy (CRAN). Three topics have been studied this year: system identification with a continuous time autoregressive model, system identification with quantized data, and Hammerstein-Wiener system identification.

Though discrete time models are widely used in system identification, some advantages of continuous time models are also of practical importance, in particular, the ability of fully benefiting from fast sampling devices. Our studies on this topic have resulted in a continuous time black-box model structure for nonlinear system identification, together with an efficient model estimation method. This model structure belongs to the class of continuous time nonlinear ARX (AutoRegressive with eXogenous input) models, with the particularity of being integrable. By applying techniques of adaptive observer, models of the proposed structure can be efficiently estimated from input-output data. This result has been presented at the last Journées Identification et Modélisation Expérimentale [49].

System identification is usually based on sampled and quantized data, because of the important role of digital computers. When quantized data are coded with a sufficiently large number of bits, the effect of quantization is often ignored in the design of system identification methods. However, when data are quantized with few bits, sometimes to a single bit leading to binary data, then the effect of quantization must be explicitly taken into account. Data quantization can be modeled as a non differentiable hard nonlinearity, hence the well known gradient-based optimization methods cannot be used for the identification of such nonlinear systems. We have developed a quadratic programming-based method for system identification from quantized data, which, in contrast to most existing methods, can be applied to systems with general input excitations. This result has been presented at the last IFAC World Congress [46].

A Hammerstein-Wiener system is composed of a dynamic linear subsystem preceded and followed by two static nonlinearities. Typically, the nonlinearities of such a system is caused by actuator and sensor distortions. The identification of such systems with a continuous time model had been studied by colleagues of CRAN with the refined instrumental variable (RIV) method. Stable low-pass filters were used to overcome the difficulties related to the continuous time nature of the model. Our study of this year is about the application of the Kalman filter at the place of the previously used low-pass filters. The advantages of this new method include the stability of the numerical algorithm and the fact that the Kalman filter does not color white noises.

5.1.2. Model-based fault diagnosis

Participants: Abdouramane Moussa Ali, Qinghua Zhang.

The increasing requirements for higher performance, efficiency, reliability and safety of modern engineering systems call for continuous research investigations in the field of fault detection and isolation. In the framework of the MODIPRO project funded by Paris Region ASTech, we are currently studying model-based fault diagnosis for nonlinear systems. Motivated by an application in the MODIPRO project, the considered system is modeled by nonlinear algebro-differential equations, with the particularity that the differential part of the model is linear in state variables. Instead of using general numerical solvers of algebro-differential equations, we are developing a method based on ordinary differential equation solvers, by taking advantage of the particular algebro-differential structure of the considered system.
5.2. Observation, control and traveling waves in systems modeled by partial differential equations

5.2.1. Inverse scattering for soft fault diagnosis in electric transmission lines

Participants: Michel Sorine, Huaibin Tang, Qinghua Zhang.

The inverse scattering theory is helpful for efficient use of the reflectometry technology in the field of electric transmission line fault diagnosis. Our recent studies on this topic have been published in [35], [33], [32]. The main progress of this year in our study has been the experimental validation of the inverse scattering-based method for soft fault diagnosis. In collaboration with Florent Loete of LGEP (Laboratoire de Génie Electrique de Paris), we have tested the inverse scattering-based method on cables used in Trucks. By slightly separating the two wires of a twisted pair following a predefined spatial profile, a soft fault in the cable is physically simulated. The spatially smoothly varying characteristic impedance of the cable is computed from the physical and geometrical parameters of the cable, and also computed from the reflection coefficient measured with a network analyzer at one end of the cable. The two results are close enough to clearly detect and to locate the physically simulated soft fault from the measured reflection coefficient. A demonstration software has been developed and registered at Agence pour la Protection des Programmes (APP). See Section 4.2.

5.2.2. Modeling of electric transmission networks

Participants: Mohamed Oumri, Michel Sorine, Filippo Visco Comandini, Qinghua Zhang.

The increasing number and complexity of wired electric networks in modern engineering systems is amplifying the importance of the reliability of electric connections. In the framework of the ANR 0-DEFECT project, we have studied mathematical models of complex electric networks with the aim of designing an algorithm for fault diagnosis (see [34], [20] for some theoretical results). A generalization of the Baum-Liu-Tesche (BLT) equation to the case of inhomogeneous transmission lines has been developed this year. Efforts have been made in particular to elaborate a fully automatized method for numerical simulation of complex networks with inhomogeneous transmission lines. An efficient method has been designed for the computation of the propagation matrix of each inhomogeneous transmission line and also for the computation of the scattering matrix at each network node. The implemented numerical simulator is based on these propagation and scattering matrices associated to the BLT equation, and on a numerical solution of this equation.

5.2.3. Diagnosis of insulator degradation in long electric cables

Participants: Leila Djaziri, Michel Sorine, Huaibin Tang, Qinghua Zhang.

For the diagnosis of insulator degradation in long electric cables, the estimation of the shunt conductance of such cables have been studied, in the framework of the ANR INSCAN project. The shunt conductance of a healthy electric cable is usually very weak. Even when the insulator in the cable is significantly degraded, the shunt conductance can still remain at a quite low level. The main difficulty in this study is due to the fact that the measurements made at the ends of a cable are hardly sensitive to the variations of the shunt conductance. To overcome this difficulty, two methods have been studied. The first one is based on the processing of long time data records. It is designed for the estimation of distributed shunt conductance, in order to detect and to locate inhomogeneous degradation of the insulator. The main idea of this method is to compensate the weak sensitivity of the measurement by long time data records. Numerical simulations have confirmed its feasibility. The second method aims at assessing the average shunt conductance along a cable. It is based on the analysis of the sensitivity of the wave propagation velocity to the shunt conductance. This method is currently tested through experiments made on cables of SNCF (Société Nationale des Chemins de Fer français).

5.3. System theory approach of some quantum systems

5.3.1. Design of strict control-Lyapunov functions for quantum systems with QND measurements

Participants: Hadis Amini, Mazyar Mirrahimi, Pierre Rouchon.
We have proposed a feedback scheme for quantum systems undergoing discrete-in-time non-destructive measurements. Under some observability assumptions, the proposed feedback law ensures the stabilization of any desired equilibrium state of the measurement process. This theoretical contribution has given rise to a primary conference paper [40] and we are currently working on a more complete journal paper that proves the convergence in presence of various measurement noises and uncertainties. The proposed feedback scheme has been applied in a recent experiment realized by Serge Haroche and Jean-Michel Raimond’s group at Ecole Normale Supérieure and has given rise to a journal paper [29].

5.3.2. Approximate stabilization of an infinite dimensional quantum stochastic system

Participants: Ram Somaraju, Mazyar Mirrahimi, Pierre Rouchon.

Extending our previous feedback schemes dealing only with finite dimensional quantum systems, we have proven the approximate stabilization of any desired Fock state in the microwave cavity setup of Ecole Normale Supérieure. By appropriately choosing the Lyapunov function, we avoid the mass-loss phenomena through high energy levels and ensure the pre-compactness (in probability) of the trajectories. This work has given rise to a conference paper [48] and a submitted journal paper [56].

5.3.3. On stability of continuous-time quantum filters

Participants: Hadis Amini, Mazyar Mirrahimi, Pierre Rouchon.

We have studied the stability of quantum filters for continuous-in-time measurement processes. Indeed, we have proven that the filter between the quantum state governed by a continuous time stochastic master equation driven by a Wiener process and its associated quantum-filter state is a sub-martingale. This result has given rise to a conference paper [41].

5.4. Modeling, observation and control in biosciences - Reproductive system

5.4.1. Numerical simulation of the selection process of the ovarian follicles

Participants: Benjamin Aymard, Frédérique Clément.

Collaboration with Frédéric Coquel and Marie Postel.

We have designed and implemented a numerical method to simulate a multiscale model describing the selection process in ovarian follicles [9], [8]. The PDE model consists in a quasi-linear hyperbolic system of large size, namely $N_f \times N_f$, ruling the time evolution of the cell density functions of $N_f$ follicles (in practice $N_f$ is of the order of a few to twenty). These equations are weakly coupled through the sum of the first order moments of the density functions. The time-dependent equations make use of two structuring variables, age and maturity, which play the roles of space variables. The problem is naturally set over a compact domain of $\mathbb{R}^2$. The formulation of the time-dependent controlled transport coefficients accounts for available biological knowledge on follicular cell kinetics. We introduce a dedicated numerical scheme that is amenable to parallelization, by taking advantage of the weak coupling. Numerical illustrations assess the relevance of the proposed method both in term of accuracy and HPC achievements [50], [51].

5.4.2. Multiscale modeling of follicular ovulation as a mass and maturity dynamical system

Participants: Frédérique Clément, Philippe Michel, Danielle Monniaux.
We have analyzed the dynamics of the solutions using bifurcation tools on a reduced, ODE model [73]. In a first stage, the 2D PDE model is reduced to a 1D PDE model, where the only remaining variable is the age. This reduction is based on a result of exponential convergence in maturity. We have proved that the granulosa cell density of each follicle converges to a “dirac mass in maturity”, which can be understood as: “the follicle becomes uniform in maturity”. The proof is based on the crucial decay property of the maturity speed rate with respect to the maturity variable, so that the support of the cell density of each follicle concentrates its mass around a curve given by a characteristic equation. In a second stage, the mitosis rate is averaged in age, reducing the 1D PDE to a simpler system of two coupled nonlinear ODE, where each follicle is characterized by its cell number (the follicle mass) and global maturity. These variables correspond respectively to the zero-order moment and first-order moment in maturity of the cell density in the original model. The dynamics of one given follicle can then be studied with respect to the pressure exerted collectively by all other growing follicles, in the framework of dynamical games. In some sense, the pressure can be considered as an exogenous parameter, so that we can detect dynamical bifurcations according to the pressure value. Each follicle plays against the others for its survival. In the course of its terminal development, a follicle first remains in the proliferative zone of the mass-maturity plane and then enters the differentiated zone. At the transition from proliferation to differentiation, the follicle is highly sensitive to the pressure. In the worst (doomed) case, the follicle becomes atretic, due to prolonged cell loss. In the best (saved) case, it manages to go through the vulnerability zone and becomes insensitive to the pressure of other follicles.

5.4.3. Optimal control for a conservation law modeling the development of ovulation

Participants: Frédérique Clément, Peipei Shang.

Collaboration with Jean-Michel Coron

We are now investigating control problems associated to the multiscale model of follicle selection. The conditions for the triggering of the ovulatory surge, coupled with the sorting of the ovulatory follicles, define a complex, nested reachability problem. We have considered a more tractable version of that problem, which is centered on defining the optimal local control corresponding to a single ovulatory trajectory. Under some simplifying assumptions (no loss term and constant aging velocity), we have obtained analytical and numerical results in the case when the density is idealized by one or several Dirac mass. We are extending our results to the PDE original model.

5.4.4. Multiscale analysis of mixed-mode oscillations in a phantom bursting model

Participants: Frédérique Clément, Mathieu Desroches, Maciej Krupa, Alexandre Vidal.

We have carried on the study of our fast-slow model of the GnRH (gonadotropin-releasing hormone) pulse and surge generator [5], [4]. If we relax a little the constraints imposed by the biological specifications on the parameters, very rich and complex behaviours can be further exhibited by the model. More precisely, both a delay to the surge and a post-surge pause (before pulsatility resumption) may occur. A detailed examination of the pause has revealed that it is shaped by mixed-mode oscillations (MMO). We are currently investigating how the precise sequence of MMO is determined by the global return map from the surge to the pulse regime.

5.4.5. Transient synchronization of calcium oscillations in cultures of GnRH neurons.

Participants: Frédérique Clément, Maciej Krupa, Alexandre Vidal.

We have started to study the individual dynamics of GnRH neurons and the conditions under which they may synchronize. We are more specifically tackling the issue of synchronization of calcium oscillations in cultures obtained from the olfactory placodes of rhesus monkey embryos [81]. We have introduced a class of models explaining the synchronization events; their main idea was to introduce a global variable controlling the onset of synchronization that was subsequently reset by the subsequent high firing rate caused by the activation of an adaptation current.

5.5. Clinical and physiological applications

5.5.1. DynPeak: An algorithm for pulse detection and frequency analysis in hormonal time series

Participants: Frédérique Clément, Claire Médigue, Alexandre Vidal, Qinghua Zhang.
Collaboration with Stéphane Fabre (UMR CNRS-INRA 6175).
The endocrine control of the reproductive function is often studied from the analysis of luteinizing hormone (LH) pulsatile secretion by the pituitary gland. Whereas measurements in the cavernous sinus cumulate anatomical and technical difficulties, LH levels can be easily assessed from jugular blood. However, plasma levels result from a convolution process due to clearance effects when LH enters the general circulation. Simultaneous measurements comparing LH levels in the cavernous sinus and jugular blood have revealed clear differences in the pulse shape, the amplitude and the baseline. Besides, experimental sampling occurs at a relatively low frequency (typically every 10 min) with respect to LH highest frequency release (one pulse per hour) and the resulting LH measurements are noised by both experimental and assay errors. As a result, the pattern of plasma LH may be not so clearly pulsatile. Yet, reliable information on the InterPulse Intervals (IPI) is a prerequisite to study precisely the steroid feedback exerted on the pituitary level. Hence, there is a real need for robust IPI detection algorithms. We have designed an algorithm for the monitoring of LH pulse frequency, basing ourselves both on the available endocrinological knowledge on LH pulse (shape and duration with respect to the frequency regime) and synthetic LH data generated by a simple model [57]. We make use of synthetic data to make clear some basic notions underlying our algorithmic choices. We focus on explaining how the process of sampling affects drastically the original pattern of secretion, and especially the amplitude of the detectable pulses. We then describe the algorithm in details and perform it on different sets of both synthetic and experimental LH time series. We further comment on how to diagnose possible outliers from the series of IPIs which is the main output of the algorithm.
5. New Results

5.1. Mathematical Modelling

5.1.1. Mathematical and numerical model for nonlinear viscoplasticity

Participants: Nicolas Favrie, Sergey Gavrilyuk.

A macroscopic model describing elastic plastic solids is derived in a special case of the internal specific energy taken in separable form: it is the sum of a hydrodynamic part depending only on the density and entropy, and a shear part depending on other invariants of the Finger tensor. In particular, the relaxation terms are constructed compatible with the von Mises yield criteria. In addition, Maxwell-type material behaviour is shown up: the deviatoric part of the stress tensor decays during plastic deformations. Numerical examples show the ability of this model to deal with real physical phenomena [15].

5.1.2. A discrete model for compressible flows in heterogeneous media

Participants: Olivier Le Métayer, Alexandre Massol, Nicolas Favrie, Sarah Hank.

This work deals with the building of a discrete model able to describe and to predict the evolution of complex gas flows in heterogeneous media. In many physical applications, large scales numerical simulation is no longer possible because of a lack of computing resources. Indeed the medium topology may be complex due to the presence of many obstacles (walls, pipes, equipments, geometric singularities etc.). Aircraft powerplant compartments are examples where topology is complex due to the presence of pipes, ducts, coolers and other equipment. Other important examples are gas explosions and large scale dispersion of hazardous materials in urban places, cities or underground involving obstacles such as buildings and various infrastructures. In all cases efficient safety responses are required. Then a new discrete model is built and solved in reasonable execution times for large cell volumes including such obstacles. Quantitative comparisons between experimental and numerical results are shown for different significant test cases, showing excellent agreement [18].

5.1.3. A hyperbolic Eulerian model for dilute two-phase suspensions

Participants: Sarah Hank, Richard Saurel, Olivier Le Métayer.

Conventional modeling of two-phase dilute suspensions is achieved with the Euler equations for the gas phase and gas dynamics pressureless equations for the dispersed phase, the two systems being coupled by various relaxation terms. The gas phase equations form a hyperbolic system but the particle phase corresponds to a hyperbolic degenerated one. Numerical difficulties are thus present when dealing with the dilute phase system. In the present work, we consider the addition of turbulent effects in both phases in a thermodynamically consistent way. It results in two strictly hyperbolic systems describing phase's dynamics. Another important feature is that the new model has improved physical capabilities. It is able, for example, to predict particle dispersion, while the conventional approach fails. These features are highlighted on several test problems involving particles jets dispersion and are compared against experimental data. With the help of a single parameter (a turbulent viscosity), excellent agreement is obtained for various experimental configurations studied by different authors [17].

5.1.4. Diffuse interface model for compressible fluid - Compressible elastic-plastic solid interaction

Participants: Nicolas Favrie, Sergey Gavrilyuk.
An Eulerian hyperbolic diffuse interface model for elastic plastic solid fluid interaction is constructed. The system of governing equations couples Euler equations of compressible fluids and a visco-plastic model of Maxwell type materials (the deviatoric part of the stress tensor decreases during plastic deformations) in the same manner as models of multicomponent fluids. In particular, the model is able to create interfaces which were not present initially.

The model is thermodynamically compatible: it verifies the entropy inequality. However, a numerical treatment of the model is particularly challenging. Indeed, the model is non-conservative, so a special numerical splitting is proposed to overcome this difficulty. The numerical algorithm contains two relaxation procedures. One of them is physical and is related to the plastic relaxation mechanism (relaxation toward the yield surface). The second one is numerical. It consists in replacing the algebraic equation expressing a mechanical equilibrium between components by a partial differential equation with a short relaxation time. The numerical method was tested in one dimensional case (Wilkins’ flying plate problem), two-dimensional plane case (impact of a projectile on a plate) and axisymmetrical case (Taylor test problem, impact with penetration effects, etc.). Numerical examples show the ability of the model to deal with real physical phenomena [13].

5.1.5. Criterion of hyperbolicity for non-conservative quasilinear systems admitting a partially convex conservation law

Participants: Alain Forestier, Sergey Gavrilyuk.

A system of conservation laws admitting an additional convex conservation law can be written as a symmetric $l$-hyperbolic in the sense of Friedrichs system. However, in mathematical modeling of complex physical phenomena, it is customary to use non-conservative hyperbolic models. We generalize the Godunov Friedrichs Lax approach to this new class of models [16].

5.1.6. A new model of roll waves: comparison with Brock’s experiments

Participants: Gaël Richard, Sergey Gavrilyuk.

We derive a mathematical model of shear flows of shallow water down an inclined plane. Periodic stationary solutions to this model describing roll waves were obtained. The solutions are in good agreement with experimental profiles of roll waves measured in Brock’s experiments (1967). In particular, the height of the vertical front of the waves, the shock thickness and the wave amplitude are well captured by the model [21].

5.1.7. Modelling gas dynamics in one-dimensional ducts with abrupt area change

Participants: R Menina, Richard Saurel, M Zereg, Lazhar Houas.

Most gas dynamic computations in industrial ducts are done in one dimension with cross-section-averaged Euler equations. This poses a fundamental difficulty as soon as geometrical discontinuities are present. The momentum equation contains a non-conservative term involving a surface pressure integral, responsible for momentum loss. Definition of this integral is very difficult from a mathematical standpoint as the flow may contain other discontinuities (shocks, contact discontinuities). From a physical standpoint, geometrical discontinuities induce multidimensional vortices that modify the surface pressure integral. In the present paper, an improved one-dimensional flow model is proposed. An extra energy (or entropy) equation is added to the Euler equations expressing the energy and turbulent pressure stored in the vortices generated by the abrupt area variation. The turbulent energy created by the flow area change interaction is determined by a specific estimate of the surface pressure integral. Model’s predictions are compared with two-dimensional averaged results from numerical solution of the Euler equations. Comparison with shock tube experiments is also presented. The new one dimensional averaged model improves the conventional cross-section-averaged Euler equations and is able to reproduce the main flow features [19].

5.2. Applications for specific flow problems

5.2.1. Modelling cavitating flow around underwater missiles

The diffuse interface model of Saurel et al. [9] is used for the computation of compressible cavitating flows around underwater missiles. Such systems use gas injection and natural cavitation to reduce drag effects. Consequently material interfaces appear, separating liquid and gas. These interfaces may have a really complex dynamics such that only a few formulations are able to predict their evolution. Contrarily to front tracking or interface reconstruction method the interfaces are computed as diffused numerical zones, that are captured in a routinely manner, as is done usually with gas dynamics solvers for shocks and contact discontinuity. With the present approach, a single set of partial differential equations is solved everywhere, with a single numerical scheme. This leads to very efficient solvers. The algorithm derived in Saurel et al. [43] is used to compute cavitation pockets around solid bodies. It is first validated against experiments done in cavitation tunnel at CNU. Then it is used to compute flows around high speed underwater systems (Shkval-like missile). Performance data are then computed showing method ability to predict forces acting on the system [20].

5.2.2. Propagation of a planar shock wave through a two-phase gas-liquid medium

**Participants:** Alain Chauvin, Georges Jourdan, Éric Daniel, Lazhar Houas, R Tosello.

We conducted a series of shock tube experiments to study the influence of a cloud of water droplets on the propagation of a planar shock wave. In a vertically oriented shock tube, the cloud of droplets was released downwards into the air at atmospheric pressure while the shock wave propagated upwards. Two shock wave Mach numbers, 1.3 and 1.5, and three different heights of clouds, 150 mm, 400 mm, and 700 mm, were tested with an air-water volume fraction and a droplet diameter fixed at 1.2 % and 500 µm, respectively. From high-speed visualization and pressure measurements, we analyzed the effect of water clouds on the propagation of the shock wave. It was shown that the pressure histories recorded in the two-phase gas-liquid mixture are different from those previously obtained in the gas-solid case. This different behavior is attributed to the process of atomization of the droplets, which is absent in the gas-solid medium. Finally, it was observed that the shock wave attenuation was dependent on the exchange surface crossed by the shock combined with the breakup criterion [12].
6. New Results

6.1. Embedded data management

**Participants:** Nicolas Anciaux, Luc Bouganim, Yanli Guo, Lionel Le Folgoc, Philippe Pucheral, Shaoyi Yin.

Inspired by low cost economic models, this work draws the idea of a one-dollar database machine, with the objective to disseminate databases everywhere, up to the lightest smart objects. In contrast to traditional database machines relying on massively parallel architectures, the one-dollar database machine considers the cheapest form of computer available today: a microcontroller equipped with GBs size (external) Flash storage. Designing such a database machine is very challenging due to a combination of conflicting RAM and NAND Flash constraints. To tackle this challenge, this work proposes a new paradigm based on database serialization (managing all database structures in a pure sequential way) and stratification (restructuring them into strata when a scalability limit is reached). We show that a complete DBMS engine can be designed according to this paradigm and demonstrate the effectiveness of the approach through a performance evaluation.

This work capitalizes on previous results related to the indexing of Flash resident data [39] and has also obvious connections with the more general study we are conducting on Flash-based data management (see Section 6.2). Partial elements of this solution have been demonstrated at [28].

6.2. Flash-based Data Management

**Participant:** Luc Bouganim.

**Bimodal flash devices.** While disks have offered a stable behavior for decades, thus guaranteeing the timelessness of many database design decisions, flash devices keep on mutating. Many researchers have proposed to adapt database algorithms to existing flash devices. However, today, there is no reference DBMS design based on solid assumptions of flash devices behavior, precisely because flash device behavior varies across models, across firmware updates and possibly over time for the same model: database researchers are running after flash memory technology. In this study, we took the reverse approach and defined how flash devices should support database management. We advocated that flash devices should provide guarantees to a DBMS so that it can devise stable and efficient IO management mechanisms. Based on the characteristics of flash chips, we defined a bimodal FTL that distinguishes between a minimal mode where sequential writes, sequential reads and random reads are optimal while updates and random writes are forbidden, and a mode where updates and random writes are supported at the cost of sub-optimal IO performance. This work started at the end of 2010 and was published at CIDR’11 [19], in cooperation with the IT University of Copenhagen. DBMS/Flash device co-design considerations were the focus of a tutorial on flash devices given recently at VLDB 2011 [20].

6.3. Privacy-Preserving Data Publishing

**Participants:** Tristan Allard, Benjamin Nguyen, Philippe Pucheral.

While most PPDP works make the assumption of a trusted central publisher, this study advocates a decentralized way of publishing anonymized datasets. More precisely, our work concerns the proof of feasibility of adapting traditional PPDP schemes, such as $k$-anonymity, $\ell$-diversity or differential privacy to encompass the use of secure portable devices. In the applications we consider, each secure device is a data provider with weak computing capacities and weak connectivity (frequency and duration of connections are unpredictable)\(^1\). Weak

\(^1\)E.g., in the e-health context, patients may have their medical folder embedded in a secure device and connect it sporadically when they visit their physician or when they want to consult it at home.
connectivity precludes any P2P solution to the problem. A server allowing asynchronous communications between the devices becomes necessary to implement a distributed PPDP mechanism but this server does not benefit from the same trustworthiness as the participating devices. Our work aims to provide a generic method to adapt an important subclass of PPDP algorithms to this context, using both the limited secure computation capacities of each device (but taking advantage of their number) and the powerful computation abilities of an untrusted server available 24/7. Our proposal is based on a meta algorithm divided in three phases: (1) a collection phase where encrypted data is collected by the untrusted server, (2) a construction phase where the untrusted server performs a sound computation of a given privacy mechanism to generate sanitization rules and (3) a sanitization phase where the encrypted data is decrypted then sanitized by the devices to produce a final clear-text result. The last phase can be distributed using many different devices for better efficiency. In [15], [17], we showed how it is possible to transform existing anonymity mechanisms into decentralized ones using secure devices, while maintaining equivalent security guarantees against honest-but-curious and weakly malicious adversaries. In [16], we studied the (unlikely) event that some secure devices might be compromised, and can collude with the untrusted server. We provided schemes to detect the compromised devices with a probability that can be fixed as close to 1 as desired (the trade-off being the latency of the protocol).

6.4. Minimal Exposure

Participants: Nicolas Anciaux, Benjamin Nguyen.

When users request a service, the service provider usually asks for personal documents to tailor its service to the specific situation of the applicant. For example, the rate and duration of consumer’s loans are usually adapted depending on the risk based on the income, assets or past lines of credits of the borrower. In practice, an excessive amount of personal data is collected and stored. Indeed, a paradox is at the root of this problem: service providers require users to expose data in order to determine whether that data is needed or not to achieve the purpose of the service. We currently explore a reverse approach, where service providers would publicly describe the data they require to complete their task, and where the applicants would confront those descriptions with their own data to determine themselves the minimal subset of information to expose. We have first investigated solutions for simplistic tasks (e.g., evaluating a decision tree to determine the loan rate and duration a given applicant can claim), and we plan to address more complex ones (e.g., building the profile of customers, mining association rules, etc.) in the short term. The work on Minimal Exposure has just started and a first paper is under evaluation.

6.5. Experiment in the medical field

Participants: Nicolas Anciaux, Luc Bouganim, Lionel Le Folgoc, Philippe Pucheral, Alexei Troussov.

The PlugDB engine is being experimented in the field since September 2011 to implement a secure and portable medical-social folder. The objective is to improve the coordination of medical care and social services provided at home for dependent people. Details related to this experiment conducted with about 120 practitioners and patients are given in Section 7.2. While this action did not generate new academic results (though it helped us validating some previous results), it imposed us a strong investment in terms of test and optimization for our prototype and in terms of communication to promote this experiment at the regional level.
STEEP Exploratory Action

5. New Results

5.1. Definition of the research priorities, and first works

As STEEP addresses pluri-disciplinary research topics that are new both for INRIA and for the STEEP members, our very first goal of this year has been to define and specify the four research priorities described above: (a) development of numerical systemic models (economy / society / environment) at local scales; (b) calibration and convergence of integrated models; (c) consideration and management of uncertainties in integrated models; (d) environmental impacts of urban policies.

To gain better insight into these issues, we choose to start with the TRANUS model, as first experimental framework. We collaborate closely with IDDRI (Institut du Développement Durable et des Relations Internationales, Paris [http://www.iddri.org/]), that has implemented a TRANUS model applied to the city of Grenoble in the context of the AETIC project. We make use of this model as starting point to investigate the three first topics.

(a) We have started a project consisting in designing and implementing an integrated model by ourselves, in close collaboration with the EDDEN laboratory (laboratoire d’Economie du Développement Durable et de l’Energie, Grenoble [http://webu2.upmf-grenoble.fr/LEPII/spip/spip.php?article22]) and IDDRI. The goal in to enrich the transport / land use Grenoble model with energy sectors, using the data and analysis our partners are generating in the context of the AETIC project. The goal here is to find a way to encapsulate in or combine the energy models proposed by EDDEN with the TRANUS model implemented by IDDRI for Grenoble.

(b) We participated to the still on-going calibration procedure of the Grenoble models, which is leaded by IDDRI and Modelistica. This helped us to identify the keypoints of the calibration of such a model, and to propose first semi-automatic approaches based on simple parameters optimizations.

(c) We started an uncertainty analysis of this model.

Parallel to that, we have taken an interest in the LEAM model and URBANSIM and we are preparing an ANR project on TRANUS and URBANSIM which would allow us to deeply compare the very different representations on which they are based on.

5.2. Building of Partnerships

This year, we have spent a considerable amount of time and energy to build various partnerships.

We have started a collaboration with Modelistica and Tómas de la Barra, the author of TRANUS Model. Tómas de la Barra came at INRIA for a week in June 2011. We have submitted a project to ECOS-Nord program (TRACER). Among others, we are closely working with him on TRANUS calibration.

Our collaboration with EDDEN is now fully set up. We are working with them on the design of a transport-land use-energy integrated model for the city of Grenoble using the data and analysis they are generating in the context of the AETIC project. This work is based on the TRANUS model implemented by IDDRI for Grenoble. In the same way, our collaboration with IDDRI has started to be effective. With IDDRI, we work on TRANUS calibration issues and practically on the Grenoble model they are implementing. IDDRI is the coordinator of TRACER project submitted to ECOS-Nord program.

In other respects, with AURG (Agence d’Urbanisme de la Région Grenobloise [http://www.aurg.org/]) and EDDEN, we are one of the driving forces behind the MUTERA project. This project aims at gathering the main actors in urban planning and transport of the Rhône-Alpes region to work on the issues regarding land-use and transport models. This group includes technicians, politicians and researchers. The kick-off meeting should take place in the beginning of 2012.
We have also started a collaboration with the LECA laboratory (Laboratoire d’Ecologie Alpine, Grenoble http://www-leca.ujf-grenoble.fr/). In June 2011, we have submitted a project to FRB Flagship program with them (ESNET).

In parallel of that, we got in touch with a number a potential partners and colleagues ones of which are the LET laboratory (Laboratoire d’Economie des Transport, Lyon http://www.let.fr/), the department of urban and regional planning of the university of Illinois at Urbana-Champaign (visit to Brian Deal), Veolia Environnement, SOGREAT etc. A number of them have been contacted in the framework of the development of an ANR project which should be submitted to 2012 “Modèles numériques” program or in the framework of CIFRE or industrial partnerships.

5.3. First results on material flow, production and consumption analysis

This theme of research has been started this year through a 6 month internship with a student of Ecole Centrale de Lyon. A large database has been constructed, that allows to analyze material flows, production and consumption by type (and origin and destination in case of flows) at the level of the French region and departments. This database compiles data from a variety of public institutions and private organizations. Almost all the data are in the public domain. A large amount of work has gone into building the database, normalizing the different data sources at least in terms of classification, and into building tools to manipulate the data and produce usable information.

At present, this “physical accounting” has been performed on all French regions for a limited number of materials (in particular cereals, fossil fuels, and construction materials). Furthermore, it has been performed for the same materials at the departement level in the Rhone-Alpes region.

This work is now focusing on various issues:

- By correlating the relevant quantities with other variables (such as, e.g., population or land use, etc), it is possible to downscale the consumption and waste production data at the level of urban regions (where a large part of this information is unavailable). Such an information is critical for the development of decision-help tools at the level of urban areas.

- A process of quantification of the major source of information on material transports is the SitraM database (transportation database maintained by the Ministry of Ecology and Sustainable Development). These data are statistical in nature, but the statistical error is unknown. We are in the process of developing a way to estimate this error.

- The next step will then be to transform this material use in terms of environmental impact. Various types of impacts (global and local) have been identified. The quantification will rely on various known approaches (Life Cycle Analysis, regional Input-Analysis), notably drawing on part of the work performed in this area by the Global Footprint Network (even for impacts that cannot be quantified in terms of land, carbon or water footprint).
5. New Results

5.1. Flexible Radio Node

Participants: Florin Hutu, Tanguy Risset, Jacques Verdier, Guillaume Villemaud, Cédric Levy-Bencheton.

This section summarizes the early results obtained from the research axis flexible radio nodes.

In [41], [75], a candidate architecture for LTE-Advanced receiver is proposed. Based on the combination of MIMO techniques and flexible spectrum access, LTE-Advanced terminals will require the increasing of the analog front-end complexity. To reduce the complexity of the analog front-end, an innovative architecture based on the merge between the double IQ and the code multiplexing structures is proposed. Simulation and measurement results show that, in a Gaussian case, the bit error rate is similar when using the proposed architecture and the state of the art front-end stack-up structure. A complexity evaluation study reveals significantly reduced power consumption of the proposed single front-end architecture.

The current generation of mobile terminals can communicate on multiple modes using several antennas. However, their energy consumption remains a critical parameter. In [58], [74], we explore the combination of multiple communication modes and MIMO as a possible way to reduce the energy consumption of both the terminals and the network. We propose a realistic energy model for the PHY layer of a MIMO and multi-mode terminal, taking into account the MAC layer behaviour. We show that the combination of MIMO and multi-mode provides a solution to reduce global energy consumption.

Software means programmable. Hence software defined radio means that the radio should now be programmable. We know what computer programming means, and we agree, up to a certain level, on how it should be done. But do we know what programming a radio means? Several questions are still open: what will an SDR platform look like in ten years? Will there exist software radio code? What will be the technical challenges and commercial issues behind this code? Programming is more precise than configuring or tuning, it implies a much greater level of freedom for the programmer. But it also means much cheaper implementations in many cases and in particular a re-use of the same hardware for different protocols (i.e. with different programs). This is, to our point of view [76], the main difficulty of software radio programming: reconfiguration and in particular dynamic reconfiguration. Dynamic (i.e. very fast) reconfiguration is now mandatory because some protocols, 3GPP-LTE (Third Generation Partnership Program Long Term Evolution) for instance, propose channel adapting for each frame, requiring a setting of the channel estimation parameter in a few milliseconds.

5.2. Agile radio resource sharing

Participants: Jean-Marie Gorce, Claire Goursaud, Katia Jaffrès-Runser, Nikolaï Lebedev, Guillaume Villemaud, Paul Ferrand, Philippe Mary.

This section presents our recent results concerning the realistic modeling of wireless links to develop realistic models and efficient simulations. This work include theoretical developments like symbol error outage modeling, but also some applications in the context of LTE multi-cells association, or opportunistic relaying in the context of wireless sensor networks. Other contributions about resource sharing are presented in next sections below, in the section 'network optimization' and the section ‘network coding’.

In [28], we addressed the problem of finding a tractable expression for the symbol error outage (SEO) in flat Nakagami-m fading and shadowing channels. We deal with M-ary phase shift keying (M-PSK) and quadrature amplitude modulation (M-QAM) which extends our previous results on BPSK signaling. We propose a new tight approximation of the symbol error probability (SEP) holding for M-PSK and M-QAM signals which is accurate over all signal to noise ratios (SNRs) of interest. We derive a new generic expression for the inverse SEP which facilitates the derivation of a tight approximation of the SEO in a lognormal shadowing environment.
In [44], we consider on-body BAN nodes transmitting information towards a common sink, in a star topology (Body Area Networks (BAN) offer amazing perspectives to instrument and support humans in many aspects of their lives). While this setup is usual in wireless networks, the high instability of the BAN radio channel and the proximity of the body make classical communication protocols inefficient. These networks are further constrained by the low transmission power required for both battery life and health concerns. Opportunistic cooperation techniques are of great interest in such environment to ensure reliable communications. In previous works, we studied simple opportunistic relaying schemes under independent BAN links, using a packet error outage criterion. In this paper, we introduce a more realistic case where shadowing variations around the body are now assumed strongly correlated. Generally speaking, there is a lack of definitive measurements and models for the shadowing correlation in multi-hop networks, while it can play a crucial role at the higher layers. Based on the measurement and simulation results of the French BANET project, we use the BAN context as an illustrative example to exhibit how shadowing correlations have a strong impact on relaying approaches performance.

Opportunistic networking aims at exploiting sporadic radio links to improve the connectivity of a multi-hop network and to foster data transmissions. Broadcast nature of the wireless channel is an important feature that can be exploited to improve transmissions by using several potential receivers. Opportunistic relaying is thus the first brick for opportunistic networking. However, the advantage of opportunistic relaying may be balanced by energy increase related to having simultaneous active receivers. In [32], we proposed a thorough analysis of opportunistic relaying efficiency under different realistic radio channel conditions. The study aims at finding the best trade-off between two objectives: energy and latency minimizations, under a hard reliability constraint. We derive an optimal bound, namely, the Pareto front of the related optimization problem, which offers a good insight into the benefits of opportunistic routings compared with classical multi-hop routing schemes. Meanwhile, the lower bound provides a framework to optimize the parameters in physical layer, MAC layer and routing layer from the viewpoint of cross layer during the design or planning phase of a network.

This work has been extended in In [70] for relay channels. The gain induced by using relay channels in a linear network under both a capacity constraint and a realistic energy model is evaluated. We express a general model based on a convex optimization problem, allowing us to use numerical tools to obtain similar results for outer and inner bounds to the capacity of the full and half duplex relay channel. We then further the study with more complex networks based on relay channels, especially networks formed by a linear chain of nodes. We describe the Pareto optimal solutions of the minimization problem for with respect to the consumed energy and latency in such a linear network. From the simple case of the linear multi-hop network, we study the gains when implementing a linear chain of relay channels and compare these results to the simpler multi-hop transmission. This work will be published in 2012 in IEEE WCNC.

In [82] we extended this formalisms derived for a linear network to a more general case: the problem of deriving fundamental trade-off bounds for wireless ad hoc networks when multiple performance criteria are of interest. It proposes a MultiObjective (MO) performance evaluation framework composed of a broadcast and interference-limited network model, a steady state performance metric derivation inspired by a discrete Markov chain formalism and formulates the associated MO optimization problem. Pareto optimal performance bounds between end-to-end delay and energy for a capacity-achieving network are given for the 1-relay and 2-relay networks and assessed through simulations.

5.3. **Autonomous wireless networking**

**Participants:** Isabelle Augé-Blum, Bernard Tourancheau, Fabrice Valois, Ibrahim Amadou, Cédric Chauvenet, Quentin Lampin, Alexandre Mouradian, Bilel Romdhani.

Designing protocols for large scale wireless sensors networks is a challenging issue, if realistic environments are considered. Finding a trade-off between energy consumption and delay, or capacity, is difficult. The most promising ideas rely on zero-protocol approaches and on virtual coordinates use. the special case of VANETs is presented in the next section.
In [64], we focus on Wireless Sensor Networks (WSNs) in a more realistic case than classical studies and previous works: we consider wireless sensor nodes having different transmission ranges according to the environment and/or to the wireless chipset. The main consequence of this heterogeneity is the existence of asymmetric links. Such links in a WSN degrade the performance of most protocols which have not been designed to support this heterogeneity and to deal with asymmetric links: so, mainly, these links are pruned. Under this assumption, we propose a routing protocol for data collection from sensors nodes to the sink node in heterogeneous WSNs. Our proposal detects and takes benefit from asymmetric links caused by this heterogeneity. Our proposal, denoted MURA, (1) provides a high delivery ratio, (2) reduces the number of duplicated packets and (3) reduces the number of hop counts by exploiting the asymmetric links.

Due to the efficiency and scalability of greedy routing in WSNs and the financial cost of GPS chips, Virtual Coordinate Systems (VCSs) for WSNs have been proposed. A category of VCSs is based on the hop-count from the sink, this scheme leads to many nodes having the same coordinate. The main advantage of this system is that the hops number of a packet from a source to the sink is known. Nevertheless, it does not allow to differentiate the nodes with the same hop-count. We propose in [87] a novel hop-count-based VCS which aims at classifying the nodes having the same hop-count depending on their connectivity and at differentiating nodes in a 2-hop neighborhood. Those properties make the coordinates, which also can be viewed as a local identifier, a very powerful metric which can be used in WSNs mechanisms.

Duty-cycled medium access protocols allow for long lasting autonomous networks by periodically putting nodes to sleep. However, this life expectancy improvement comes at the cost of a lesser network capacity and a poor adaptability to bursty traffic loads. Indeed, existing contention algorithms do not provide efficient algorithms to dynamically elect multiple senders per wake-up periods. In [84], the medium is divided in several logical channels (e.g., obtained by a time/frequency division of the communication medium) and we propose to allocate them dynamically among senders. For this purpose, we propose a joint contention/scheduling algorithm, named Extended Slot Selection (ESS), that schedules multiple sender/receiver pairs to available logical channels.

Energy-efficient communication protocol is a primary design goal for Wireless Sensor Networks (WSNs). Many efforts have been done to save energy: MAC with duty cycle, energy-aware routing protocols, data aggregation schemes, etc. Recently, beacon-less strategies have emerged as new direction to improve considerably the WSN lifetime. However, the main contributions are not suitable to real radio environments because of hole avoiding strategies based on either planarization or explicit neighbor solicitations. We propose in [34] PFMAC (Pizza-Forwarding Medium Access Control), which combines beacon-less geo-routing and energy efficient MAC protocol via a cross-layer design to save more energy with higher reliability. PFMAC supports radio interferences, asymmetric radio links, etc. PFMAC supports a greedy forwarding strategy and, a reactive and optimized neighborhood discovery at 2-hop to deal with holes. Intensive simulations are proposed to highlight the behavior and the performance of PFMAC compared to BOSS over BMAC.

To provide for reliability in Wireless Sensor Networks (WSNs), Medium Access Control (MAC) protocols must be adapted by mechanisms taking cross-layer approaches into account. In [51], [52], we describe AreaCast which is designed for enhancing reliability in WSNs. AreaCast is a MAC layer mechanism independent of the routing layer, but uses only local topological and routing information to provide a communication by area instead of a traditional, node-to-node communication (i.e., unicast). In AreaCast, a source node addresses a set of nodes: an explicit relay node chosen as the next hop by a given routing protocol, and k other implicit relay nodes. The neighboring nodes select themselves as implicit relays according to their location from the explicit relay node. This mechanism uses overhearing to take advantage of the inherent broadcast nature of wireless communications. Without changing the routing protocol, AreaCast is able to dynamically avoid a byzantine node or an unstable link, allowing to benefit from the inherent topological redundancy of densely deployed sensor networks. Simulation results show that AreaCast significantly improves the packet delivery rate while having a good reliability-energy consumption trade-off.

Improving the network lifetime is an important design criterion for wireless sensor networks especially if we want to use standard solution like IPv6. In [38], we propose a novel approach which applies source-coding on addresses in heterogeneous IPv6 Cluster-based wireless sensor network. We formulate the problem
of maximizing the network lifetime when Slepian-wolf coding is applied on addresses in network composed of line-powered and battery-powered sensors. The numerical results show that a significant network lifetime improvement can be achieved (about 25% in typical scenario). In [36], we investigate the sinks mobility in IPv6-based wireless sensors networks and specially in the new IETF proposed protocol RPL (Routing Protocol for Low power and Lossy Networks). We also show that even the mobility of sinks is not an explicit design criteria, the use of mobile sinks improves the network lifetime.

5.4. Wireless networking in VANETs

Participants: Marco Fiore, Sandesh Uppoor.

VANETS (Vehicular Ad hoc Networks) represents a challenging context for designing new protocols as it offers new challenges related to the high dynamicity of the network. In cooperation with external researchers, we derived recent results on mobility modeling and data dissemination in VANETS. This work is a part of the work on 'Autonomous wireless networking', but dedicated specially for VANETs.

Simulation is the tool of choice for the large-scale performance evaluation of upcoming telecommunication networking paradigms that involve users aboard vehicles, such as next-generation cellular networks for vehicular access, pure vehicular ad hoc networks, and opportunistic disruption-tolerant networks. The single most distinguishing feature of vehicular networks simulation lies in the mobility of users, which is the result of the interaction of complex macroscopic and microscopic dynamics. Notwithstanding the improvements that vehicular mobility modeling has undergone during the past few years, no car traffic trace is available today that captures both macroscopic and microscopic behaviors of drivers over a large urban region, and does so with the level of detail required for networking research. In [66], we present a realistic synthetic dataset of the car traffic over a typical 24 hours in a 400-km² region around the city of Koln, in Germany. We outline how our mobility description improves today’s existing traces and show the potential impact that a comprehensive representation of vehicular mobility can have on the evaluation of networking technologies.

In [21], [30], we investigate data dissemination in vehicular networks. Content downloading in vehicular networks is a topic of increasing interest: services based upon it are expected to be hugely popular and investments are planned for wireless roadside infrastructure to support it. We focus on a content downloading system leveraging both infrastructure-to-vehicle and vehicle-to-vehicle communication. With the goal to maximize the system throughput, we formulate a max-flow problem that accounts for several practical aspects, including channel contention and the data transfer paradigm. Through our study, we identify the factors that have the largest impact on the performance and derive guidelines for the design of the vehicular network and of the roadside infrastructure supporting it.

In [45] We address cooperative caching in wireless networks, where the nodes may be mobile and exchange information in a peer-to-peer fashion. We consider both cases of nodes with large- and small-sized caches. For large-sized caches, we devise a strategy where nodes, independent of each other, decide whether to cache some content and for how long. In the case of small-sized caches, we aim to design a content replacement strategy that allows nodes to successfully store newly received information while maintaining the good performance of the content distribution system. Under both conditions, each node takes decisions according to its perception of what nearby users may store in their caches and with the aim of differentiating its own cache content from the other nodes’. The result is the creation of content diversity within the nodes neighborhood so that a requesting user likely finds the desired information nearby. We simulate our caching algorithms in different ad hoc network scenarios and compare them with other caching schemes, showing that our solution succeeds in creating the desired content diversity, thus leading to a resource-efficient information access.

Performance and reliability of content access in mobile networks is conditioned by the number and location of content replicas deployed at the network nodes. In [27], we design a practical, distributed solution to content replication that is suitable for dynamic environments and achieves load balancing. Simulation results show that our mechanism, which uses local measurements only, approximates well an optimal solution while being robust against network and demand dynamics. Also, our scheme outperforms alternative approaches in terms of both content access delay and access congestion.
5.5. Optimization in wireless networks

In the context of the common lab between Inria and Alcatel Lucent Bell Labs and the ANR Ecoscells project, we work on optimizing wireless networks performance. In one side, we work on distributed algorithms for optimal resource allocation and/or mobile-BS association. On the other side, we work on mesh wireless networks optimization.

Multi-cell processing, also called Coordinated Multiple Point (CoMP), is a promising distributed technique that uses neighbor cells’ antennas [48]. It is expected to be the part of next generation cellular standards such as LTE-A. Small cell networks in dense urban environments are limited by interferences and CoMP can strongly take advantage of this fact to improve cell-edge users’ throughput. The present study introduces a distributed criterion for mobiles to select their optimal set of Base Stations (BS) to perform CoMP, and evaluates the impact of this association on the fairness and the total cell throughput. For that, we use a known theoretical expression for the capacity outage probability of CoMP under Rayleigh fading and evaluate the goodputs of antennas associations. The proposed criterion is used in combination with fair resource allocation to perform a joint double-objective optimization of fairness and efficiency. In [48], [91], we provide the analysis of the downlink Coordinated Multiple Point (CoMP) used in conjunction with the basic MIMO. The CoMP is the joint multi-cell transmission from several BS to mobiles, coupled here to an open-loop MIMO technique that does not require the perfect channel state knowledge. We show by simulation, that even for $4 \times 4$ MIMO transmission, the CoMP can improve the spectral efficiency for some mobiles, depending on capacity outage requirements.

In [33], we considered downlink transmission in cellular networks where we target to reduce the energy consumption by switching off some base stations by such a way that the distribution of SINR remains unchanged. This is a mean of green networking in cellular networks in downlink consideration. This paper analyzes for line and plane cases, the gain in power consumption obtained after switching off base stations. By computations we observe that the more the operational cost the more the gain in power consumption.

In [47], we propose an autonomous radio resource allocation and optimization scheme that chooses the transmit power and precoding vector among codebooks for multiple antennas transmitters to improve spectral and power efficiency and provide user fairness. Network self-optimization is an essential feature for supporting the cell densification in future wireless cellular systems. The proposed self-optimization is inspired by Gibbs sampler. We show that it can be implemented in a distributed manner and nevertheless achieves system-wide optimization which improves network throughput, power utilization efficiency, and overall service fairness. In addition, we extend the work and include power pricing to parametrize and enhance energy efficiency further. Simulation results show that the proposed scheme can outperform today’s default modes of operation in network throughput, energy efficiency, and user fairness.

In [55], we focused on broadband wireless networks based on OFDMA resource management, such as LTE systems. We have investigated two optimization problems, one concerning a backhauling mesh infrastructure while the other is the allocation of modulation and coding, subcarriers and power to users in LTE. Considering a realistic SINR model of the physical layer with a fine tuned power control at each node, a linear programing model using column generation has been developed for computing power efficient schedules with high network capacity for wireless mesh backhauling networks. Correlation between capacity and energy consumption have been analyzed as well as the impact of physical layer parameters - SINR threshold and path-loss exponent. With these models, we highlight that there is no significant tradeoff between capacity and energy when the power consumption of idle nodes is important. We also show that both energy consumption and network capacity are very sensitive to the SINR threshold variation. Finally, simulation results show that compared to classic reuse schemes the proposed approach is able to pack more users into the same bandwidth, decreasing the probability of user outage.

In [62], we focus on broadband wireless mesh networks like 3GPP LTE-Advanced. This technology is a key enabler for next generation cellular networks which are about to increase by an order of magnitude...
the capacity provided to users. Such an objective needs a significative densification of cells which requires an efficient backhauling infrastructure. In many urban areas as well as under-developed countries, wireless mesh networking is the only available solution. Besides, economical and environmental concerns require that the energy expenditure of such infrastructure is optimized. We propose a multi-objective analysis of the correlation between capacity and energy consumption of LTE-like wireless mesh networks. We provide a linear programing modeling using column generation for an efficient computation of the Pareto front between these objectives. Based on this model, we observe that there is actually no significant capacity against energy trade-off.

In [63], broadband wireless mesh networks based on OFDMA resource management are studied considering a realistic SINR model of the physical layer with a fine tuned power control at each node. A linear programing model using column generation leads to compute power efficient schedules with high network capacity. Correlation between capacity and energy consumption is analyzed as well as the impact of physical layer parameters - SINR threshold and path-loss exponent. We highlight that there is no significant tradeoff between capacity and energy when the power consumption of idle nodes is important. We also show that both energy consumption and network capacity are very sensitive to the SINR threshold variation.

5.6. Network coding in WSN

**Participants:** Jean-Marie Gorce, Cédric Lauradoux, Marco Fiore, Claire Goursaud, Marine Minier, Anya Apavatjrut, Yuanyuan Zhang, Wassim Znaidi.

Network coding associated with Fountain codes is a very efficient approach to increase the throughput of multi-hop networks. However severa outcomes are still expected, especially to develop robust and energy efficient approaches for transmitting data over a large scale networks. Network coding is also very promising for security issues as presented below.

Diversity is a powerful means to increase the transmission performance of wireless communications. For the case of fountain codes relaying, it has been shown previously that introducing diversity is also beneficial since it counteracts transmission losses on the channel. Instead of simply hop-by-hop forwarding information, each sensor node diversifies the information flow using XOR combinations of stored packets. This approach has shown to be efficient for random linear fountain codes. However, random linear codes exhibit high decoding complexity. In [19], we propose diversity increased relaying strategies for the more realistic and lower complexity Luby Transform code in a linear network. Results are provided herein for a linear network assuming uniform imperfect channel states.

In [29], the exact probability that a receiver obtains N linearly independent packets among K over N received packets is computed, when the sender/s use/s random linear network coding over a Galois Field of size q. Such condition maps to the receiver’s capability to decode the original information, and its mathematical characterization helps to design the coding so to guarantee the correctness of the transmission. The proposed formulation represents an improvement over the current upper bound for the decoding probability, and provides theoretical grounding to simulative results in the literature.

In [35], we focus on the proper use of fountain codes for the transmission of sporadic data in a wireless sensor network (WSN). Fountain codes offer great perspectives for the self-organization of WSNs: they self adapt to the channel error rate without any control data. When deploying fountain codes on a WSN, two problems arise. First, the size of the data transmitted by a sensor is small in comparison to the size considered traditionally with fountain codes. Second, the communications are done in an hop-by-hop fashion. It implies that the destination of the data can not acknowledge instantaneously its reception to the source. Therefore, the transmissions of useless packets for the destination can not be prevented. The flooding traffic has been evaluated as well through realistic simulations for three different relaying strategies where packets are lost due to both small scale fading and collisions for an unslotted IEEE 802.15.4 medium access layer.

Network coding has attracted the attention of many researchers in security and cryptography. We have investigated several aspects of network coding security. In [20], we propose efficient solutions to thwart pollution attacks in which an adversary injects false information into data flow. This work was further expanded
in [54] to find rational strategies to minimize the energy cost and the impact of the attack. We also came to the conclusion that dealing with pollution attacks was not enough as long as the acknowledgment messages are not also protected. The risk is to suffer from a flooding attack. This goes beyond the capabilities of cryptographic solutions and we investigate the security capabilities of multipath acknowledgment in [67].

5.7. Security

Security is an important issue for wireless networks, especially for wireless sensor networks facing an amazing increase of the number of nodes. We review in this section all contributions related to the security issue, some of them being strongly related with the PHY layer or the networking protocols. As it can be seen below, some results are strongly connected to the models and protocols derived in the other sections.

In [59], we provide the first independent analysis of the (2nd-round tweaked) 256-bit version of the SHA3 candidate SHA-3vite-3. By leveraging recently introduced cryptanalysis tools such as rebound attack or Super-Sbox cryptanalysis, we are able to derive chosen-related-salt distinguishing attacks on the compression function on up to 8 rounds (12 rounds in total) and free-start collisions on up to 7 rounds. In particular, our best results are obtained by carefully controlling the differences in the key schedule of the internal cipher. Most of our results have been implemented and verified experimentally.

In [50], we study a class of insider attacks called the terrorist fraud. This is a relay attack against distance bounding protocols where the prover conspires with an adversary to misrepresent the distance between himself and the verifier. In ideal situations, the adversary does not gain any knowledge about the prover’s long-term secret. This makes designing a distance bounding protocol resistant to such fraud tricky: the secrets of an honest prover must be protected, while those of a dishonest one should be disclosed as an incentive not to cheat. We demonstrate that using a secret-sharing scheme, possibly based on threshold cryptography, is well suited for thwarting the terrorist fraud. Although such an idea has been around since the work of Bussard and Bagga, this is the first time that secret-sharing and terrorist fraud have been systematically studied altogether.

In [40], we deal with the problem of radio jamming. Jamming is a major threat against wireless communications. In this paper, we evaluate the effect of jamming on an UWB link employing a PPM non-coherent receiver. We optimize the jammer parameters that are the central frequency and the bandwidth based on the metric of the signal-to-jamming ratio. The optimization depends on different system parameters such as the channel model and the integration time of the receiver.

In [23], we focus on the resiliency of wireless sensor network routing protocols against selective forwarding attacks by compromised nodes. Informally, resiliency should be understood as the capacity of the routing protocol to endure and mitigate the presence of a certain number of compromised nodes seeking to disturb the routing process. To provide for security when nodes may be compromised, cryptographic solutions must be completed by algorithmic solutions considering “beyond cryptography” approaches. After discussing the shortcomings of existing routing protocols against packet-dropping malicious nodes we describe some protocol behaviors enhancing routing resiliency under several combined routing attacks. We propose in this paper the behaviors enhancing the resiliency of routing protocols under several combined routing attacks.

5.8. Network simulation tools

Several works in 2011 have been using simulation results. Nevertheless, Swing members are strongly working on improving network simulation frameworks to provide realistic simulations. Several contributions to the simulation tools wiplan ans wsnets have been proposed.

Some contributions to WSnet concern BAN environments implementation [44] and network coding features [19], [81]. Different protocols have been also implemented for wireless sensor networks [34], [84], specifically in the context of our collaboration with Orange Labs, Grenoble.
The wiplan simulator has been developed at CITI for several years. It is based of a frequency domain ParFlow (MR-FDPF) implementation that represents a unique finite elements based method for estimating the radio propagation in complex environments. In the context of heterogeneous networks, femtocells are very promising. In order to properly simulate their behavior and their impact on the macrocell layer, it is necessary to be able to simulate the radio coverage of femtocells. Hence ParFlow is a possible deterministic model that can be used for such simulation. In [42], two implementations of ParFlow are presented: time domain and frequency domain. The performance are compared and the advantages/drawbacks of each model are investigated.

In [56], we propose to use finite difference propagation methods to evaluate the wide band properties of the fast fading. For this purpose we adapted the MR-FDPF propagation model to simulate large bandwidth by combining numerous narrow band simulations. The results are compared with a channel sounder measurement campaign covering a bandwidth of up to 70 MHz. It is verified that fading characteristics in wireless channels varies with frequency and the MR-FDPF method is capable for simulating this variation of fadings for wide band systems.

In [56], a new approach is proposed allowing extracting the fading statistics for indoor radio channels based on the electric field strength predicted with the MR-FDPF method. The performance of the proposed approach is verified both by simulations and measurements.

In [65], we propose a new hybrid modeling method for indoor-to-outdoor radio coverage prediction. The proposed method is a combination of a ray-optical channel modeling approach and the frequency domain ParFlow method. While the former is widely used for modeling outdoor propagation environments, the latter is computationally efficient and accurate for modeling indoor environments.

In [90], we propose to use finite difference propagation methods to evaluate the wide band properties of the fast fading. For this purpose we adapted the MR-FDPF propagation model to simulate large bandwidth by combining numerous narrow band simulations. The results are compared with a channel sounder measurement campaign covering a bandwidth of up to 70 MHz. It is verified that fading characteristics in wireless channels varies with frequency and the MR-FDPF method is capable for simulating this variation of fading for wide band systems.
SYMBIOSE Project-Team

6. New Results

6.1. Advanced tools for data management

Participants: Olivier Collin [contact], Dominique Lavenier, François Moreews, Olivier Sallou, Anthony Bretaudeau, Jonathan Piat.

- **Annotation and databases**: The AnnotQTL server is a tool designed to gather the functional annotation of genes from several institutional databases for a specific chromosomal region. [14] [Online publication: http://dx.doi.org/10.1093/NAR/GKR361]. SigReannot-mart is a query environment populated with regularly updated annotations for different oligo sets. It stores the results of the SigReannot pipeline that has mainly been used on farm and aquaculture species [17] [Online publication: http://database.oxfordjournals.org/content/2011/bar025]. BioMart Central Portal is a first of its kind, community-driven effort to provide unified access to dozens of biological databases spanning genomics, proteomics, model organisms, cancer data, ontology information and more. [11] [Online publication: http://database.oxfordjournals.org/content/2011/bar041].

- **Bioinformatics Workflow for Intensive Computation**: SLICEE proposes to abstract the calls to the cluster scheduler by handling command submission and takes care of exploiting the data parallelism. It enables an easy implementation maintaining and sharing for bioinformatics workflows using intensive computation resources [32]. OBIWEE is a virtual cluster deployment tool associated with SLICEE. It can be deployed either on private cloud or a public cloud architecture. It helps at facing the increasing demand for bioinformatics intensive treatments, in a context of large dissemination of sequencing technologies usages. [29] http://vapor.gforge.inria.fr/. We also developed a library of bioinformatics softwares implemented on manycore structures such as GPU [27].

6.2. Sequences assembly, alignement and comparison

Participants: Dominique Lavenier [contact], Claire Lemaitre, Pierre Peterlongo, Fabrice Legeai, Guillaume Chapuis, Rayan Chikhi, Nicolas Maillet, Delphine Naquin, Raluca Uricaru, Pavlos Antoniou, Thomas Derrien.

- **Hardware accelerator**: Designing FPGA-based accelerators is a difficult and time-consuming task that can be eased by High Level Synthesis Tools. A C-to-hardware methodology has been used to develop an efficient systolic array for the genomic sequence alignment problem. [42], [25] [Online publication 1: http://www.eetimes.com/design/programmable-logic/4217568/How-to-accelerate-genomic-sequence-alignment-4X-using-half-an-FPGA?Ecosystem=programmable-logic] [Online publication 2: http://www.springerlink.com/content/37l00567qm18h146/]

- **De novo assembly of NGS data**: A novel framework has been introduced for de novo assembly of next-generation sequencing data. The new paired string graphs and localized assembly models are implemented in the Monument assembler [24]. [Online publication: http://www.springerlink.com/content/f5g305j5k73x3k14/]

- **International competition de novo genome assembly**: The Symbiose team (IRISA/CNRS/ENS Cachan Brittany) participated to this competition. [9]. [Online publication: http://genome.cshlp.org/content/early/2011/09/16/gr.126599.111.abstract]

- **Indexation of NGS data**: A novel data structure is described for indexing NGS data. The structure is coupled with filtering algorithms that enable memory-efficient and parallel indexing. [23]

- **Breakpoints in genomes**: We analysed the correlation between 3D chromatin interaction data and breakpoint regions resulting from evolutionary rearrangements in the human genome. We found that two loci distant in the human genome but adjacent in the mouse genome are significantly more often observed in close proximity in the human nucleus than expected. [21]. [Online publication: http://www.biomedcentral.com/1471-2164/12/303]
• **Repeat detection:** A tool has been presented for detecting long similar fragments that occur two or more times in a set of biological sequences. This is achieved by using a filter as a preprocessing step, and by using the information that the filter has gathered also in the successive inference phase. [26]. [Online publication: http://www.stringology.org/event/2011/p08.html]

• **Targeted assembly of NGS data:** Mapsembler is an iterative targeted assembler which processes large datasets of reads on commodity hardware. Mapsembler checks for the presence of given regions of interest in the reads and reconstructs their neighborhood, either as a plain sequence (consensus) or as a graph (full sequence structure). [39]

• **Transcriptome assembly and annotation:** We established and analyzed two catalogues of transcripts by assembling EST sequences, and performed their functional annotations using the gene ontology for the following 2 species: spodoptera littoralis [15] and cabomba [20].

• **Substitution matrices:** A general and simple methodology has been proposed to build new matrices fitted to specific compositional bias of proteins. It was then applied to the large scale comparison of Mollicute AT-rich genomes [16]. [Online publication: http://www.biomedcentral.com/1471-2105/12/457/]

### 6.3. Genome Structure

**Participants:** Jacques Nicolas [contact], Dominique Lavenier, François Coste, Catherine Belleannée, Olivier Sallou, Fabrice Legeai, Guillaume Rizk, Guillaume Chapuis, Matthias Gallé, Anthony Bretaudneau.

• **GPU accelerated RNA folding algorithm** The main kernel of the widely used RNA folding package Unafold has been accelerated using GPU boards by reordering computations to enable tiled computations and good data reuse [37]. [2]

• **GPU accelerated QTL algorithm** Our GPU/multicore implementation performs up to 20 times faster than the previous multicore implementation and allows extensive QTL analysis to be conducted in a reasonable time, while maintaining the same level of precision [35].

• **Hierarchical structure of genomes.** In [7], we proposed to split the classical smallest grammar problem into two tasks: (1) choosing the constituents of the grammar and (2) finding the smallest grammar parsing given these constituents. This defines properly the search space for this problem and, as we have shown how to solve in polynomial time the second task, this opens doors for new algorithms finding smaller grammars as shown on a generic compression benchmark (up to 10%). In [6], we have worked on the scalability to propose a new algorithm able to handle whole genomes: on this kind of sequences, the size reduction is still about 10% for a comparable execution time with respect to state-of-the-art algorithms.

• **Data compression** By using grammars with rigid patterns as words, we were able to achieve a compression rate up to 25% better compared to the previous best DNA grammar-based coder, and just below state-of-the-art dedicated DNA compressors [1].

• **CRISPR Modeling and identification:** CRISPR (Clustered regularly interspaced short palindromic repeats) are small repeats present in a number of bacterial and archaeal species. We proposed the most complete database on these elements (http://crispi.genouest.org), elaborating for the first time a complete study of the palindromic nature of these repeats. The analysis has made an extensive use of our Logol Parser to decipher stem-loop structures [40].

• **Aphid genetics** We participated in a genetic study aiming at comparing the rates of evolution of genes enclosed in aphid sexual chromosome (X) to autosomal genes. In order to do so, we provided particular microsatellites for the selection of genomic sequences, as well as tools for studying their genomic environment. [13] [Online publication: http://mbe.oxfordjournals.org/content/early/2011/10/12/molbev.msr252]
6.4. Protein Sequences and Structures

Participants: Rumen Andonov [contact], Antonio Mucherino, François Coste, Jacques Nicolas, Andres Burgos, Gaëlle Garet, Pavel Senin, Mathilde Le Boudic-Jamin.

- **Branch & Prune Algorithm**: We proposed an extension of the Branch & Prune (BP) algorithm for the Discretizable Molecular Distance Geometry Problem (DMDGP) which is able to exploit all symmetries of the research domain of the corresponding combinatorial optimization problem [30].

- **Modeling protein sequences with long distance correlations**: To initiate this new line of research, we have set up a framework to learn context-free grammars on protein sequences based on the identification of conservation blocks and substitutability of non-terminals. A first implementation of the learning algorithms showed the interest of this approach [38].

- **Maximum Contact Map Overlap (CMO)** is a popular measure for quantifying the similarity between protein structures. A new integer programming model was presented for CMO and an exact branch-and-bound algorithm was designed with bounds obtained by a novel Lagrangian relaxation. The efficiency of the approach was demonstrated on known benchmarks on which sets our approach significantly outperforms the best existing exact algorithms [3].

- **Alignment of protein structures**: First successes were obtained on provably optimal pairwise alignment of protein inter-residue distance matrices, using the popular Dali scoring function. We proposed the first mathematical model for computing optimal structural alignments based on dense inter-residue distance matrices and present algorithm engineering techniques to handle the huge integer linear programs [22]. In a second paper, a strategy was proposed for sparsifying distance matrices in which only the distances needed for uniquely reconstructing the conformations of the proteins are kept. [31].

- **Protein Family Identification**: Identification of protein families is a computational biology challenge that needs efficient and reliable methods. First, we used the comparison tool A_purva, which is based on Contact Map Overlap (CMO), to classify protein structure coming from the CATH database. The obtained results showed that A_purva was able to correctly classify 92% of the structures, and that introducing the notion of dominance drastically reduced the computational time needed for classifying the protein structures [33]. Then, we introduced this concept of dominance in a novel combined approach based on Distance Alignment Search Tool (DAST), which contains an exact algorithm with bounds. Our experiments showed that this method successfully finds the most similar proteins in a set without solving all instances [28].

- **Local Protein Threading, sequence-structure alignment**: A novel approach to PTP has been investigated. It aligns a part of a protein structure onto a protein sequence in order to detect local similarities [8]. [Online publication: http://www.sciencedirect.com/science/article/B6TYW50G78H4-1/2/947312da7a7bbf175cab7b3288ba4f03]

6.5. Systems Biology

Participants: Anne Siegel [contact], Jérémie Bourdon, Michel Le Borgne, Nathalie Theret, Geoffroy Andrieux, Oumarou Abdou-Arbi, Sylvain Prigent, Pierre Blavy, Andres Aravena, Santiago Videla, Valentin Wucher, Brivael Trelhu.

- **Average-case analysis for quantitative data integration**: We proposed a probabilistic modeling framework that integrates heterogeneous data. Average case analysis methods were used in combination with Markov chains to link qualitative information about transcriptional regulations to quantitative information about protein concentrations. The approach was illustrated by modeling the carbon starvation response in Escherichia coli. It accurately predicted the quantitative time-series evolution of several protein concentrations using only knowledge of discrete gene interactions and a small number of quantitative observations on a single protein concentration [5]. [Online publication: http://dx.plos.org/10.1371/journal.pcbi.1002157]
• **Combining genetic and metabolic regulations:** We mixed Gale-Nikaido reduction steps and differential inequalities to understand how genetic regulation modifies the behavior of a very abstracted model of lipid metabolism [18]. [Online publication: http://www.springerlink.com/content/n437048670560782/]

• **Extract relevant information with respect to a cancer phenotype:** We designed dedicated logical rules to model the static response of biomolecular interactions implied in the cancer network. This allowed us to trace back genes implied in the cancer phenotype [12]. [Online publication: http://www.computer.org/portal/web/csdl doi/10.1109/TCBB.2010.71]

• **Integrative biology for brown algal** We proposed a protocol focusing on integrating heterogeneous knowledge gained on brown algal metabolism. The resulting abstraction of the system helps understanding how brown algae cope with changes in abiotic parameters within their unique habitat [19].

• **Search for key regulators** A method was proposed to model the effects of all transcriptional and metabolic regulations contained in transpath in a single influence network. The network was analyzed to find a set of candidates that explain the variations of a set of targets [34].

• **Identification of co-regulation patterns.** We introduced a new approach based on the compilation of Simple Shared Motifs (SSM), groups of sequences defined by their length and similarity and present in conserved sequences of gene promoters. We proved that Simple Shared Motifs analysis provides a clearer definition of expression networks [10]. [Online publication: http://www.biomedcentral.com/1471-2105/12/365]

• **Probabilistic models for systems biology** We reviewed, in a book chapter, some classical concepts concerning probabilistic models and their applications in systems biology. Probabilistic boolean networks were presented in deep with a focus on the effect of synchronization of genes and on stochastic simulation of such networks [36].
6. New Results

6.1. MLIF

TALARIS contributes to ISO TC 37 committee “Terminologies and other Language Resources”, and more specifically to the activities of its SC3 “Computer Applications in Terminology”, and SC4 “Linguistic Resources Management”. Within TC37/SC4, TALARIS is currently contributing, as project leader, to the definition and specification of the Multi Lingual Information Framework (MLIF) [ISO FDIS 24616]. MLIF is being designed with the objective of providing a common abstract model being able to generate several formats used in the framework of translation and localization. MLIF has been released as FDIS (Final Draft International Standard) and it should finally be published as an official ISO standard soon. MLIF has been extensively used within the ITEA2 META VERSE1 project. [42], [43], [12].

6.2. TEXT CLASSIFICATION

Neural clustering algorithms show high performance in the general context of the analysis of homogeneous textual datasets. We have recently proposed a new incremental growing neural gas algorithm using the cluster label maximization (IGNGF) [44] [34]. In this strategy the use of a standard distance measure for determining a winner is completely suppressed by considering the label maximization approach as the main winner selection process. One if its important advantage is that it provides the method with an efficient incremental character as it becomes independent of parameters. Although it performs better than the standard clustering methods on textual data, we have shown this year than the obtained results are not as efficient as expected whenever an analysis of very complex heterogeneous textual datasets is performed [33]. We have thus explored several variations of IGNGF approach based on combination of distance based criteria and cluster label maximization. Our new results on all kinds of datasets, especially on the most complex heterogeneous textual datasets, clearly reflect the advantages of our new algorithm as compared to other existing algorithms and to our former adaptations [29]. Cluster quality evaluation represents a key process for all kinds of data analysis tasks, and more especially for textual data. We have recently presented different variations of unsupervised Recall/Precision and F-measures measures that cope with the defects of classical indexes, like inertia-based indexes. Our new indexes directly exploit the maximized features of the data associated to each cluster after the clustering process without prior consideration of clusters profiles. As compared to classical indexes, their main advantage is thus to be independent of the clustering methods and of their operating mode. They thus altogether permit the objective comparison of clustering methods and represent a sound technique for efficient cluster labeling. We have more especially worked this year on the large scale validation our indexes using reference labeled textual datasets [35].

We are also currently investigating to set up a platform for efficiently assisting the patents experts in the process of patents validation. Reaching such a goal has implied to develop new semi-supervised classification methods or propose in-deep adaptation of existing ones in order to establish relevant relationships between hierarchical patents classification and bibliographical references describing research covering the fields related to the different patents classes. In this context, we have successfully explored this year new classification techniques based on taboo search [14].

To cope with the current defects of existing incremental clustering methods, an alternative approach for analyzing information evolving over time consists in performing diachronic analysis. We have thus explored this year different an original technique based on this approach on texts by the use of the combination of cluster labeling with unsupervised Bayesian reasoning between cluster labels extracted from clustering model issued from different time periods. Based on a reference dataset issued from the IST-PROMTECH project, we have clearly shown that these new techniques, whilst providing a new framework for automatizing such kind of analysis, outperformed existing ones [32] [31] [30].
6.3. DIALOG

Within the Emospeech project, we developed the Emospeech Dialogue Toolkit (cf. Software section); used the Wizard of Oz infrastructure it includes to collect dialog data; and trained an interpreter and a dialog manager. The collected data comprises 591 dialogues in French collected within the context of the Mission Plastechnology serious game, 4874 utterances, 77854 words and 1321 player utterances containing 12901 word tokens and 1427 word types. We collected in average 50 conversations for each sub-dialogue in the game. Dialog length varies from 78 to 142 with an average length of 106 utterances per dialog.

6.4. GIVE

For the Generation of Instruction in Virtual Environment challenge edition 2.5 (GIVE), we developed two systems. The first system is the successor of the system that we presented to the GIVE 2 challenge (2010). We solved two known problems of this system, namely the indefinite presupposition problem and the ambiguity arising from underspecified referring expressions [26]. The GIVE 2.5 challenge proved that these improvements were efficient, and showed an increase of 21% in terms of task success (47% in GIVE 2, 68% in GIVE 2.5). The second system, developed in collaboration with the University of Cordoba is the first to our knowledge that uses a human-human corpus to provide whole utterances thanks to plan matching techniques [22], [21]. The system ranked fifth in terms of task success (58%), but second in terms of referring targets identification. The naturalness of instructions and the simplified system development makes it an interesting research track to follow.

6.5. Verb Classification

To help computer systems in the task of understanding and representing the full meaning of a text, verb classifications have been proposed which group together verbs with similar syntactic and semantic behaviour. For English verbs, VerbNet provides such a large scale classification but there are no similar French resource available. We investigated different ways both of automatically constructing such a resource; and of evaluating it.

Using Formal Concept Analysis (FCA), we developed a method for classifying verbs based on their (syntactic) subcategorisation information extracted from existing French lexical resources; and by translating the English Verbnet, we showed how to associate the obtained classes with semantic information represented by Verbnet’s thematic role sets ([27]). As a result, a VerbNet like classification for French verbs can be constructed fully automatically.

The FCA approach we pursued, first builds a classification based on verbs and verb features and second filters this classification using various metrics (e.g., concept probability, concept stability). We are currently comparing this approach with a clustering approach which makes use of detailed evaluation metrics [44] and uses probabilistic information to guide classification. First results are promising and outperform the state of the art methods in this domain [63].

One important difference between the clustering and the FCA approach we experimented with is that only the second, allows a verb to belong to several classes. Since verbs are highly ambiguous, this is an important difference. To evaluate the impact of this difference on the usability of the classifications built by each of the methods, we are currently conducting a task-based, extrinsic evaluation of both classifications by analysing their impact when used in a Semantic Role Labeling task on a French corpus.

6.6. I-FLEG

Within the Allegro project, we developed the I-FLEG game [16], [15], a virtual world in which the learner exercises French by clicking on objects and answering the questions raised by the system. The language learning exercises produced by I-FLEG are automatically generated using the GenI sentence generator from a knowledge base describing the virtual world. A preliminary evaluation of I-FLEG with school children [17] suggests that the “game” aspect increases learner motivation and that spoken output is essential in maintaining learner interest.
6. New Results

6.1. Point counting

In joint work with Pierrick Gaudry (CARAMEL) and David Kohel (Marseille), B. Smith developed an accelerated Schoof-type point counting algorithm for genus 2 curves with efficiently computable real multiplication endomorphisms. This project has made the computation of cryptographic-sized group orders practical for curves of genus 2 over prime finite fields. Going beyond the current cryptographic range, the algorithm has been used to compute the group order of a 1024-bit Jacobian (smashing the previous 256-bit record of Gaudry and Schost). The article describing this algorithm has been awarded the Best Paper prize at ASIACRYPT 2011 [26], and an extended version has been invited for submission to Journal of Cryptology (the leading journal in the field).

6.2. Complex multiplication

F. Morain has been investigating new invariants for building class polynomials with small coefficients. This is still work in progress, though advertised in some talks of his.

6.3. Steganography

D. Augot, M. Barbier and Caroline Fontaine randomized the bounded syndrome coding problem on wet paper—an important embedding problem in steganography—such that this problem always has a solution [24]. This randomization is inspired the Courtois–Finiasz–Sendrier signature scheme, and shows nice results for linear perfect codes. In the special case of binary Hamming codes, this new method reaches exactly the necessary and sufficient bounds to ensure the embedding. The previous bounds were introduced by Carlos Munuera and M. Barbier [19]. These bounds depend on the dual distance of the code used. Thanks to the generalized Hamming weight, they proved that codes with low MDS rank are better in this context. Since the nature of their results are combinatorial, the authors generalized a bound for systematic non linear codes and showed that the non-linear systematic codes could be good candidates, as shown by the example of the Nadler code.

6.4. Homomorphic encryption

D. Augot, in collaboration with L. Perret from Salsa team, and Bochum Universität [22], designed a “secret-key” homomorphic encryption scheme, which is much more efficient than the public-key ones. It is based on $q$-ary Reed-Muller codes (or multi-variate evaluation-interpolation schemes). The main drawback is a severe restriction on the number of uses of a given secret key, but the ease of decrypting leads to think that the scheme can reencrypt its keys, enabling its reuse.

6.5. List decoding

D. Augot, M. Barbier and A. Couvreur wrote on how to decode binary Goppa codes. Augot, Barbier, and Couvreur presented a simple way, with a clean study of the complexity [23]. Using this list decoding algorithm, Barbier and Paulo Barreto proposed a key reduction for the McEliece cryptosystem [25]. The list decoding algorithm above allowed them to add more errors during the McEliece encryption step, making decoding attacks more difficult. At the same complexity of these attacks, using the list decoding algorithm decreases the public key size, which is the main drawback of this cryptosystem.
6.6. Explicit isogeny constructions

B. Smith constructed six infinite series of families of pairs of algebraic curves of arbitrarily high genus [20], defined over number fields, together with an explicit isogeny between the Jacobians of the curves splitting multiplication by 2, 3, or 4.

6.7. Quasi-cyclic codes

M. Barbier, Christophe Chabot and G. Quintin exhibited a bijective correspondence between the $\ell$-quasi-cyclic codes over $\mathbb{F}_q$ of length $m\ell$ and the set of ideals of $M_{\ell}(\mathbb{F}_q)[X]/(X^m - 1)$ [29]. They proposed also two new classes called the quasi-BCH and quasi-evaluation codes. For the first one, they introduced a unambiguous decoding algorithm, and thanks to the second one they designed 49 new codes over $\mathbb{F}_4$ which have a bigger minimum distance than previously known codes.

6.8. Root-finding over Galois rings

Jérémy Berthomieu, Grégoire Lecerf and G. Quintin presented a new algorithm to find all the roots of a given polynomial with coefficients in a Galois ring [30]. It has been used to study the behavior of the Sudan algorithm for Reed-Solomon codes over Galois rings. The algorithm has been adapted to work over rings of power series in several variables. It was implemented in the Quintix package of Mathemagix.
6. New Results

6.1. Autonomous Computing

Participants: Cécile Germain-Renaud, Michèle Sebag, Balázs Kégl, Yusik Kim, Julien Nauroy, Dawei Feng.

Within the classical objectives of Autonomics (self-*), two transversal lines of research have emerged.

Coping with non-stationarity  Most existing work on modeling the dynamics of grid behavior assumes a steady-state system and concludes to some form of long-range dependence (slowly decaying correlation) in the associated time-series. But the physical (economic and sociologic) processes governing the grid behavior dispel the stationarity hypothesis. [68] proposes a categorization of the methods integrate non-stationarity into grid modeling. [9] considers a specific class of models: a sequence of stationary processes separated by breakpoints. The model selection question is now defined as identifying the breakpoints and fitting the processes in each segment, together with a validation methodology that empirically addresses the current lack of theoretical results concerning the quality of the estimated model parameters. Even when stationarity is acceptable, the markovian assumption might be too bold. [54] integrate Echo State Network-based regression into a reinforcement learning in continuous state space for fitting the Q function, with application to reactive grid scheduling.

Traces mining  In order for an autonomic system to continuously infer knowledge from its monitoring (the so-called MAPE-K, Monitor-Analyze-Plan-Execute-Knowledge) loop, heterogeneous sources of data have to be integrated. [37] exemplifies two use cases of the Grid Observatory data on evaluating the performance of the major EGI scheduler, and blackhole detection.

The Green Computing Observatory [38] data include the detailed monitoring of the processors and motherboards, as well as the global site information, such as overall consumption and overall cooling. The data schema for publication is grounded in an ontology of measurements developed in collaboration with the MIS (Modélisation, Information et Systèmes) laboratory of University Picardie Jules Verne.

[42] proposes a new approach for analyzing behavioral traces: as most of them are indeed text documents, state of the art techniques in text mining, including Latent Dirichlet Allocation, can be exploited. The advantages are twofold: providing some level of explanation inferred from the data; and a relatively scalable way to capture the temporal variability of the behavior of interest, while retaining the full dimensionality of the problem at hand. A promising perspective for combining this approach and inferred segmentation has been identified and is currently explored.

6.2. Complex Systems

Participants: Jamal Atif, Nicolas Bredèche, Matthias Brendel, Cyril Furtlehner, Philippe Caillou, Jean-Marc Montanier, Hélène Paugam-Moisy, Marc Schoenauer, Michèle Sebag.

Evolutionary AI Planning: Divide And Evolve (DAE) DAE solves AI-planning problems by using an Evolutionary Algorithm to sequentially divide them into hopefully simpler problems that are handled by some embedded “classical” planner. Within the ANR project DESCARWIN, work has continued in collaboration with Thalès Research & Technology and ONERA Toulouse. A large part of the work this year has been devoted to writing a brand new version of the DAE software, facing difficulties of parallelization [90]. The resulting program entered the 7th International Planning Competition (IPC 2011) at the 21st International Conference on Planning and Scheduling (ICAPS 2011) and won the Gold Medal in the Temporal Track. Note that the Silver Medal was won by Vincent Vidal,
also member of the DESCARWIN team, using his planner YAHSP2 – the one that won the Gold Medal while embedded in DAE, thus demonstrating one more the added value of the DAE approach. Meanwhile, because DAE has many parameters (like most Evolutionary Algorithms), parameter tuning within DAE remains a difficult task, and an original approach has been proposed to learn the parameters based on some instance features [49], [50], [51]. Note that this method is however relevant of the “Crossing the Chasm” SIG (see Section 6.3), as it can be applied to any optimization algorithm that handles several instances of the same class.

Distributed Autonomous Robotics  Resuming work done in 2010, we investigated further the issue of robotic swarm control whenever the environment is partially or completely unknown. This research is at the cross-road of Evolutionary Computation, Machine Learning and Robotics, and a light influence from Evolutionary Ecology, but with a strong focus on engineering (ie. the goal remains to design algorithms). The topic we are interested in is the design of environment-driven self-adaptive distributed algorithms to enable survival at the level of a population of independent robotic units. The population is limited in size, and hardware implementation within real robots has already been achieved [7]. We have also focused our attention on specific aspects of swarm evolutionary dynamics under specific constraints, including the evolution of cooperative and/or altruistic behaviours [53], [52]. This research yielded interesting results, such as the emergence of altruistic behavior under simple, but specific, algorithmic constraint, as well as tuning mechanism to control the level of altruistic behavior in a population of robots. Perspectives of this work is currently under investigation.

The work done in 2010 about the division of labor among asynchronous and decentralized agents, where each agent is modelled from the competition between two spiking neurons, was further analyzed within a spatio-temporal (simulated) frame. The phase transitions between the asynchronous, the aperiodic and periodic synchronous regimes (depending on the sociability and excitability of the agents) was confirmed, with some counter-intuitive results about the overall merits and efficiency of synchronous behaviors [23].

We have also explored objective-driven online learning within real robotic hardware, both for single robot online behavior learning [78] as well as small group of robots for pattern formation learning [43]. Our activity in Evolutionary Robotics has also been strengthened by the publication of book which gather several contributions from major actors in the field [75], including an introduction paper on current trends and challenges in this domain [76].

From a slightly different perspective, our work on evolving generative and developmental representations has been continued, with an extensive study of robustness within developmental systems [8] and an investigation of the temporal dynamics at work within genetic regulatory networks for design [32]. While not strictly related to robotics, these contributions share the distributed nature of computation and ultimately aim at providing an efficient representation for designing and controlling large scale passive or active assembly of units (e.g. robots with complex morphologies).

Statistical Physics Perspective  Basic tools from statistical physics (scaling, mean-field techniques and associated distributed algorithms, exactly-solvable models) and probability have been used to model and optimize complex systems, either standalone or combined with MABS approaches. Results are

- In the context of the ANR TRAVESTI project dealing with spatial and temporal modelling of traffic congestion we have studied in [83] some specific properties of the Belief Propagation algorithm used for inference; we have proposed a way to encode dependencies between real variables with a latent binary MRF [89]; we have analyzed macro-states on traffic data and how these relate to belief propagation fixed points [35].
• Also in the ANR Travesti context [36], [88] for modelling congestion at the microscopic level we have proposed a new family of queueing processes where the service rate is coupled stochastically to the number of clients. With this formulation we have been able to relate an asymmetry between acceleration and braking to some condensation mechanism. In this framework we have also proposed a large deviation formulation of the fundamental diagram of traffic flow.
• In the design of multi-objective message passing algorithms we have shown how the state-of-the-art MAXSAT solver SP-Y can be used directly by an endogeneous clause elimination procedure, to sample Pareto Front of multi-objective 3-SAT problems [87].

Multi-agent and games
• Within the InnovNation serious game project, in collaboration with Paraschool and BlueNove, we developed an e-brainstorming prototype for collaborative ideation. The prototype was tested on 150 students and is being improved to be commercialized. The realist network generator used to analyze the prototype games was also used to study the labor market, and to study the relative importance of friends and colleagues while seeking for a job without ([44] or with [64] variable information transmission speed. We have shown that friends were the most useful when the labor market was at the equilibrium (approximately the same number of jobs and applicants).
• To analyze the logs of multi-agent based simulations (for example for the InnovNation project), we developed a tool to describe homogeneous agent clusters and their evolution ([73]). We use the cluster description to build agent models and generate new simulations with this model to validate the results. • Also in the complex social system analysis context, we applied LSA text mining tools on research projects and patent category descriptions to associate research clusters to their main research fields [70]. This was used to build a classification of the French research clusters based on their context, and especially the adequation of the cluster research specialization with the regional specialization [72].

Image understanding
• Within the context of image understanding, a new sequential recognition framework has been proposed in [10]. Sequential image understanding refers to the decision making paradigm where objects in an image are successively segmented/recognized following a predefined strategy. Such an approach generally raises some questions about the “best” segmentation sequence to follow and/or how to avoid error propagation. In [10], we propose original approaches to answer these questions in the case where the objects to segment/recognize are represented by a model describing the spatial relations between objects. The process is guided by a criterion derived from visual attention, and more precisely from a saliency map, along with some spatial information to focus the attention. This criterion is used to optimize the segmentation sequence. Spatial knowledge is also used to ensure the consistency of the results and to allow backtracking on the segmentation order if needed. The proposed approach was applied for the segmentation of internal brain structures in magnetic resonance images. The results show the relevance of the optimization criteria and the interest of the backtracking procedure to guarantee good and consistent results. From a logical standpoint, sequential object recognition is formulated as an abduction process in [14], [66]. A scene is viewed as an observation and the task of interpretation is considered as the “best” explanation considering the prior knowledge about the scene context. Towards this aim, we introduce an algebraic-based framework unifying mathematical morphology, description logics and formal concept analysis. We propose to compute the best explanations of an observation through algebraic erosion over the Concept Lattice of a background theory which is efficiently constructed using tools from Formal Concept Analysis. We show that the defined operators are sound and complete and satisfy important rationality postulates of abductive reasoning.

6.3. Crossing the Chasm

Participants: Alejandro Arbelaez, Anne Auger, Robert Busa-Fekete, Nikolaus Hansen, Balázs Kégl, Manuel Loth, Nadjib Lazaar, Marc Schoenauer, Michèle Sebag.
Due to the departure of both PhD students funded within the Microsoft-INRIA joint lab after their successful defenses (Alvaro Fialho and Alejandro Arbelaez), some of the activities of this SIG have been slightly redefined this year, with the one-month visit of Prof. Th. Runarsson (University of Iceland) in October, and the arrival in November of two new post-docs, also funded by the joint lab (Nadjib Lazaar and Manuel Loth). A new direction of research has appeared, in line with both Adaptive Operator Selection (Alvaro Fialho’s PhD) and Continuous Search (Alejandro Arbelaez’ PhD).

Bandit-based choice of heuristics in combinatorial optimization. This new direction of research deals with heuristic choice within an existing combinatorial solver using bandit-like algorithms, and the very first results deal with scheduling problems and will be published in early 2012 [57].

Adaptive Operator Selection. In line with his PhD work, Alvaro Fialho has successfully used his Adaptive Operator Selection method to the on-line tuning of Differential Evolution in the multi-objective case [96].

Learn and Optimize (LaO), an instance-based parameter-tuning method. Though originally designed for Divide-And-Evolve framework (see Section 6.2), LaO is a generic method that learns the relationship between some instance features and the optimal parameters of the optimizer. The current version [49], [50], [51] uses Neural Network to directly learn the optimal parameters, and average performance increase compared to the default parameter set (that has won the temporal track in the IPC7 competition) is of more than 10%. On-going work uses rankSVM to learn a partial order on the features × parameter space.

Adaptive Constraint Programming. Alejandro Arbelaez defended his PhD on May 31, led under the supervision of Youssef Hamadi and Michèle Sebag [1]. A survey of his PhD work has been published as a book chapter [74] and some of his last work was more concerned with optimizing the collaboration in distributed SAT solving in highly parallel environments [13].

Ranking by calibrated AdaBoost. In [22], [21] we describe a learning-to-rank technique based on calibrated multi-class classification. We train a set of multi-class classifiers using AdaBoost.MH, we calibrate them using various techniques to obtain diverse class probability estimates, and, finally, we approximate the Bayes-scoring function (which optimizes the popular Information Retrieval performance measure NDCG), through mixing these estimates into an ultimate scoring function. Our method outperforms many standard ranking algorithms on the LETOR benchmark datasets, most of which are based on significantly more complex learning to rank algorithms than ours.

6.4. Continuous Optimization

Participants: Yohei Akimoto, Anne Auger, Zayed Bouzarkouna, Alexandre Chotard, Nikolaus Hansen, Ilya Loshchilov, Verena Heidrich-Meisner, Raymond Ros, Marc Schoenauer, Olivier Teytaud, Fabien Teytaud.

Our main expertise in continuous optimization is on stochastic search algorithms. We address theory, algorithm design and applications. The methods we investigate are adaptive techniques able to learn iteratively parameters of the distribution used to sample solutions. The Covariance Matrix Adaptation Evolution Strategy (CMA-ES) is nowadays one of the most powerful method for continuous optimization without derivatives. We work on different variants of the CMA-ES to improve it in various contexts as described below. In addition we have contributed to give an information geometry perspective to stochastic optimization unifying both continuous and discrete algorithms using a family of probability distribution parametrized by continuous parameters. The framework proposed in this context allow to retrieve many existing stochastic optimization algorithms when instantiante with different family of probability distributions including the CMA-ES when using gaussian distributions [85]. We have moreover clarified important design principles based on invariances [85], [11].

New algorithms based on derandomization and for mixed-integer optimization. A new variant of CMA-ES to address problem with mixed-integer variables (vectors with both discrete and continuous variables) has been designed [81]. New algorithms using new selection schemes combined with
derandomization have been designed and thoroughly theoretically and empirically investigated [16], [17]. A local search algorithm using an adaptive coordinate descent has been proposed [45]. We have as well investigated how to inject solutions in CMA-ES so as to improve performances if an oracle provide good solutions [82].

Distributed optimization We have proposed simple modifications of evolutionary algorithms so that they reach asymptotically the optimal $\log(\lambda)$ speed-up with $\lambda$ processors and the linear speed-up $\Theta(\lambda)$ for a number of processors of order at most the dimensionality of the problem (for a pointwise solution); in particular bounding the selected population size in the Self-Adaptation algorithm and variants of this idea for fastening the decrease of the step-size in a relevant manner. All these works and more are part of Olivier Teytaud’s HDR thesis [3], defended on April 22., and also build the first part of Fabien Teytaud’s PhD [2], defended on December 8.. We wrote a chapter on lower bounds for distributed derivative free optimization in [79].

Benchmarking We have continued our effort for improving standards in benchmarking and pursued the development of the COCO - COmparing Continuous Optimizers platform [80]. We are organizing for the GECCO 2012 conference the Black-Box-Optimization Workshop4.

Optimization with meta-models and surrogate We have investigated optimization using a coupling of CMA-ES and surrogates and applied it for the optimization of well placement [6]. We have proposed a new meta-model CMA-ES for the optimization of partially separable functions [19] and shown that it improves performances for solving the well placement problem [19].

Hyperparameter optimization In [18] we present hyper-parameter optimization results on tasks of training neural networks and deep belief networks (DBNs). We optimize hyper-parameters using random search and two new greedy sequential methods based on the expected improvement criterion. The sequential algorithms are applied to the most difficult DBN learning problems and find significantly better results than the best previously reported.

Multi-objective optimization We have investigated theoretically multi-objective algorithms based on the hypervolume [4] and proposed new selection operators based on tournament and multi-armed bandit framework [46].

Multimodal optimization We have shown in [58] a simple algorithm (a $(1 + 1)$-ES with quasi-random restart and murder operator), which, at least in the sequential case, performs as efficiently as much more tricky algorithms.

Mathematical bounds for noisy optimization The paper [27] shows upper and lower confidence bounds and/or experiment algorithms in the noisy optimization setting; in particular we compared an optimization algorithm based on bandits and an surrogate-model version; whereas the bandit approach is much faster if the noise decreases quickly to zero around the optimum, the surrogate-model version is faster if the noise does not decrease to zero.

6.5. Optimal Decision Making

Participants: Olivier Teytaud, David Auger, Michèle Sebag, Cyril Furtlehner, Jean-Baptiste Hoock, Nataliya Sokolovska, Fabien Teytaud, Hassen Doghmen, Jean-Joseph Christophe, Jérémie Decock.

- Monte-Carlo Tree Search (MCTS) and Upper Confidence Trees (UCT) are main areas of the team. In particular, we ultra-weakly solved 7x7 Go by winning 20 games out of 20 against professional players in 7x7 Go, thanks to a Meta-Monte-Carlo-Tree Search[24]. The wins were with komi 9.5 as white, and 8.5 as black, suggesting that the ideal komi in 7x7 is 9. We also applied this algorithm to the recent “NoGo” framework, aimed at challenging MCTS for a game which looks like Go but with very different goals; our paper [26] was the first one applying MCTS to NoGo and now all strong programs use the MCTS approach for NoGo. We extended RAVE (Rapid Action Value Estimates) to the continuous settings [29]. In his PhD [2], Fabien Teytaud proposed several generic

4 see http://coco.gforge.inria.fr/doku.php?id=bbob-2012
improvements of MCTS, including the use of (fast) decisive and anti-decisive moves for games, and applied it to the game of Havannah. An industrial application (to energy management) is proposed in [71]. A MCTS version for partially observable problems with bounded horizon was proposed in [86]. This version is proposed for the two-player case, but for simulations starting at the root; a version in the one-player case, starting from an arbitrary state (and therefore much more efficient for large horizon) is proposed in [30]. This work is extended by a belief state estimation by constraint satisfaction problems in [62]. Other developments and research around MCTS/UCT are described in the MoGo module.

• A related important algorithm is Nested Monte-Carlo; we got state of the art results for some traveling salesman variants with a very simple algorithm in [56].

• Fundamental analysis of partially observable games: we proved in [5] that partially observable games are undecidable (result also presented in the BIRS 2010 workshop and the Bielefeld seminar on Search Methodologies), even in the case of finite state spaces and deterministic transitions. This unexpected result is a priori a contradiction with known decidability results; this emphasizes the subtle difference between the classical decision problem (the existence of a strategy winning certainly, whatever may be the strategy of the opponent), which is used is most analysis, and the choice of the move with optimal winning probability. We pointed out that the relevant decision problem is, with no doubt, the latter; that the other decision problem has just been used because it is equivalent to choosing optimal play in the case of fully observable games; and, most importantly, that partially observable games are in fact undecidable, even in the finite deterministic case. On the other hand, on restricted settings, we have shown by some simple lemmas lower and upper bounds on the value of some partially observable games [63]. We extended Monte-Carlo Tree Search to the case of short-term partial information in [61]; this was successfully applied to the Urban Rival game, a widely played internet card game (now 17 millions of registered users) from a French company.

• Tuning of strategies: tuning strategies is a noisy optimization problem in which the convenient “variance of noise decreasing to zero around the optimum” usually does not hold. We have shown that in such a setting, the local bandit-style algorithms are slower than surrogate models; this is detailed in the continuous optimization part.

• We organized various computer-Go events, as due to the fame of our program MoGo we are often invited for such events; reports can be found in [95].

• We developed the “double progressive widening” trick, which is aimed at making consistent an algorithm from the finite case to the continuous stochastic case; we got good results in [60] on Q-Learning (with no mathematical proof) and on MCTS [28] (mathematical proof to be submitted soon).

• We have also worked on Nash equilibria of Matrix Games, where we proposed an algorithm for finding Nash equilibria faster when the Nash equilibrium is sparse [48], [47]; a mathematical proof is ready and will be submitted soon.

• Some works are in progress around applications of previous tools to active learning; active learning has also been investigated through conditional random fields in [59].

• Another related work, with motivations from autonomous robotics, combines the exploration of the search space through UCT, with an explicit model of the safe regions explored so far, called Deja-Vu. The Deja-Vu is used to constrain the exploration, mostly in the random phase, and is updated from the current explorations [67].

• The Ilab “Metis” just started; it’s an Ilab between Tao, the Inria-Saclay team MaxPlus, and the SME Artelys http://www.artelys.com for a joint work on numerical libraries in Energy Management.

### 6.6. Large and Deep Networks

**Participants:** Ludovic Arnold, Sylvain Chevallier, Anthony Mouraud, Hélène Paugam-Moisy, Sébastien Rebecchi, Michèle Sebag.
Deep networks: RBM or AA  The two main families of deep networks are implemented and studied by TAO: stacked RBM (Restricted Boltzmann Machines) and stacked AA (Auto-Associators).

Learning sparse features for deep networks  Inspired by the theory of compressed sensing and beyond the common methods based on dictionary learning, we have proposed to learn sparsity and accuracy simultaneously by alternating two constraints on the weights of an Auto-Associator [55].

Spiking neuron networks for swarm robotics  The model "SpikeAnts" [91] has been applied to a spatial robotic environment [23], in collaboration with Nicolas Bredeche (see Section 6.2), and has demonstrated even more its interest in the context of swarm robotics.
6. New Results

6.1. Octagonal Domains for Continuous Constraints (continuous)

Participants: Marie Pelleau, Charlotte Truchet, Fréderic Benhamou.

Domains in Continuous Constraint Programming (CP) are generally represented with intervals whose \( n \)-ary Cartesian product (box) approximates the solution space. We propose a new representation for continuous variable domains based on octagons \[ 28 \]. We generalize local consistency and split to this octagon representation, and we propose an octagonal-based branch and prune algorithm \[ 22 \]. Experimental results in IBEX on the COCONUT benchmarks suite show promising performance improvements on several classical benchmarks.

The corresponding paper Octagonal Domains for Continuous Constraints got the Best Student Paper Award at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011) \[ 22 \].

6.2. A Constraint Seeker (classification, constraints and application)

Participants: Nicolas Beldiceanu, Helmut Simonis.

We design a Constraint Seeker application which provides a web interface to search for global constraints in the global constraint catalog, given positive and negative ground examples. Based on the given instances the tool returns a ranked list of matching constraints, the rank indicating whether the constraint is likely to be the intended constraint of the user. A systematic evaluation is provided over the complete global constraint catalog.

The corresponding paper A Constraint Seeker: Finding and Ranking Global Constraints from Examples \[ 16 \] was published at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011) and the corresponding tool is available as a web service at http://www.emn.fr/z-info/sdemasse/gccat/.

6.3. Soft Problems (modelling and filtering)

Participants: Thierry Petit, Alexis De Clerq, Nicolas Beldiceanu, Narendra Jussien.

1. Side-constrained problems We experimentally shown that solving some classes of over-constrained problems requires an efficient (global) propagation of side constraints on variables representing violations. This work completes our previous studies, which highlighted the interest of a variable-based representation of violations for sake of modelling.

The corresponding paper Global Propagation of Side Constraints for Solving Over-constrained Problems was published in the Annals of Operations Research journal \[ 14 \].

2. Soft cumulative scheduling We proposed a new constraint for handling cumulative problems with exceeds of capacities, int the case where the time horizon is fixed and the capacity can vary over time. Sweep and Edge-finding algorithms for classical cumulative problems have been modified so as to provide a filtering algorithm for our constraint. Experiments shown that instances involving several hundreds of activities can be solved with our approach.

The corresponding paper Filtering Algorithms for Discrete Cumulative Problems with Over-loads of Resource was published at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011), \[ 17 \].
6.4. **Constraints with costs (modelling and filtering)**  
**Participants:** Thierry Petit, Nicolas Beldiceanu.

1. **Distribution of costs** We presented a new cardinality constraint dedicated to sequences of totally ordered cost. This constraint is useful to impose a precise (fair) distribution of the values taken by the cost variables in a given sequence, for instance in a bin packing with safety rules or in cumulative scheduling with overloads of resource. We came up with a generalized arc-consistency filtering algorithm, whose time complexity is linear in the sum of the number of variables and the number of values in the union of their domains. 

The corresponding paper the *Ordered Distribute Constraint* was published in the International Journal on Artificial Intelligence Tools [15].

2. **The objective sum constraint.** Constraint toolkits generally provide a sum constraint whose propagation is poor to solve optimization problems. Therefore, solving real-world problems requires to develop ad-hoc techniques for handling sums, based on the particular properties of each problem. We proposed a generic technique which improves the standard sum constraint by exploiting the propagation of a set of constraints defined on the variables involved in a sum. 

The corresponding paper *The Objective Sum Constraint* was published in the 8th International Conference on Integration of Artificial Intelligence and Operations Research Techniques in Constraint Programming for Combinatorial Optimization Problems (CPAIOR 2011) [25].

3. **the increasing sum constraint** Given a sequence of variables X of length n, we consider the increasing sum constraint, which imposes the variables of X to be sorted in non strictly order, and that the sum of the variables of X is equal to s. We propose an linear time bound-consistency algorithm for increasing sum. This work is related to problems with variable symmetries, when some of the symmetric variables are involved in sum constraints. 

The paper *A Theta(n) Bound-Consistency Algorithm for the Increasing Sum Constraint* was published at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011). [24].

These works were all done in collaboration with J.-C. Régin (Univ. Nice).

6.5. **Efficient Filtering Algorithms for Generic Constraints (filtering)**  
**Participants:** Nicolas Beldiceanu, Xavier Lorca, Thierry Petit.

**Counting constraints** We identified a family of counting constraints for which performing a complete filtering is a tractable problem. We provided a generalized arc-consistency algorithm and its specialization to some well-known global constraints. For some of them the obtained time complexity is linear in the sum of domain sizes, which improve or equals the best known results in the literature. 

The corresponding paper *A Generalized Arc-Consistency Algorithm for a Class of Counting Constraints* was published at the 22th International Joint Conference on Artificial Intelligence (IJCAI’11) [23].

6.6. **Efficient Filtering Algorithms and Heuristics for Dedicated Constraints (filtering)**  
**Participants:** Jean-Guillaume Fages, Xavier Lorca, Arnaud Malapert, Narendra Jussien.

1. **Revisiting the tree constraint** We revisit the tree constraint introduced at CPAIOR 2005 in [35] which partitions the nodes of a n-nodes, m-arcs directed graph into a set of node-disjoint anti-arborescences for which only certain nodes can be tree roots. We introduce in a new filtering algorithm that enforces generalized arc-consistency in O(n+m) time while the original filtering algorithm reaches O(nm) time. This result allows to tackle larger scale problems involving graph partitioning in CHOCO.
The corresponding paper Revisiting the tree Constraint was published at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011), [18].

2. An Optimal Constraint Programming Approach to the Open-Shop Problem We present an optimal constraint programming approach for the Open-Shop problem, which integrates recent constraint propagation and branching techniques with new upper bound heuristics for the Open-Shop problem. Randomized restart policies combined with nogood recording allow to search diversification and learning from restarts. This approach closed all remaining problems of the Brucker et al. and Guéret and Prins benchmarks with cpu times that are orders of magnitude lower than the best known metaheuristics.

The corresponding paper An Optimal Constraint Programming Approach to the Open-Shop Problem was published in the INFORMS Journal on Computing [13]. This work was done in collaboration with H. Cambazard (4C, INP Grenoble), C. Guéret (IRCCyN), A. Langevin (Ecole Polytechnique Montréal) and L.-M. Rousseau (Ecole Polytechnique Montréal).

6.7. Explanations for Constraint Programming (solver)

Participants: Narendra Jussien, Charles Prud’homme.

Constraint programming, despite its numerous successes in practice, suffers from not being really user-friendly when used by software engineers. Indeed, when faced with a no solution message from a constraint solver, it is hard yet impossible to identify the cause of this message: is it from a bad modelling, an ill-written constraint, a bug in the solver, .... Explanations for constraint programming have addressed this issue but are not yet widely used in the CP community. Recent work in the field tend to demonstrate that providing explanation-based user-oriented features can be done quite easily in modern constraint solvers. The objective of this line of work is to specify an user-oriented explanation-module for flexible solver architectures. This line of work is financed through a Google focused research grant. First results provide a complete solver independent specification of explanation algorithms, data structure for encoding nogoods and treatment algorithms. A reference implementation is being made within the new version of our solver CHOCO.

6.8. Bin repacking (constraints and application)

Participants: Sophie Demassey, Xavier Lorca, Fabien Hermenier.

A datacenter can be viewed as a dynamic bin packing system where servers host applications with varying resource requirements and varying relative placement constraints. When those needs are no longer satisfied, the system has to be reconfigured. Virtualization allows to distribute applications into Virtual Machines (VMs) to ease their manipulation. In particular, a VM can be freely migrated without disrupting its service, temporarily consuming resources both on its origin and destination.

We introduce the Bin Repacking Scheduling Problem in this context. This problem is to find a final packing and to schedule the transitions from a given initial packing, accordingly to new resource and placement requirements, while minimizing the average transition completion time. Our CP-based approach uses CHOCO and is implemented into Entropy, an autonomous VM manager which detects reconfiguration needs, generates and solves the CP model, then applies the computed decision. CP provides the awaited flexibility to handle heterogeneous placement constraints and the ability to manage large datacenters with up to 2000 servers and 10000 VMs.

The corresponding paper Bin-Repacking Scheduling in Virtualized Datacenters was published at the 17th International Conference on Principles and Practice of Constraint Programming (CP 2011), [19].

6.9. A Global Constraint for Multi-Agent Localization (constraints and application)

Participants: Gilles Chabert, Sophie Demassey.
This work has been initiated in the context of the Angels research project, in which G. Chabert has been involved during two years. The idea was to provide a new method for inter-localizing a group of autonomous underwater robots, traditional Kalman-based methods being inadequate in this context due to the highly nonlinear models derived from the sensing technology (electric fish robots).

We proposed, through a rough discretization of the signals, to consider the problem as a whole and under a combinatorial form. The level of the signal is basically associated to a cardinality of surrounding objects. This led to a global constraint, namely a conjunction of among constraint with interval value domains and in multiple dimension (objects are variables with several components).

Conjunction of among constraints had been already studied but not in the case of interval value domains. We therefore conducted a theoretical study and proved that the problem was tractable in the one-dimensional case, but not in higher dimension. We have also investigated different decompositions and filtering algorithms. This work is submitted to CPAIOR 2012. An INRIA research report has also been issued in June 2011, where the robotics aspects are described.
6. New Results

6.1. Analysis and modeling for compact representation and navigation

6.1.1. Joint projection/filling method for virtual view synthesis

Participants: Christine Guillemot, Vincent Jantet.

This study is carried out in collaboration with INSA/IETR (Luce Morin). Associated with a view synthesis method, a multi-view plus depth video allows the generation of virtual views of the scene from any viewpoint. Many algorithms have thus been developed to synthesize virtual views from one or several input views video plus depth data. These rendering algorithms are either based on Image-Based Rendering (IBR) techniques or Geometry-Based Rendering (GBR) techniques, according to the amount of 3D information they use. IBR techniques require limited geometric information to synthesize intermediate views and allow the generation of photo-realistic virtual views at the expense of virtual camera freedom. GBR techniques require detailed 3D models of the scene to synthesize arbitrary viewpoints (points of view). GBR techniques are sensitive to the accuracy of the 3D model, which is difficult to estimate from real multi-view videos. Depth-Image-Based Rendering (DIBR) techniques include hybrid rendering methods between IBR and GBR techniques. DIBR methods are based on warping equations, which project a reference view onto a virtual viewpoint. Each input view is defined by a "color" (or "texture") map and a "depth" map, which associates a depth value to each image pixel.

In classical DIBR schemes, the rendering proceeds in several distinct steps, each one designed to solve a specific problem. First, the input depth map is warped onto the virtual viewpoint. The obtained warped depth map contains disocclusions, cracks and ghosting artifacts. Second, this virtual depth map is filtered with a median filter, in order to remove the cracks, and then to dilate disocclusion areas on the background side, in order to avoid ghosting artifacts during view synthesis. Third, the filtered depth map is used in a backward warping to compute the color of each pixel of the virtual view. Fourth, this resulting depth map is inpainted, to fill in disocclusion areas. Finally, this complete depth map is used by a depth-aided inpainting algorithm to fill in disocclusions in the color map. However, all these steps are inter-dependent, and errors introduced by each one are amplified by the following one. Connectivity information is lost during the first projection step, as shown in Fig. 2. Without this connectivity information, every inpainting method fails to fill in background disocclusions if the disoccluded area is surrounded by foreground objects. This case may happen each time a foreground object is not convex, and contains holes, as shown in Fig. 2 -(a). As a result, depth-aided inpainting uses wrong foreground patches to fill in background disocclusions, producing annoying artifacts, as shown in Fig. 2 -(b).

We have developed two DIBR techniques, both based on a novel forward projection technique, called the Joint Projection Filling (JPF) method [16]. The JPF method performs forward projection, using connectivity information to fill in disocclusions in a single step. The first proposed DIBR method is designed to extrapolate virtual views from a single input view plus depth video sequence. The synthesis of virtual depth maps by the JPF method avoids the use of dedicated filtering and inpainting processes and leads to synthesized depth maps of higher quality. The second proposed DIBR method is designed to interpolate intermediate views from multiple input view plus depth sequences. This interpolation method uses the Floating Texture approach to register multiple inputs view plus depth sequences before blending. The JPF method fills in disocclusion areas during the projection, to ensure that geometrical structures are well preserved. The method uses the occlusion-compatible ordering presented by McMillan, which uses epipolar geometry to select a pixel scanning order. The occlusion-compatible ordering is used to handle disocclusions gracefully. Cracks are filled in by interpolation of neighboring pixels, whereas disocclusions are only filled in by background pixels. This technique can also be used with non-rectified views, avoiding prior creation of parallax maps.
6.1.2. 2D/3D image inpainting for virtual view synthesis

**Participants:** Josselin Gauthier, Christine Guillemot, Mouid Keskes, Olivier Le Meur.

Inpainting methods play an important role in a wide range of applications. Removing text and advertisements (such as logos), removing undesired objects, noise reduction and image reconstruction from incomplete data are the key applications of inpainting methods. Algorithms can be classified into two categories: PDE (Partial Derivative Equation)-based schemes and examplar-based schemes. The former uses diffusion schemes in order to propagate structures in a given direction. Their drawback is the introduction of blur due to diffusion. The latter relies on the sampling and the copying of texture from the known parts of the picture.

We have proposed a novel inpainting algorithm combining the advantages of both aforementioned methods. As in Criminisi et al’s approach, the proposed method involves two steps: first, a filling order is defined to favor the propagation of structure in the isophote direction. Second, a template matching is performed in order to find the best candidates to fill in the hole. Compared to previous approaches, the main contributions concern the use of structure tensors to define the filling order instead of field gradients. The structure tensor is defined as follow:

\[
J = \sum_{i \in \{R, G, B\}} \nabla I_i \nabla I_i^T
\] (39)

\(J\) is the sum of the scalar structure tensors \(\nabla I_i \nabla I_i^T\) of each image channel \(I_i (i \in \{R, G, B\})\). Information about local geometry can be deduced by computing the eigenvalues and eigenvectors of \(J\). The local vector geometry is computed from the structure tensor \(J\). Its eigenvectors \(v_{1,2}\) (\(v_i \in \mathbb{R}^n\)) define an oriented orthogonal basis and its eigenvalues \(\lambda_{1,2}\) define the amount of structure variation. \(v_1\) is the orientation with the highest fluctuations (orthogonal to the image contours), and \(v_2\) gives the preferred local orientation. This

eigenvector (having the smallest eigenvalue) indicates the isophote orientation. The use of structure tensor allows to retrieve a more coherent local geometry. The computation of the filling order as proposed by Criminisi et al is then replaced by a term coming from PDE-based schemes, called Coherence Enhancing Diffusion. The use of structure tensor in an exemplar-based approach leads to a more robust algorithm that visually improves the quality of the inpainted areas.

Additionally, the simple template matching originally used in previous methods has been improved by using a $K$-nearest neighbor approach. The weights of the linear combination of the first $K$ best candidate are adjusted by taking into account that all candidate patches are not equally reliable. Note that the number $K$ is also locally adjusted in function of the local spatial complexity.

The 2D inpainting algorithm described above has been extended to deal with 3D content. In this work the goal is to synthesize novel views directly from the original images. Image-based rendering (IBR) is commonly used to render a virtual view. It generates a nearby viewpoint image by projecting a point from the reference view to the virtual view using the depth data. However, when the viewpoint is shifted, occluded regions in the original viewpoint are disoccluded. Handling these disocclusions (holes) is a difficult problem. We propose to use an extension of the 2D inpainting method to fill in these holes. For this goal, we have modified the computation of the structure tensor by adding the depth information. Equation (2) is simply modified as follow:

$$J = \sum_{i=(R,G,B,Z)} \nabla I_i \nabla I_i^T$$

where $Z$ represents the depth map. As previously, the tensor is used to compute the filling order. A directional term is also included in order to favor a filling direction. Specifically, when the viewpoint is shifted from left to right in the horizontal direction, occluded regions in the left image appear in the right image around the right side of the object. Therefore, it is recommended to start the filling from the right to the left. This filling is performed by a modified template matching using texture information as well as depth data. Figure 3 illustrates the inpainting quality for different approaches.

**Figure 3. Virtual synthesized view. From left to right: original view projected into the new viewpoint; disocclusions filled by Criminisi’s approach, Daribo’s approach and the proposed method.**

### 6.1.3. Computational modelling of visual attention

**Participants:** Josselin Gauthier, Olivier Le Meur.

#### 6.1.3.1. Eye-movement study:

In 2011, we have investigated whether two populations of visual fixation exist in 2D context. The question is simple: do all visual fixations have the same role in the free viewing of natural scenes? Recent studies suggest that there are at least two types of visual fixations: focal and ambient fixations. The former is believed to be used to inspect local areas accurately, whereas the latter is used to obtain the context of the scene.
From a collaboration with Technicolor (P. Guillotel and C. Chamaret) and LUTIN (T. Baccino), we found new evidence to support a focal-ambient dichotomy. Our results published in the journal i-Perception [14] indicate that the determining factor to classify the visual fixations is the saccade amplitude. We proposed an automatic system to cluster visual fixations in two groups using four types of natural scene images. From this automatic classification, the terms focal saliency map and ambient saliency map have been introduced. The dependence on the low-level visual features and the time course of these two kinds of visual fixations were examined. Our results demonstrate that there is an interplay between both fixation populations and that focal fixations are more dependent on low-level visual features than ambient fixations. These results might have a strong impact on both the computational modelling of visual attention and their performance assessment.

A second study related to eye-movement dealt with the role of the binocular disparity depth cue in the deployment of visual attention. To address this point, we compared eye tracking data recorded while observers viewed natural images in 2D and 3D conditions. The influence of disparity on the inter-observers congruency, saliency, center and depth bias was first examined. Results show that visual exploration in depth layer detection task is affected by the binocular disparity. In particular, participants tend to look first at closer areas just after the stimuli onset with the introduction of disparity, and then direct their gaze to more widespread locations. Our results has been submitted in the journal Cognitive Computation.

6.1.3.2. Model of visual attention:

Since 1998 with the publication of the influential work of Itti, Kock and Niebur [11], the computational modelling of the visual attention has known an increasing interest. The former models only used the low-level visual features for getting a saliency map. They perform well in a number of cases in predicting where an observer would look at. However, to improve the quality of the prediction, it seems unavoidable to use high-level information in order to account for visual deployment.

This work aims at designing a computational model mixing low-level and high-level features. Among the different factors influencing our gaze, we have focused our works on two cues: the dominant depth and the horizon line position. The dominant depth and the spatial position of the horizon line were inferred from the low-level visual features. A training database has been set up to perform a learning. Results indicate that the proposed model outperforms state-of-the-art models [37].

From behavioural studies on eye-movement in a 3D context, we have proposed a model of visual attention able to predict saliency of 3D pictures. The method developped aims at using the depth cue, the central bias and the low-level visual features. The predicted saliency is obtained by linearly combining these cues. The weights of the linear combination are learnt from a training database and are time-dependent. This study is under revision in the journal Cognitive Computation.

6.1.3.3. Predicting the inter-observer visual congruency:

This work aims at predicting the inter-observer visual congruency (IOVC), indicating the congruence or the variability among different subjects looking at the same image [35]. Predicting this congruence is of interest for image processing applications where the visual perception of a picture matters such as website design, advertisement, etc. We proposed a computational model of the IOVC. This new model is a mixture of low-level visual features extracted from the input picture. Model’s parameters are learned by using a large eye-tracking database. In this study, we also proposed a new scheme to compute the depth of field of a picture. Finally, once the training and the feature extraction have been carried out, a score ranging from 0 (minimal congruency) to 1 (maximal congruency) is computed. A value of 1 indicates that observers would focus on the same locations and suggests that the picture presents strong locations of interest. To illustrate the interest of the proposed model, we have used it to automatically rank personalized photographs. Figure 4 illustrates the proposed approach.

6.1.4. Visual cues analysis and modelling

Participants: Safa Cherigui, Christine Guillemot.

---

This work is carried out in collaboration with Technicolor (D. Thoreau, Ph. Guillotel, P. Perez) and aims at designing a compression algorithm based on the concept of epitomes. An epitome is a condensed representation of an image (or a video) containing the essence of the textural properties of this image. Different forms of epitomes have been proposed, such as a patch-based probability model learned either from still image patches or from space-time texture cubes taken from the input video. These probability models together with appropriate inference algorithms, are useful for content analysis inpainting or super-resolution. Another family of approaches makes use of computer vision techniques, like the KLT tracking algorithm, in order to recover self similarities within and across images. In parallel, another type of approach consists in extracting epitome-like signatures from images using sparse coding and dictionary learning.

The method developed aims at tracking self-similarities within an image using a block matching (BM) algorithm [25]. The epitome is constructed from disjoint pieces of texture (“epitome charts”) taken from the original image and a transform map which contains translational parameters (see Fig. 5-middle row). Those parameters keep track of the correspondences between each block of the input image and a block of the epitome. An Intra image compression scheme based on the epitome has been developed showing a rate saving of up to 12.

6.2. Representation and compression of large volumes of visual data

6.2.1. 3d representations for multi-view video sequences

Participants: Christine Guillemot, Vincent Jantet.

Multi-view plus depth video content represent very large volumes of input data which need to be compressed for storage and transmission to the rendering device. The huge amount of data contained in multi-view sequences indeed motivates the design of efficient representation and compression algorithms. In collaboration with INSA/ETR (Luce Morin), we have studied layered depth image (LDI) and layered depth video (LDV) representations as a possible compact representation format of multi-view video plus depth data. LDI give compact representations of 3D objects, which can be efficiently used for photo-realistic image-based rendering (IBR) of different scene viewpoints, even with complex scene geometry. The LDI extends the 2D+Z representation, but instead of representing the scene with an array of depth pixels (pixel color with associated depth values), each position in the array may store several depth pixels, organised into layers.

Various approaches exist to construct LDI, which all organize layers by visibility. The first layer contains all pixels visible from a chosen reference viewpoint. The other layers contain pixels hidden by objects in previous layers. With classical construction solutions, each layer may contain pixels from the background and pixels from objects in a same neighbourhood, creating texture and depth discontinuities within the same layer. These
Figure 5. Epitome and reconstructed images: (top row) Original images (columns a and b); (middle) Epitomes; (bottom) Reconstructed images from epitome texture and transform map.
discontinuities are blurred during the compression process which in turn significantly reduces the rendering quality.

We have thus developed a novel object-based LDI representation which is more tolerant to compression artifacts, as well as being compatible with fast mesh-based rendering techniques [34]. This representation organises LDI pixels into two separate layers (foreground and background) to enhance depth continuity (see Fig. 6). The construction of this object-based LDI makes use of a foreground-background region-growing segmentation algorithm followed by inpainting of both colour and texture images to have a complete background layer (without the holes corresponding to disocclusion areas). The costly inpainting algorithm is thus processed once, during the LDI classification, and not during each view synthesis, which helps to speed up the rendering step.

6.2.2. From sparse to spread representations

**Participant:** Jean Jacques Fuchs.

Sparse representations, where one seeks to represent a vector on a redundant basis using the smallest number of basis vectors, appear to have numerous applications. The other extreme, where one seeks a representation that uses all the basis vectors, might be of interest if one manages to spread the information nearly equally over all of them. Minimizing the $\ell_\infty$-norm of the vector of weights is one way to find such a representation. Properties of the solution and a dedicated fast algorithm have been developed. While the application of such models in robust data coding and in improving achievable data rates over amplitude constrained channels seems to be wishful thinking, its use in indexing techniques appears to be promising. In this context, one further replaces the optimal vector by its sign vector (potentially associated with a re-evaluated scalar weight) to get a binary vector that is not only cheap to store and (somehow) easy to search for but also allows for an explicit reconstruction unlike all other Hamming embedding functions used to map real vectors into binary vectors.
6.2.3. On-line dictionary learning methods for prediction

Participants: Christine Guillemot, Mehmet Turkan.

One crucial question to the problem of sparse approximation, and hence also of prediction based on sparse approximation, is the choice of the dictionary. Various advanced dictionary learning schemes have been proposed in the literature for the sparse signal approximation problem, so that the dictionary used is well suited to the data at hand. The popular dictionary learning algorithms include the K-SVD, the Method of Optimal Directions (MOD), Sparse Orthonormal Transforms (SOT), and (Generalized) Principle Component Analysis (PCA). However, the above learning methods are often used off-line since their computational complexity, which results from the number and the dimension of training samples, makes them inappropriate for online learning. In addition, these methods are adapted to the learning of basis to be used for approximating input data vectors, but not to the problem of predicting unknown samples from noisy observed samples in a causal neighborhood.

In 2011, we have developed a method for on-line training dictionaries adapted to the prediction problem [41]. Let $A$ be the input dictionary, which is divided into two sub-dictionaries: $A_c$ and $A_t$. The goal is to have a simple on-line dictionary learning method which is adapted to the prediction problem, i.e., which will learn both sub-dictionaries so that sparse vectors found by approximating the known samples (the template) using the first sub-dictionary ($A_c$) will also lead to a good approximation of the block to be predicted when used together with the second sub-dictionary ($A_t$). When dealing with the prediction problem, the sparse signal approximation is indeed first run with a set of masked basis functions (dictionary $A_c$), the masked samples corresponding to the location of the pixels to be predicted. The principle of the approach is to first search for the linear combination of basis functions which best approximates known sample values in a causal neighborhood, and keep the same linear combination of basis functions, but this time with the unmasked samples (dictionary $A_t$) to approximate the block to be predicted. The decoder similarly runs the algorithm with the masked basis functions and taking the previously decoded neighborhood as the known support. The use of masked basis functions converts the complete approximation problem into an overcomplete approximation problem. Because of its simplicity, of the limited number of training samples it requires, can be used for online learning of dictionaries, i.e. while doing the block-wise encoding of the image. The training samples are all possible previously coded/decoded texture patches (blocks of pixels) within a search window located in a causal neighborhood of the block to be predicted.

6.2.4. Neighbor embedding methods for image prediction and inpainting

Participants: Christine Guillemot, Mehmet Turkan.

The problem of texture prediction as well as image inpainting can be regarded as a problem of texture synthesis. Given observations, or known samples in a spatial neighborhood, the goal is to estimate unknown samples of the block to be predicted or of the patch to be filled in inpainting. We have developed texture prediction methods as well as a new inpainting algorithm based on neighbor embedding techniques which come from the area of data dimensionality reduction. The methods which we have more particularly considered are Locally Linear Embedding (LLE) and Non-negative Matrix Factorization (NMF). The first step in the developed methods consists in searching, within the known part of the image, for the $K$ nearest (KNN) patches to the set of known samples in the neighborhood of the block to be predicted or of samples to be estimated in the context of inpainting. This first step can be seen as constructing a dictionary matrix by stacking in the matrix columns the vectorized K-NN texture patches. The non-negative dictionary matrix $A \in \mathbb{R}^{N \times M}$, is formed by $K$ nearest neighbors to the vector formed by the known samples in the neighborhood of the samples to be predicted. These $K$ nearest neighbors are texture patches of the same shape taken from the known part of the image. This dictionary can then be used for approximating the known samples by masking the rows of the matrix which correspond to the position of the unknown samples, solving a least squares problem under the constraint of sum-to-one of the weights in the case of LLE, or under the constraint of non-negativity of the weights for NMF. It is actually a variant of NMF since one of the components matrices is fixed (the one corresponding to the dictionary matrix) and only the matrix containing the weights of the linear approximation must then be found. The approaches are thus intended to explore the properties of the manifolds on which the
input texture patches are assumed to reside. The underlying assumption is that the corresponding uncomplete and complete patches have similar neighborhoods on some nonlinear manifolds. The new prediction methods give RD performances which are significantly better than the ones given by the H.264 Intra prediction modes, in particular for highly textured images [21], the highest gain being achieved with NMF.

A new examplar-based inpainting algorithm using neighbor embedding techniques has been developed. A new priority order has been proposed in order to inpaint first patches containing structures or contour information. The methods have also been shown to enhance the quality of inpainted images when compared to classical examplar-based solutions using simple template matching techniques to estimate the missing pixels, (see Fig. 7).

Figure 7. Inpainting results: (left) mask of the image to be inpainted; (middle) Inpainting results with classical examplar-based inpainting; (right) Inpainting results with LLE (right).

6.2.5. Lossless coding for medical images

Participants: Claude Labit, Jonathan Taquet.

Last year, we developed a hierarchical oriented prediction (HOP) algorithm, for resolution scalable lossless and near lossless compression of biomedical images. In 2011, the algorithm has been slightly improved with an iterative optimization of the predictors in order to get better results on less noisy/smooth images [39].

Recently, there have been a growing interest for the compression of an emerging imaging modality: the virtual microscopy (VM). It is used in anatomopathology and may produce huge images of more than 1 Gigabytes. We have studied the efficiency for lossless and lossy compression of our previously developed algorithms HOP and OWD (optimized wavelet decomposition) and of two extensions of OWD: near-lossless and/or region of interest (ROI) coding. The lossless results, which are slightly better than JPEG-LS and JPEG-2000 standards with about 3:1 compression ratio, show that lossless compression is not suited to VM. By compressing only the information area (ROI) which represents about 20 percents of the size of test images, 9:1 ratio could be obtained, and combined with near-lossless approach, depending on the required quality, ratio can reach 17:1 with no visual losses to more than 30:1 with some visual losses (or approximately about 6:1 for ROI only data). We have concluded that it would probably be better to use lossy or efficient quality scalable compression. Because those images have specific contents (cellular tissue for example) we have also introduced and investigated new learning based methods. We have developed an optimization process for designing multiple KLT (Karhunen-Loeve Transform) in order to get orthonormal bases that are optimal for decorrelation and quality scalability. This learning approach has been applied as an a-posteriori transform of a wavelet decomposition in order to propose transforms with no blocking artefacts. A fully quality-scalable coding algorithm allows to obtain interesting PSNR improvements compared to the optimized coding process.
of JPEG-2000. Gain is around 0.5 dB for 16:1 compression of ROI only data, and more than 1 dB for 8:1 compression ratio.

6.3. Distributed processing and robust communication

6.3.1. Loss concealment based on video inpainting

Participants: Mounira Ebdelli, Christine Guillemot, Olivier Le Meur.

In 2011, we have started developing a loss concealment scheme based on a new video exemplar-based inpainting algorithm. The developed video inpainting approach relies on new patch priority functions as well as on a motion confidence-aided neighbor embedding techniques. Neighbor embedding approaches aim at approximating input vectors (or data points) as a linear combination of their neighbors. The search of the weights of the linear combination (i.e. of the embedding) are formulated as constrained least squares problems. When using the locally linear embedding, the constraint is that the sum of the weights is equal to 1. We have also considered non-negative matrix factorization to solve the problem, in which case the constraint is that the weights and the other vector are non-negative. The motion confidence introduced in the neighbor embedding improves the robustness of the algorithm in the sense that it limits the error propagation effects which otherwise result from uncertainties on the motion information of the unknown pixels to be estimated. A new patch similarity measure which accounts for the correlation between motion information has been defined for the $K$-NN search inherent to neighbor embedding techniques. Evaluations of the algorithm in a context of video editing (object removal) are on-going. The next step will be to assess the performance of the approach in a context of loss concealment, that is to estimate unknown pixels after decoding when the corresponding transport packets have been lost on the transmission network.

6.3.2. Unequal Erasure Protection and Object Bundle Protection

Participant: Aline Roumy.

In 2011, we started a new collaboration in the framework of the Joint INRIA/Alcatel Lucent lab. In this work, carried out with V. Roca (Planete, INRIA), B. Sayadi and R. Imad (Alcatel Lucent), we proposed and analyzed a novel technique capable of providing both an unequal erasure protection service and an object bundle protection service.

Unequal Erasure Protection: When a data flow contains information of different priority levels, it is natural to try to offer an unequal protection where the high priority data benefits from a higher protection than the rest of data. In this work we focused on the “erasure channel”, for instance the Internet where the UDP/IP datagram integrity is guaranteed by the physical layer FCS (or CRC) and the UDP checksum. In this context UEP refers to an Unequal Erasure Protection (rather than Error) and the FEC code being used is one of the various Application-Layer Forward Erasure Correction (AL-FEC) codes that have been designed and standardized in the past years, like Reed-Solomon, one of the LDPC variants, or Raptor(Q) codes. Offering an unequal protection in this context can be achieved by one of the following three general approaches: by using dedicated UEP-aware FEC codes, by using a dedicated UEP-aware packetization scheme, or by using an UEP-aware signaling scheme. In this work we ignored the first approach as we wanted to reuse existing AL-FEC codes. Instead we focused on and compared the last two approaches and more precisely the well known Priority Encoding Transmission (PET) scheme that belongs to the UEP-aware packetization category and a Generalized Object Encoding (GOE) scheme, we proposed \[53\], that belongs to the UEP-aware signaling category. Through a careful modeling of both proposals \[55\], whose accuracy has been confirmed by simulations, we have demonstrated that the protection performance (i.e. erasure resiliency and average decoding delay) of both approaches are equivalent, not only asymptotically but also in finite length conditions. In fact the key differences between these approaches become apparent when applying them in practical systems. Such metrics as the simplicity of the solution, the number of packets processed, the maximum memory requirements, the number of FEC encoding and decodings, as well as the system of linear equations complexity (number of variables) are in favor of the GOE approach.
Object Bundle Protection: we considered the use of PET, more precisely an extension called Universal Object Delivery (UOD), and GOE in situations where one needs to send a bundle of small object (e.g. files). If both solutions can address this need, we showed that once again the GOE scheme is highly recommendable for practical realizations. This is mostly due to the lack of flexibility of the PET/UOD approach. For instance the limited size of a packet creates an upper bound to the number of objects that can be considered together (e.g. UOD limits this number to 255), the symbol size has a coarse granularity (e.g. UOD requires symbols to be multiple of 4 bytes when used with RaptorQ codes) which can create rounding problems with certain sets of objects (i.e. the actual packet size may be significantly shorter than the target, and/or the actual code rate significantly different than its target). GOE has no such constraints. In particular GOE offers the possibility to adjust the packet interleaving to the use-case and channel erasure features. One can easily trade robustness in front of long erasure bursts for very short decoding delays of high priority objects and low memory requirements, which can be a key asset in case of small, lightweight terminals or timely delivery services. This feature may be sufficiently important to justify by itself the use of a GOE FEC Scheme [55].

6.3.3. Distributed compressed sensing

Participants: Aline Roumy, Velotiaray Toto-Zarasoa.

This work has been performed in collaboration with E. Magli and G. Coluccia (Politecnico di Torino) in the framework of the FP7 IST NOE NEWCOM++ (Jan. 2008 - Apr. 2011). A new lossy compression scheme for distributed and sparse sources under a low complexity encoding constraint has been proposed in [26]. This problem naturally arises in wireless sensor networks. Indeed, nodes of a sensor network may acquire temperature readings over time. The temperature may vary slowly over time, and hence consecutive readings have similar values. However, they also have inter-sensor correlation, as the sensors may be in the same room, in which the temperature is rather uniform. The question hence arises of how to exploit intra- and inter-sensor correlations without communication between the sensors and with a low complexity acquisition process in order to save energy consumption at the sensor. Therefore, we consider continuous, correlated, distributed and sparse (in some domain) sources and perform lossyuniversal compression under a low encoding complexity constraint.

In order to meet the low complexity encoding constraint, the encoding stage is performed by a lossy distributed compressed sensing (CS). More precisely, the proposed architecture is based on the joint use of CS to capture memory of a signal, and DSC to take advantage of inter-sensor correlations. First, we showed that the resilience of CS to quantization error also holds in the distributed setup. Moreover, the optimal number of measurements can be chosen as the one guaranteeing (close-to-)perfect reconstruction. In addition, using joint decoding, dequantization and reconstruction techniques allows to boost performance even further. The joint use of CS and DSC allows to save 1.18 bit per source sample for the same PSNR quality w.r.t. the non-distributed CS scheme. Compared to the DSC scheme (without CS), we observe a gain increasing with the rate for the same PSNR quality. All these results makes the proposed scheme an attractive choice for environments such as sensor networks, in which the devices performing acquisition and processing are severely constrained in terms of energy and computations.

6.3.4. Super-resolution as a communication tool

Participants: Marco Bevilacqua, Christine Guillemot, Raul Martinez-Noriega, Aline Roumy.

In 2011, we started a new collaboration in the framework of the Joint INRIA/Alcatel Lucent lab. In this work, carried out with M-L. Alberi (Alcatel Lucent), we proposed a novel technique capable of producing a high-resolution (HR) image from a single low-resolution (LR) image. This method that belongs to the class of single-image super-resolution (SR), offers the promise of overcoming the inherent limitations of the video acquisition and transmission systems. More precisely, one can think of sending a low resolution video to adapt to the complexity constraint of the encoder and/or the bandwidth limitation of the network, while the decoder reconstructs a high-resolution video.
As a first step toward the more ambitious goal of compressing video through SR, we proposed a novel method for single-image super-resolution based on a neighbor embedding technique. Each low-resolution input patch is approximated by a linear combination of nearest neighbors taken from a dictionary. This dictionary stores low-resolution and corresponding high-resolution patches taken from natural images and is thus used to infer the HR details of the super-resolved image. The entire neighbor embedding procedure is carried out in a feature space. Features which are either the gradient values of the pixels or the mean-subtracted luminance values are extracted from the LR input patches, and from the LR and HR patches stored in the dictionary. The algorithm thus searches for the $K$ nearest neighbors of the feature vector of the LR input patch and then computes the weights for approximating the input feature vector. The so-obtained weights are finally used to compute a linear combination of the corresponding HR patches, which yields the super-resolved image. The use of a positive constraint for computing the weights of the linear approximation is shown to have a more stable behavior than the use of sum-to-one constraint and lead to significantly higher PSNR values for the super-resolved images.
6. New Results

6.1. Advanced algorithms of data analysis, description

6.1.1. Advanced description techniques

6.1.1.1. Image joint description and compression

Participant: Ewa Kijak.

*This is a joint work with the TEMICS project-team (J. Zepeda and C. Guillemot).*

In the context of ANR project ICOS-HD ended at december 2010, in collaboration with Christine Guillemot from TEMICS, we investigated sparse representations methods for local image description. We have developed methods for learning dictionaries to be used for sparse signal representations. These methods lead to dictionaries which have been called Iteration-Tuned Dictionaries (ITDs), Basic ITD (BITD), Tree-Structured ITD (TSITD) and Iteration-Tuned and Aligned Dictionaries (ITAD). All three proposed ITD schemes (BITD, TSITD and ITAD) have been shown to outperform the state-of-the-art learned dictionaries in terms of PSNR versus sparsity. The performance of these dictionaries has also been assessed for both compression and de-noising applications. ITAD in particular has been used to produce a new image codec that outperforms JPEG2000 for a fixed image class and leads in 2011 to two new publications [49], [20].

6.1.1.2. Bag-of-colors

Participant: Hervé Jégou.

*This is joint work with Christian Wengert (Kooaba) and Matthijs Douze (INRIA LEAR and SED project-teams).*

This work investigates [48] the use of color information when used within a state-of-the-art large scale image search system. We introduce a simple color signature generation procedure, used either to produce global or local descriptors. As a global descriptor, it outperforms several state-of-the-art color description methods, in particular the bag-of-words method based on color SIFT. As a local descriptor, our signature is used jointly with SIFT descriptors (no color) to provide complementary information.

6.1.1.3. Aggregating local image descriptors into compact codes

Participant: Hervé Jégou.

*This is joint work with Matthijs Douze (INRIA LEAR and SED project-teams), Patrick Pérez (Technicolor), Florent Perronnin (Xérox Research Center Europe) and Cordelia Schmid (INRIA LEAR).*

This work [19] addresses the problem of large-scale image search and consolidates and extends results from a previous work [78]. Different ways of aggregating local image descriptors into a vector are compared, and the Fisher vector is shown to achieves better performance than the reference bag-of-visual words approach for any given vector dimension. We then jointly optimize dimensionality reduction and indexing in order to obtain a precise vector comparison as well as a compact representation. The evaluation shows that the image representation can be reduced to a few dozen bytes. Searching a 100 million image dataset takes about 250 ms on one processor core.

6.1.2. Browsing multimedia databases

Participant: Laurent Amsaleg.

*This is a joint work with Björn Þór Jónsson and Grímur Tómasson from the School of Computer Science, Reykjavik University, Iceland.*
Since the introduction of personal computers, personal collections of digital media have been growing ever larger. It is therefore increasingly important to provide effective browsing tools for such collections. We have proposed a multi-dimensional model for media browsing, called ObjectCube, based on the multi-dimensional model commonly used in OLAP applications. We implemented a prototype of a media browser based on the ObjectCube model. We then ran evaluations of its performance using three different underlying data stores and photo collections of up to one million photos.

6.1.3. Advanced data analysis techniques

6.1.3.1. Factorial analysis and output display for text and textual streams mining

Participant: Annie Morin.

Textual data can be easily transformed in frequency tables and any method working on contingency tables can be used to process them. Besides, with the important amount of available textual data, we need to find convenient ways to process the data and to get invaluable information. It appears that the use of factorial correspondence analysis allows us to get most of the information included in the data. We start exploring temporal changes in textual data and mainly focus on the visualization of results: we try to detect the topics if they have not already been identified and to study the evolution of the previous vocabulary inside a topic through time. In fact, as with economical datasets, we try to find seasonal components and cycling components in the documents and to characterize these components.

6.1.3.2. Intensive use of SVM for text and image mining

Participants: François Poulet, Thanh Nghi Doan.

Support Vector Machines (SVM) and kernel methods are known to provide accurate models but the learning task usually needs a quadratic program, so this task for very large datasets requires a large memory capacity and a long time. We have developed new algorithms. The first versions of the algorithms were based on a CPU distributed software program, then we have used GP-GPU (General Purpose GPU) versions to significantly improve the algorithm speed (130 times faster than the CPU one, 2500 times faster than libSVM, SVMPerf or CB-SVM). We have extended the least squares SVM algorithm (LS-SVM) to adapt the algorithm to datasets having a very large number of dimensions and have applied boosting to LS-SVM for datasets having simultaneously a very large number of vectors and dimensions on standard computers. In image classification, the usual frameworks involve three steps: feature extraction, building codebook by feature quantization and training the classifier with a standard classification algorithm (eg. SVM). However, task complexity becomes very large when applying this approach on large scale datasets like the ImageNet dataset containing more than 14 million images and 21,000 classes. The complexity is both about the time needed to perform each task and the memory and disk usage (eg. 11TB are needed to store the SIFT descriptors computed on the full datasets). Efficient algorithms must be used into these three steps: - obviously, the descriptors computed for one image are independent of the other image ones, so they can be computed in a parallel way, - the quantization step usually uses a k-means algorithm, we have developed different versions of parallel k-means algorithms to use on GPU or a cluster of CPUs, - for the learning task, we have developed a parallel version of LibSVM. The first results on the ten largest classes of ImageNet dataset are promising [55], we have developed a fast and efficient framework for large scale image classification.

6.1.4. Security of media

6.1.4.1. Security of content based image retrieval

Participants: Thanh Toan Do, Ewa Kijak, Laurent Amsaleg, Teddy Furon.

Over the years, the level of maturity reached by content-based retrieval systems (CBRSs) has significantly increased. CBRSs have so far been used in very friendly settings where cultural enrichments are paramount. CBRSs are also used in quite different settings where the control, the surveillance and the filtering of multimedia information are central, such as for copyright enforcement systems. While an abundant literature assesses that today’s CBRSs are robust against general-purpose attacks, we address in this work the security of content-based retrieval systems. Because of our expertise, we focus on security of content-based image retrieval, where images are described by SIFT descriptors and indexed by NV-Tree. We proved in one
preliminary study that a real system fails to match a specifically attacked image and its quasi-copy, breaking its otherwise excellent copyright protection performances. After proposing specific attacks that aim to disturb the descriptor detection stage by both prevent some key-points of being detected and create new ones [75], [74], we pursue the work by considering attacks dedicated to the description computation stage.

6.1.4.2. Estimation of the false alarm probability in watermarking and fingerprinting

**Participant:** Teddy Furon.

A key issue in watermarking and fingerprinting applications is to satisfy the requirement on the probability of false detection or false accusation. Assume commercial contents are encrypted and watermarked and that future consumer electronics storage devices have a watermark detector. These devices refuse to record a watermarked content since it is copyrighted material. The probability of false alarm is the probability that the detector considers an original piece of content (which has not been watermarked) as protected. The movie that a user shot during his holidays could be rejected by his storage device. This absolutely non user-friendly behavior really scares consumer electronics manufacturers.

In fingerprinting, users’ identifiers are embedded in purchased contents. When this content is found in an illegal place (e.g. a P2P network), the copyright holders decode the hidden message, find an identifier, and thus they can trace the traitor, i.e. the customer who has illegally broadcast his copy. However, the task is not that simple because dishonest users might collude. For security reason, anti-collusion codes have to be employed. Yet, these solutions have a non-zero probability of error (defined as the probability of accusing an innocent). This probability should be, of course, extremely low, but it is also a very sensitive parameter: anti-collusion codes get longer (in terms of the number of bits to be hidden in content) as the probability of error decreases. Fingerprint designers have to strike a trade-off, which is hard to conceive when only rough estimation of the probability of error is known. The major issue for fingerprinting algorithms is the fact that embedding large sequences implies also assessing reliability on a huge amount of data, which may be practically unachievable without using rare event analysis.

In collaboration with the team-projects ASPI and ALEA, we developed a novel strategy for simulating rare events and an associated Monte Carlo estimation of tail probabilities. Our method uses a system of interacting particles and exploits a Feynman-Kac representation of that system to analyze their fluctuations. Our precise analysis of the variance of a standard multilevel splitting algorithm reveals an opportunity for improvement. This leads to a novel method that relies on adaptive levels and produces, in the limit of an idealized version of the algorithm, estimates with optimal variance. Some numerical results show performance close to the idealized version of our technique for these practical applications. This work has been published in the journal Statistics and computing [13]. Algorithms for estimating extreme probabilities and quantiles are implemented as a Matlab package.

6.1.4.3. New decoders for fingerprinting

**Participant:** Teddy Furon.

So far, the accusation process of a Tardos fingerprinting code is based on single decoders which compute a score per user. Users with the highest score or whose scores is above a threshold are then deemed guilty. In the past years, we have contributed to this approach bringing two improvements: the ‘learn and match’ strategy aims at estimating the collusion process and using the matched score function; a rare event analysis translates this score into a more meaningful probability of being guilty. A fast implementation computes the scores of one million of users within 0.2 second on a regular laptop. Therefore, contrary to common belief, although a single decoder is exhaustive with a linear complexity in $O(n)$, it is not slow.

This fast implementation allows us to propose iterative decoders. A first idea is that conditioning by the identities of some colluders bring more discrimination power to the score function. The first iteration is thus a single decoder, users we are extremely confident to accuse are enrolled as side information. The next iteration computes new scores for the remaining users etc. A second idea is that information theory proves that a joint decoder computing scores for pairs, triplets, or in general $t$-tuples is more powerful than single decoders working with scores for single users. However, nobody did try them for large scale setups since the number of $t$-tuples is in $O(n^t)$. We propose in a first iteration to use a single decoder, to prune out users who are
definitely innocents (because their scores are low) and keeping $O(\sqrt{n})$ individual suspects. The second iteration is a joint decoding working on pairs of users etc. Iteratively, we prune out enough users such that it is manageable to run a joint decoder on bigger $t$-tuples. This work has been done under a collaboration of TEMICS, and published in a series of conference papers [37], [38], [36]. A journal version has been submitted to IEEE Trans. on Information Forensics and Security. A Tardos code software suite (generation of code, collusion attacks, accusation algorithms) is available as a C package.

6.1.4.4. Protocols for fingerprinting

**Participant:** Teddy Furon.

A key assumption of the fingerprinting schemes developed so far is that the colluders may know their own codewords but they ignore the codeword of any other innocent user. Otherwise, the collusion can very easily forge a pirated content framing an innocent user because it contains a sequence close enough to his/her codeword. This puts a lot of pressure on the versioning mechanism which creates the personal copy of the content in accordance to a codeword. For instance, suppose that the versioning is done in the user’s setup box, the unique codeword being loaded into this device at the manufacture. If the code matrix ends up in the hands of an untrustworthy employee, then the whole fingerprinting system is pulled down. This is one argument of the motivation for designing cryptographic protocols for the construction, the versioning and the accusation.

We have proposed a new asymmetric fingerprinting protocol dedicated to the state-of-the-art Tardos codes. We believe that this is the first such protocol, and that it is practically efficient. The construction of the fingerprints and their embedding within pieces of content is based on oblivious transfer and do not need a trusted third party. Note, however, that during the accusation stage, a trusted third party, like a Judge, is necessary like in any asymmetric fingerprinting scheme we are aware of. This work has been done in collaboration with the team-project TEMICS, Lab-STICC Telecom Bretagne and University College London, and presented at Information Hiding [22]. Ana Charpentier defended her PhD. thesis in October 2011 [72].

6.1.4.5. Reconstructing an image from its local descriptors

**Participant:** Hervé Jégou.

We show [47] that an image can be approximately reconstructed based on the output of a black-box local description software such as those classically used for image indexing. Our approach consists first in using an off-the-shelf image database to find patches which are visually similar to each region of interest of the unknown input image, according to associated local descriptors. These patches are then warped into input image domain according to interest region geometry and seamlessly stitched together. Final completion of still missing texture-free regions is obtained by smooth interpolation. As demonstrated in our experiments, visually meaningful reconstructions are obtained just based on image local descriptors like SIFT, provided the geometry of regions of interest is known. The reconstruction allows most often the clear interpretation of the semantic image content. As a result, this work raises critical issues of privacy and rights when local descriptors of photos or videos are given away for indexing and search purpose.

6.2. Multi-dimensional indexing and clustering

6.2.1. Improved NV-tree

**Participant:** Laurent Amsaleg.

*This is a joint work with Björn Pór Jónsson from the School of Computer Science, Reykjavik University, Iceland and with Herwig Lejsek, Videntifier Technologies, Iceland.*

We have further improved the NV-Tree (Nearest Vector Tree) indexing techniques. It addresses the specific, yet important, problem of efficiently and effectively finding the approximate $k$-nearest neighbors within a collection of a few billion high-dimensional data points. The NV-Tree is a very compact index, as only six bytes are kept in the index for each high-dimensional descriptor. It thus scales extremely well when indexing large collections of high-dimensional descriptors. The NV-Tree efficiently produces results of good quality, even at such a large scale that the indices cannot be kept entirely in main memory any more. We have demonstrated this with extensive experiments using a collection of 2.5 billion SIFT (Scale Invariant Feature Transform) descriptors. Additional experiments involving more than 30 billion SIFT descriptors show results are still of a good quality and that disks are handled as efficiently as they can be.
6.2.2. Indexation of time series

Participants: Laurent Amsaleg, Romain Tavenard.

Dynamic Time Warping (DTW) is the most popular approach for evaluating the similarity of time series, but its computation is costly. Therefore, simple functions lower bounding DTW distances have been designed, accelerating searches by quickly pruning sequences that could not possibly be best matches. The tighter the bounds, the more they prune and the better the performance. Designing new functions that are even tighter is difficult because their computation is likely to become complex, canceling the benefits of their pruning. It is possible, however, to design simple functions with a higher pruning power by relaxing the no false dismissal assumption, resulting in approximate lower bound functions. We have discovered how very popular approaches accelerating DTW such as LB_Keogh and LB_PAA can be made more efficient via approximations. The accuracy of approximations can be tuned, ranging from no false dismissal to potential losses when aggressively set for great response time savings. At very large scale, indexing time series is mandatory. These approximate lower bound functions can be used with iSAX. Furthermore, we have also observed that a k-means-based quantization step for iSAX gives significant performance gains.

6.2.3. Improved image indexing with asymmetric Hamming embedding

Participants: Patrick Gros, Mihir Jain, Hervé Jégou.

We have proposed [28] an improved asymmetric Hamming Embedding scheme for large scale image search based on local descriptors. The comparison of two descriptors relies on an vector-to-binary code comparison, which limits the quantization error associated with the query compared with the original Hamming Embedding method. The approach is used in combination with an inverted file structure that offers high efficiency, comparable to that of a regular bag-of-features retrieval systems, and consistently improves the search quality over the symmetric version on the two datasets used for the evaluation.

6.2.4. Compression techniques for nearest neighbor search

Participants: Laurent Amsaleg, Teddy Furon, Hervé Jégou, Romain Tavenard.

Part of this work on this topic was done in cooperation with Matthijs Douze and Cordelia Schmid (INRIA/L2R).

6.2.4.1. Re-ranking with source coding

An extension of our previous work on source coding techniques for high-dimensional indexing has been proposed [29]. The goal is to index a large set of vectors, as large as 1 billion vectors, with limited CPU and memory usage. Based on the product quantization-based indexing technique [18], we show that it is interesting to add an additional level of processing to refine the estimated distances. It consists in quantizing the difference vector between a point and the corresponding centroid. When combined with an inverted file, this gives three levels of quantization. Experiments performed on SIFT and GIST image descriptors show excellent search accuracy outperforming three state-of-the-art approaches. Compared with the original work [18], the proposed re-ranking technique is shown to obtain better trade-off with respect to memory, efficiency and search quality.

6.2.4.2. Anti-sparse coding for approximate nearest neighbor search

Following recent works on Hamming Embedding techniques, we propose [67] a binarization method that aims at addressing the problem of nearest neighbor search for the Euclidean metric by mapping the original vectors into binary vectors ones, which are compact in memory, and for which the distance computation is more efficient.

Our method is based on the recent concept of anti-sparse coding, which exhibits here excellent performance for approximate nearest neighbor search. Unlike other binarization schemes, this framework allows, up to a scaling factor, the explicit reconstruction from the binary representation of the original vector. We also show that random projections which are used in Locality Sensitive Hashing algorithms, are significantly outperformed by regular frames for both synthetic and real data if the number of bits exceeds the vector dimensionality, i.e., when high precision is required.
6.2.5. Architecture-aware indexing techniques for solid state disks

Participants: Laurent Amsaleg, Gylfi Gudmundsson.

This is a joint work with Björn Pór Jónsson from the School of Computer Science, Reykjavik University, Iceland.

The scale of multimedia data collections is expanding at a very fast rate. In order to cope with this growth, the high-dimensional indexing methods used for content-based multimedia retrieval must adapt gracefully to secondary storage. Recent progress in storage technology, however, means that algorithm designers must now cope with a spectrum of secondary storage solutions, ranging from traditional magnetic hard drives to state-of-the-art solid state disks. We have analyzed the impact of storage technology on a simple, prototypical high-dimensional indexing method for large scale query processing. We found that while the algorithm implementation deeply impacts the performance of the indexing method, the setup of the underlying storage technology is equally important.

6.3. New techniques for linguistic information acquisition and use

6.3.1. NLP for document description

6.3.1.1. Semantic annotation of multimedia documents based on textual data

Participants: Ali Reza Ebadat, Vincent Claveau, Pascale Sébillot, Ewa Kijak.

This work is done in the framework of the Quaero project (see below).

On this subject, TEXMEX is implied in three tasks of the Quaero project.

The first task concerns the extraction of terminology from document. The objective of this work is to study the development and the adaptation of methods to automate the acquisition and the structuring of terminologies. In this context, in 2011, we have undergone a new evaluation of terminology extraction systems. Here again, our system, relying on TermoStat (see previous reports) ranked first for the tracks in which we participated. We have also continued our work the use of morphology for biomedical terminologies. This approach relies on the decomposition of terms into morphemes and the translation of these morphemes into Japanese (kanji) sub-words. The kanji characters thus offer a semantic way to access the semantics of the morpheme and allow us to detect semantic relations between them. We have tested this approach on more languages and have proved its relevance for information retrieval problems.

The second task aims at extracting semantic and ontological relations from documents. Indeed, detecting semantic and ontological relations in texts is a key to describe a domain and thus manipulate cleverly documents. In 2011, we developed a new relation extraction system based on k-nearest-neighbors and language modeling. It has been tested in the framework of the Quaero evaluation campaign and ranked first or second for all tracks. We have also developed a clustering technique for named entities. It relies on new representation schemes called bag-of-vectors (or bag-of-bags-of-features), which perform better than the classical bag-of-word approach.

The last task directly deals with the semantic annotation of multimedia documents based on textual data, for, very often, many textual or language-related data can be found in multimedia documents or come along such documents. For example, a TV-broadcast, contains speech that can transcribed, Electronic Program Guide and standard program guide information, closed captions, associated websites, etc. All these sources offers a way to exploit complementary information that can be used to semantically annotate multimedia document. During this year, we finished the development of a football multimedia corpus. It contains the video of several matches, the speech transcripts, associated textual data from specialized websites. All these media have been manually annotated in terms of events, named entities, specialized relations (fouls, replacements, etc) and other relevant information. This corpus will be distributed under LGPL-LR license.

6.3.1.2. Text recognition in videos

Participants: Khaoula Elagouni, Pascale Sébillot.
This work is done in the context of a joint TexMEX/Orange Ph.D. thesis supported by a CIFRE grant with Orange Labs.

We aim at helping multimedia content understanding by obtaining benefit from textual clues embedded in digital video data. In 2011, we proposed an Optical Character Recognition-based method to recognize natural scene texts in images, avoiding the conventional character segmentation step. The text image is scanned with multi-scale windows and a robust recognition model is applied on each window, relying on a neural classification approach, to identify non valid characters and recognize valid ones. A graph model is used to represent spatial constraint between recognition results, and to determine the best sequence of characters. Some linguistic knowledge is also incorporated in the graph to remove errors due to recognition confusions. The method was evaluated on the ICDAR 2003 database of scene text images and outperforms state-of-the-art approaches. This work will be presented at DAS2012.

6.3.1.3. DEFT evaluation campaign participation

Participants: Vincent Claveau, Christian Raymond.

Christian Raymond and Vincent Claveau participated to DEFT (http://deft2011.limsi.fr/). Two tasks were proposed: the first one was called “the diachronic variation task” whose objective was to identify the writing year of some OCR newspapers from 1801 to 1944. The second one was a abstract/article pairing task. Their approaches based on boosting and k-nearest neighbors was ranked first on the difficult diachronic task.

6.3.2. Oral and textual information retrieval

6.3.2.1. Graded-inclusion-based Information retrieval systems

Participants: Vincent Claveau, Laurent Ughetto.

Our work on this topic is done in close collaboration with Olivier Pivert from the PILGRIM project-team of IRISA Lannion.

Databases (DB) querying mechanisms, and more particularly the division of relations was at the origin of the Boolean model for Information Retrieval Systems (IRSs). This model has rapidly shown its limitations and is no more used in Information retrieval (IR). Among the reasons, the Boolean approach do not allow to represent and use the relative importance of terms indexing the documents or representing the queries. However, this notion of importance can be captured by the division of fuzzy relations. This division, modeled by fuzzy implications, corresponds to graded inclusions. Theoretical work conducted by the PILGRIM project-team have shown the interest of this operator in IR.

Our first work was to investigate the use of graded inclusions to model the information retrieval process. In this framework, documents and queries are represented by fuzzy sets, which are paired with operations like fuzzy implications and T-norms. Through different experiments, we have shown that only some among the wide range of fuzzy operations are relevant for information retrieval. When appropriate settings are chosen, it is possible to mimic classical systems, thus yielding results rivaling those of state-of-the-art systems. These positive results have validated the proposed approach, while negative ones have given some insights on the properties needed by such a model.

More recently, the links between our fuzzy model and other classical IR models have been studied. It has been shown that our fuzzy implication-based model can be interpreted as several classical models: an Extended Boolean Model, a Logical Model, a Vector Space Model or a Language Model in IR.

6.3.2.2. Information retrieval in TV streams using automatic speech recognition

Participants: Guillaume Gravier, Patrick Gros, Julien Fayolle, Fabienne Moreau, Christian Raymond.
Automatic speech recognition outputs are by nature incomplete and uncertain, so much that lexical indexes of speech are not sufficient to overcome the errors due to out-of-vocabulary words and to most of the named entities, consisting in important semantic information from the discourse. Using if necessary a phonetic index is a solution to retrieve partially the mis-recognized words but at the price of a lower precision because the phonetic representation is also noisy. We proposed this year (still to be submitted) an indexation method which jointly model lexical and phonetic levels with finite-state transducers, offering the possibility to take a lexical path or a phonetic path between two synchronization nodes. The edges are weighted by a vector of features (edition scores, confidence measures, durations) that will be used in a supervised manner to estimate the reliability of the returned result at the search step. The experiments have shown the complementary of lexical-phonetic representations and their contribution for a task of spoken utterance retrieval using named entity queries.

6.4. New processing tools for audiovisual documents

6.4.1. TV stream structuring

6.4.1.1. Repetition detection-based TV structuring

Participants: Vincent Claveau, Guillaume Gravier, Patrick Gros, Emmanuelle Martienne, Abir Ncibi.

We work on the issue of structuring large TV streams. More precisely, we focus on the problem of labeling the segments of a stream according to their types (e.g., programs, commercial breaks, sponsoring, etc). Contrary to existing techniques, we wanted to take into account the sequential aspect of the data, and thus we used Conditional Random Fields (CRF), a classifier which has proved useful to handle sequential data in other domains like computational linguistics or computational biology. During this year, we proved the relevance of CRF in the framework of TV segments labeling. We conducted different experiments, either on manually or automatically segmented streams, with different label granularities, and demonstrated that this approach rivals existing ones. The use of this model for semi-supervised and unsupervised learning are under study.

6.4.2. Program structuring

6.4.2.1. Audiovisual models for event detection in videos

Participants: Guillaume Gravier, Patrick Gros, Cédric Penet.

This work was performed in close collaboration with Technicolor as external partner.

Following our work on the detection of audio concepts related to violence in movie soundtracks [58], we developed a system for the detection of violent scenes in movies, combining multimodal features. We investigated multimodal fusion strategies and temporal integration exploiting Bayesian networks as a joint distribution model. Several strategies for learning the structure of the Bayesian networks were compared, resulting in a complete system for violence detection. The system was evaluated on the Violent Scenes Detection task of the MediaEval 2011 international evaluation [42] that we co-organized with Technicolor and the University of Geneva [62]. A fair amount of time was dedicated this year to the organization of the evaluation campaign which includes defining the task and metrics, supervising the annotation, recruiting participants, analyzing the results and organizing the corresponding workshop session.

6.4.2.2. Unsupervised multimedia content mining

Participants: Guillaume Gravier, Anh Phuong Ta.

This work on audio content discovery was partially carried out in collaboration with Armando Muscariello and Frédéric Bimbot from the Metiss project-team.

As an alternative to supervised approaches for multimedia content analysis, where predefined concepts are searched for in the data, we investigate content discovery approaches where knowledge emerge from the data. Following this general philosophy, we pursued work on motif discovery in audio and video content.
Audio motif discovery is the task of finding out, without any prior knowledge, all pieces of signals that repeat, eventually allowing variability. In 2011, we extended our recent work on seeded discovery to near duplicate detection and spoken document retrieval from examples. First, we proposed algorithmic speed ups for the discovery of near duplicate motifs (low variability) in large (several days long) audio streams, exploiting subsampling strategies [39]. Second, we investigated the use of previously proposed efficient pattern matching techniques to deal with motif variability in speech data [40] in a different setting, that of spoken document retrieval from an audio example. We demonstrated the potential of model-free approaches for efficient spoken document retrieval on a variety of data sets, in particular in the framework of the Spoken Web Search task of the MediaEval 2011 international evaluation [41].

Video structure is often enforced through editing rules which result in a set of shots defining an event that repeats throughout the video with a high visual and audio similarity. Typical such shots are anchor persons and close-up on guests in talk-shows. We recently proposed an unsupervised multimodal approach to discover such events exploiting audio and visual consistency between two sets of independent nested clusters, one for each modality [21]. In 2011, we extended the approach in two directions. First, we improved the selection of consistent audio and visual clusters and the unsupervised selection of positive and negative examples exploiting redundancy between nested clusters. Second, we extended the method to discover several audio- visually consistent events rather than a single one in our previous work, thus enabling the use of unsupervised mining as a pre-processing step for video structure analysis.

6.4.2.3. Topic segmentation with vectorization and morpho-mathematics

Participant: Vincent Claveau.

Our work on this topic is done in close collaboration with Sébastien Lefèvre from the SEASIDE project-team of IRISA Vannes.

Segmenting a program into topics is an important step for fine-grained structuring of TV streams. Based on our work on vectorization (see previous reports), we have developed a new segmentation technique using speech transcripts. Making an analogy with image segmentation, we have adapted the watershed transform to handle these textual data and more precisely the distances computed by vectorization between possible segments.

This method has been tested on different TV collections (news, reports) as well as more usual text collection used for segmentation evaluation. In every cases, our technique has outperformed any state-of-the-art approaches.

6.4.3. Using speech to describe and structure video

Participants: Camille Guinaudeau, Guillaume Gravier, Ludivine Kuznik, Bogdan Ludusan, Pascale Sébillot.

Speech can be used to structure and organize large collections of spoken documents (videos, audio streams, etc) based on semantics. This is typically achieved by first transforming speech into text using automatic speech recognition (ASR), before applying natural language processing (NLP) techniques on the transcripts. Our research focuses firstly on the adaptation of NLP methods designed for regular texts to account for the specific aspects of automatic transcripts. In particular, we investigate a deeper integration between ASR and NLP, i.e., between the transcription phase and the semantic analysis phase.

In 2011, we mostly focused on robust transcription, hierarchical topic segmentation and collection structuring. On the one hand, we investigated the use of broad phonetic landmarks and syllable prominence to improve large vocabulary speech recognition by guiding the Viterbi search process. Several mechanisms to incorporate landmarks into the search space were studied. Significant improvements were observed on radio broadcast news data in the French language. On the other hand, we pursued our work on unsupervised topic adaptation, focusing on the automatic selection of out-of-vocabulary words combining phonetic and morpho-syntactic criteria.
Linear topic segmentation has been widely studied for textual data and recently adapted to spoken contents. However, most documents exhibit a hierarchy of topics which cannot be recovered using linear segmentation. We investigated hierarchical topic segmentation of TV programs exploiting the spoken material. Recursively applying linear segmentation methods is one solution but fails at the lowest levels of the hierarchy when small segments are targeted, in particular when transcription errors jeopardize lexical cohesion. We proposed new probabilistic measures of the lexical cohesion to emphasize the contribution of words that appears only locally, thus attenuating the impact of words which contributed to the segments at an upper level of the hierarchy \cite{11}.

Finally, we initiated work in collaboration with INA on structuring a large collection of news reports. The idea is to automatically create links and threads between reports in several months of broadcast news shows, based either on the documentary records of the shows and/or on the automatic transcripts. As preliminary step towards this goal, we investigated distances between documentary records in an information retrieval setting so as to construct a nearest neighbor graph. The next step consists in exploiting graph clustering methods.

Our research in speech for TV content structuring was illustrated through the Texmix demonstration (see Section \ref{sec:5.2}) which exploits most of our achievements in the field, including transcription, topic segmentation and collection structuring.
6. New Results

6.1. Probabilistic numerical methods, stochastic modelling and applications

Participants: Mireille Bossy, Nicolas Champagnat, Julia Charrier, Julien Claisse, Madalina Deaconu, Samuel Herrmann, James Inglis, Pierre-Emmanuel Jabin, Antoine Lejay, Sylvain Maire, Sebastian Niklitschek Soto, Nicolas Perrin, Denis Talay, Etienne Tanré, Laurent Violeau.

6.1.1. Published works and preprints

- M. Bossy in collaboration with J.-F. Jabir (Univ. Chile) proved the well posedness of the confined Lagrangian models, in association with no-permeability boundary conditions. When the confining domain is a hyperplane, they proved the strong existence of the trace of the density of particles following the kinetic stochastic equation of a simplified McKean Vlasov Lagrangian model in [12], http://hal.inria.fr/inria-00515481/en.
  When the confining domain \( \mathcal{D} \) is bounded with smooth boundary, they constructed a confined primitive of Brownian motion in \( \mathcal{D} \) and characterized the solution to the corresponding martingale problem by showing that the time marginal density is the unique solution to a mild equation with specular condition. This key step allowed them to finish the construction in the non linear case, using previous work on Vlasov-Fokker-Plank PDE with specular boundary condition. Two papers are being written.

- In collaboration with J.-F. Jabir and J. Fontbona (CMM and Universidad de Chile, Santiago de Chile), M. Bossy and P.-E. Jabin have studied the link between the Lagrangian version of divergence free constraint (and the uniform density constraint), with an additional potential term, in the Lagrangian equation, having some similarity with the role of the Eulerian pressure term. They obtained the local existence of analytical solutions for an incompressible Lagrangian stochastic model in periodic domain. An article is currently being written.

- N. Champagnat worked with A. Lambert (Univ. Paris 6) on splitting trees with Poissonian mutations. Assuming that each mutation is neutral and gives a new type in the population, they obtained in [15] explicit expressions for the expected number of types carried by a fixed number of individuals living in the population at time \( t \). In [31], they also obtained large time convergence results on the sizes of the largest families and the ages of the oldest families in the population. http://hal.inria.fr/inria-00515481/en, http://hal.inria.fr/inria-00616765/en.

- N. Champagnat and P.-E. Jabin studied the limit of some population dynamics models under the assumption that the time scale for mutations is much larger than the time scale for reproduction. They are able to provide the first full characterization of the corresponding limit equation [14], http://hal.inria.fr/inria-00488979/en.

- M. Deaconu and S. Herrmann developed a new method for the simulation of the hitting time of nonlinear boundaries for Bessel processes. This method is based on a walk on moving spheres algorithm and can be applied for the hitting time of a given level for the Cox-Ingersoll-Ross process [32], http://hal.inria.fr/hal-00636056/en. This work is part of the ANR MANDy project.

- S. Herrmann and E. Tanré worked on a scheme to construct an efficient algorithm to simulate the first hitting time of curves by a one dimensional Brownian motion. They apply the result to estimate the spiking time of leaky integrate fire models in neurosciences. This work is part of the ANR MANDy project.
• P.-E. Jabin and F. Ben Belgacem (Univ. of Monastir, Tunisia) have studied a new class of models which have seen considerable development in applications for biosciences (flocking, chemotaxis, pedestrian flows...). These models include some non linear corrections to classical linear continuity equations. In [30], they introduce new, critical regularity estimates to obtain well posedness. http://www2.cscammd.umd.edu/~jabin/transportlcs2.pdf.

• P.-E. Jabin and M. Hauray (Aix-Marseille Université) have studied the mean field limit for systems of many interacting particles. It is the only result able to deal with singular forces and physically realistic initial configurations [33], http://hal.inria.fr/hal-00609453/en.

• P.-E. Jabin and A. Nouri (Aix-Marseille Université) studied a highly singular kinetic equation in dimension 1. This equation is obtained as a quasi-neutral limit in plasma physics. In [18], they were able to prove well posedness in short time of analytic solutions. http://dx.doi.org/10.1016/j.crma.2011.03.024.

• P.-E. Jabin and G. Raoul (Cambridge University) prove the convergence to a unique stable equilibrium for a wide class of competitive models in population dynamics [19], http://dx.doi.org/10.1007/s00285-010-0370-8.

• P.-E. Jabin and J. Calvo (Universidad de Granada) investigate the long time asymptotics of a new class of models for interacting particles inspired from various phenomena in the biosciences. In this model, when two particles collide they may coalesce and then completely stop moving [13], http://hal.inria.fr/hal-00601969/en.

• In collaboration with G. Pichot (INRIA Rennes Bretagne Atlantique), A. Lejay has developed a new Monte Carlo methods for discontinuous media that relies on the simulation of the Skew Brownian motion [22], [35], http://hal.inria.fr/hal-00642194/en, http://hal.inria.fr/hal-00649170/en.

• A. Lejay developed a new method for the simulation of a stochastic process in a layered media using the properties of the Brownian path [20], http://hal.inria.fr/inria-00583127/en.

• S. Maire and C. Prissette (Univ. du Sud – Toulon – Var) have developed in [21] a stochastic algorithm to solve Sudoku puzzles using estimation of distribution coupled with restart techniques. http://hal.inria.fr/inria-00591852_v1/

• S. Maire and E. Tanré have generalised the spectral methods for elliptic PDEs developed in [39], [40] to the case of pure Neumann boundary conditions. Some additional difficulties occur because the stochastic representation of the solutions is defined only up to an additive constant and as a limit involving local time approximations [38]. By taking into account these additional properties, they still obtained a spectral matrix having a condition number converging to one.

• D. Talay and E. Tanré, in collaboration with F. Delarue and S. Rubenthaler (Univ. Nice – Sophia Antipolis), have given a precise approximation of the interspike intervals for the LIF model, describing the activity of a single neuron. This work is part of the ANR MANDy project (see Section 7.1.1).

• D. Talay, in collaboration with M. Martinez (Univ. Paris-Est), achieved to develop their stochastic approach for one-dimensional transmission parabolic problems. Owing to their stochastic representation of the solutions, they obtained accurate pointwise estimates for the derivatives of these solutions, from which they got accurate convergence rate estimates in the weak sense for a numerically effective discretization scheme of stochastic differential equations with weighted local times which are related to elliptic partial differential operators under divergence form with a discontinuous coefficient [36], http://hal.inria.fr/inria-00607967/en.

6.1.2. Other works in progress

• N. Champagnat studies in collaboration with S. Méleard (Ecole Polytechnique, Palaiseau) adaptive dynamics and evolutionary branching in individual-based models of populations competing for resources, similar to those involved in chemostat systems of ODEs.
N. Champagnat studies in collaboration with A. Lambert the process of the time to the most recent common ancestor in a family of subcritical branching processes whose genealogy is given by splitting trees.

J. Charrier joined the team in September as a post-doctoral researcher and began working with M. Bossy and D. Talay on the long time behaviour of stochastic particules systems in McKean-Vlasov interaction.

J. Claissse continued his PhD. under the supervision of N. Champagnat and D. Talay on stochastic control of population dynamics. He completed a finite-horizon and an infinite-horizon optimal control problem on a birth-death process. He is currently working on a birth-death process whose parameters depend on a controlled ordinary differential equation. In addition, he is working on applications of branching processes in biology and optimal control theory, and more specifically in cancer therapy.

M. Deaconu and S. Herrmann continue the study of the hitting time for Bessel processes in the situation of noninteger dimensions.

J. Inglis joined the team in October 2011 as a post-doctoral researcher (ANR MANDy), and began working with E. Tanré, D. Talay, F. Delarue (University of Nice) and S. Rubenthaler (University of Nice) on problems related to the rigorous justification of mean field models used in neuroscience.

J. Inglis, E. Tanré and M. Tejo (PUC, Chile) started a collaboration on the numerical simulation of spiking times of neurons described by some new stochastic models related to the Hodgkin-Huxley equation. This work is a part of Anestoch associated team.

A. Lejay and S. Maire study some new Monte Carlo methods for multi-dimensional discontinuous media.

In collaboration with J.-R. Li (INRIA Rocquencourt & Neurospin), A. Lejay studies some probabilistic representation for interface condition arising in diffusion Magnetic Resonance Imaging.

In collaboration with G. Pichot and J. Erhel (INRIA Rennes Bretagne Atlantique), A. Lejay studies Monte Carlo methods for discontinuous media as well as benchmarks and test on existing methods.

With L. Coutin (Univ. Toulouse), A. Lejay studies some perturbation results for solutions of Rough Differential Equations.

S. Maire develops with C. de Luigi (Univ. du Sud – Toulon – Var) and Jerôme Lelong (IMAG, Grenoble) resolution algorithms for the price of various european options in high dimension by coupling an adaptive deterministic integration algorithm and Principal Component Analysis tools.

S. Niklitschek continued his PhD. under the supervision of D. Talay on discretized stochastic differential equations related to one-dimensional partial differential equations of parabolic type involving a discontinuous drift coefficient. He obtained accurate pointwise estimates for the derivatives of these solutions, from which he gets convergence rate estimates in the weak sense of the stochastic discretization scheme. Now he is working on the extension of these results to the multi-dimensional setup.

N. Perrin continued his PhD. on stochastic methods in molecular dynamics under the supervision of M. Bossy, N. Champagnat and D. Talay. He is studying a method due to P. Malliavin (French Academy of Science) based on the Fourier analysis of covariance matrices with delay in order to identify the fast and slow components of a molecular dynamics and to construct simplified projected dynamics. He also studied probabilistic interpretation of the nonlinear Poisson-Boltzmann equation in Molecular Dynamics with BSDEs [37], http://hal.inria.fr/hal-00648180/en.

L. Violeau continued his PhD. on Stochastic Lagrangian Models and Applications to Downscaling in Fluid Dynamics under the supervision of M. Bossy and A. Rousseau (MERE team, INRIA Sophia Antipolis – Méditerranée, Montpellier). He studied the convergence in law of a sequence of penalized processes to the so called reflected langevin process in a convex domain. He is currently working on the rate of convergence of the particle approximation of conditional McKean stochastic models.
• P-E. Jabin and D. Talay continue to develop their innovating approach, which combines stochastic analysis and PDE analysis, for the time varying Hamilton-Jacobi-Bellman-McKean-Vlasov equations of the Lasry and Lions mean-field stochastic control theory.

6.2. Financial Mathematics

Participants: Mireille Bossy, Paul Charton, El Hadj Aly Dia, Dalia Ibrahim, Denis Talay, Etienne Tanré.

6.2.1. Published works and preprints

• In collaboration with N. Maïzi (CMA – Mines ParisTech) and O. Pourtallier (COPRIN team, INRIA Sophia Antipolis – Méditerranée), M. Bossy, and E.H.A. Dia studied the indifference pricing for carbon emission allowances, as a short term model value of carbon (see Section 7.1.2). The indifference pricing methodology describes the way an industrial agent on the emission allowances market chooses his production strategy. An utility function represents the preferences of the producer and its risk aversion. The outputs of its production have stochastic prices on the market, so that the optimal production strategy arises as the solution of a stochastic control problem.

We extended the model hypotheses under which we get the well-posedness of the stochastic control problem and the associated HJB equation. We exhibited a simple case (marginal costs constant in time) where we proved the regularity of the value function via the explicit solution of the stochastic control problem [24], http://hal.inria.fr/hal-00645033/en. This particular case now can serve as a benchmark for the numerical solver currently developed in the framework of the ADEME Convention. It will also serve as a demonstrator case, with the objective of a public diffusion of the simulator CarbonQuant.

• M. Cissé (ENSAE-Sénégal), P. Patie (Univ. libre de Bruxelles) and E. Tanré have solved explicitly the optimal stopping problem with random discounting and an additive functional as cost of observations for a regular linear diffusion [17], http://hal.inria.fr/inria-00458901/en/.

6.2.2. Other works in progress

• P. Charton continued his PhD. under the supervision of M. Deaconu and A. Lejay. He studied some hedging strategies for day ahead markets of wind energy.

• Mathematical modelling for technical analysis techniques Since November 2009, D. Ibrahim has been working on her PhD. thesis on Mathematical modeling of technical analysis in finance, under supervision of D. Talay and E. Tanrê. The aim of her work is to study the performances of a technical analysis tool designed to detect changes in the volatility term: the Bollinger Bands. First, she studied the performances of this indicator in a modified Black-Scholes model such that the rate of volatility changes at an unknown random time $\tau$, independent of the Brownian motion governing the prices. She is interested to study whether this indicator can detect the changes in the volatility. So, she aims to study the tail probability of this indicator by using Karamata’s Tauberian Theorem for Laplace-Stieltjes transforms.

Secondly, she exhibited a mathematical optimal strategy by modifying usual techniques in both the dual and the classical PDE approaches in stochastic control theory, in order to circumvent the discontinuity of the filtration generated by the price process.

This work is part of the contract with FINRISK (see Section 8.3).

• P. Protter (Columbia University) and D. Talay started to develop a new bubble time evolution model.
6. New Results

6.1. Design and Performance Analysis of Wireless Networks

Participants: François Baccelli, Florence Bénézit, Bartłomiej Blaszczyszyn, Chung Shue Chen, Mir Omid Haji Mirsadeghi, Frédéric Morlot, Tien Viet Nguyen, Van Minh Nguyen.

This axis bears on the analysis and the design of wireless access communication networks. Our contributions are organized in terms of network classes: cellular networks, wireless LANs and MANETs, VANETs. We also have a section on generic results that regard more general wireless networks. We are interested both in macroscopic models, which are particularly important for economic planning and in models allowing the definition and the optimization of protocols. Our approach combines several tools, queueing theory, point processes, stochastic geometry, random graphs, distributed control algorithms, self organization protocols.

6.1.1. Cellular Networks

The activity on cellular networks has several complementary facets ranging from performance evaluation to protocol design. The work is mainly based on strong collaborations with Alcatel-Lucent and Orange Labs.

6.1.1.1. Effect of Opportunistic Scheduling on the Quality of Service Perceived by the Users in OFDMA Cellular Networks

Our objective in [20] is to analyze the impact of fading and opportunistic scheduling on the quality of service perceived by the users in an Orthogonal Frequency Division Multiple Access (OFDMA) cellular network. To this end, assuming Markovian arrivals and departures of customers that transmit some given data volumes, as well as some temporal channel variability (fading), we study the mean throughput that the network offers to users in the long run of the system. Explicit formulas are obtained in the case of allocation policies, which may or may-not take advantage of the fading, called respectively opportunistic and non-opportunistic. The main practical results of the present work are the following. Firstly we evaluate for the non-opportunistic allocation the degradation due to fading compared to Additive White Gaussian Noise (AWGN) (that is, a decrease of at least 13% of the throughput). Secondly, we evaluate the gain induced by the opportunistic allocation. In particular, when the traffic demand per cell exceeds some value (about 2 Mbits/s in our numerical example), the gain induced by opportunism compensates the degradation induced by fading compared to AWGN. Partial results were presented at ComNet in 2009 [62].

6.1.1.2. Impact of Shadowing on QoS in Cellular Networks

Shadowing is believed to degrade the quality of service (QoS) in wireless cellular networks. Assuming log-normal shadowing, and studying mobile’s path-loss with respect to the strongest (serving) base station (BS) and the corresponding interference factor (the ratio of the sum of the path-gains form interfering BS’s to the path-gain from the serving BS), which are two key ingredients of the analysis and design of the cellular networks, in [48] we discovered a more subtle reality. We observe, as commonly expected, that a strong variance of the shadowing increases the mean path-loss with respect to the serving BS, which in consequence, may compromise QoS. However, in some cases, an increase of the variance of the shadowing can significantly reduce the mean interference factor and, in consequence, improve some QoS metrics in interference limited systems, provided the handover policy selects the strongest BS as the serving one. We exemplify this phenomenon, similar to stochastic resonance, studying the blocking probability in regular, hexagonal networks in a semi-analytic manner, using a spatial version of the Erlang’s loss formula combined with Kaufman-Roberts algorithm. More detailed probabilistic analysis explains that increasing variance of the log-normal shadowing amplifies the ratio between the strongest signal and all other signals thus reducing the interference. The above observations might shed new light, in particular on the design of indoor communication scenarios. Partial results were presented at IFIP WMNC’2010 [63].
6.1.1.3. Self-Optimization of Radio Resources in Cellular Networks

In [65], we developed mathematical and algorithmic tools for the self-optimization of mobile cellular networks. Scalable algorithms which are based on local measurements and do not require heavy coordination among the wireless devices were proposed. We focused on the optimization of transmit power and of user association. The method is applicable to both joint and separate optimizations. The global utility minimized is linked to potential delay fairness. The distributed algorithm adaptively updates the system parameters and achieves global optimality by measuring SINR and interference. The algorithms are built on Gibbs’ sampler and offer a unified framework that can be easily used for different purposes.

In [32], we investigated the joint optimization of radio resources in heterogeneous cellular networks made of a juxtaposition of macro and small cells. We showed that within this context, it is essential to use algorithms able to simultaneously solve the problems of channel selection, user association and power control. In such networks, the unpredictability of the cell and user patterns also requires self-optimized schemes. We proposed a generalized solution which is based on Gibbs’ sampler. It can be implemented in a distributed way and nevertheless achieves minimal system-wide potential delay. Results show that it is effective in both throughput and energy efficiency.

In [35], we extended it to an autonomous radio resource allocation and optimization scheme that chooses the transmit power and precoding vector among codebooks for multiple antennas transmitters to improve spectral and power efficiency and provide user fairness. Network self-optimization is an essential feature for supporting the cell densification in future wireless cellular systems. Besides, we included power pricing to parametrize and to enhance the energy efficiency. Simulation results show that the proposed scheme can outperform today’s default modes of operation in network throughput, energy efficiency, and user fairness.

Three patents were filed under the INRIA/Alcatel–Lucent joint laboratory.

6.1.1.4. Best Signal Quality in a Wireless Network

In a wireless network composed of randomly scattered nodes, the characterization of the distribution of the best signal quality received from a group of nodes is of primary importance for many network design problems. The thesis of Van Minh Nguyen [7] developed a framework for analyzing this distributions using shot noise models for the interference field. The joint distribution of the interference and the maximum signal strength was identified. The best signal quality can be represented as a function of these two quantities. Particular practical scenarios were also analyzed where explicit expressions can be obtained.

6.1.1.5. Cellular Network Tomography

The Foschini-Miljanic’s [67] algorithm is used for power control in cellular networks where users require a fixed bit rate. It leads to an optimal choice of power by the users in a distributed way when such a solution exists. If the users are too greedy or too many, the network saturates, and it is not possible to provide the required bit rates. We have been working on the question of residual bandwidth estimation in [61]. The residual bandwidth of a user is defined as the rate that this user should have to saturate the network when all other users stick to their initial rate requirement and all users use power control. The aim is to determine the residual bandwidth of a given user by local measurements. We showed that by simply changing their SINR target slightly and by listening to the evolution of interference, users can locally inverse Foschini-Miljanic’s algorithm and compute their residual bandwidth.

6.1.1.6. Coverage in Cellular Networks

Cellular networks are usually modeled by placing the base stations according to a regular geometry such as a grid, with the mobile users scattered around the network either as a Poisson point process (i.e. uniform distribution) or deterministically. These models have been used extensively for cellular design and analysis but suffer from being both highly idealized and not very tractable. Thus, complex simulations are used to evaluate key metrics such as coverage probability for a specified target rate (equivalently, the outage probability) or average/sum rate. More tractable models have long been desirable. In a joint work with J. Andrews and R. Ganti [UT Austin, USA] [9] and [34], we developed general models for multi-cell signal-to-noise-plus-interference ratio (SINR) based on homogeneous Poisson point processes and derived the coverage probability
and rate. Under very general assumptions, the resulting expressions for the SINR cumulative distribution function involve quickly computable integrals, and in some important special cases of practical interest these integrals can be simplified to common integrals (e.g., the Q-function) or even to exact and quite simple closed-form expressions. We also derived the mean rate, and then the coverage gain (and mean rate loss) from static frequency reuse. We compared the coverage predictions obtained by this approach to the standard grid model and an actual base station deployment. We observed that the proposed model is pessimistic (a lower bound on coverage) whereas the grid model is optimistic. In addition to being more tractable, the proposed model may better capture the increasingly opportunistic and dense placement of base stations in urban cellular networks with highly variable coverage radii.

Cellular networks are in a major transition from a carefully planned set of large tower-mounted base-stations (BSs) to an irregular deployment of heterogeneous infrastructure elements that often additionally includes micro, pico, and femtocells, as well as distributed antennas. In a collaboration with H. Dhillon, J. Andrews and R. Ganti [UT Austin, USA] [66], we extended the approach of we developed a model for a downlink heterogeneous cellular network (HCN) consisting of K tiers of randomly located BSs, where each tier may differ in terms of average transmit power, supported data rate and BS density. Assuming a mobile user connects to the strongest candidate BS, the resulting Signal-to-Interference-plus-Noise-Ratio (SINR) is greater than 1 when in coverage, Rayleigh fading, we derived an expression for the probability of coverage (equivalently outage) over the entire network under both open and closed access. One interesting observation for interference-limited open access networks is that at a given SINR, adding more tiers and/or BSs neither increases nor decreases the probability of coverage or outage when all the tiers have the same SINR threshold.

6.1.2. Mobile Ad Hoc Networks

A MANET is made of mobile nodes which are at the same time terminals and routers, connected by wireless links, the union of which forms an arbitrary topology. The nodes are free to move randomly and organize themselves arbitrarily. Important issues in such a scenario are connectivity, medium access (MAC), routing and stability. This year, we worked on the analysis of MAC and routing protocols in multi-hop MANETs in collaboration with Paul Mühlethaler [INRIA HIPERCOM], and on a game theoretic view of Spatial Aloha in collaboration with E. Altman and M.K. Hanawal [INRIA MAESTRO] [68].

6.1.2.1. Improvement of CSMA/CA’s Spatial Reuse

The most popular medium access mechanism for such ad hoc networks is CSMA/CA with RTS/CTS. In CSMA-like mechanisms, spatial reuse is achieved by implementing energy based guard zones. In a new collaboration with Qualcomm ([26] and [14]), we considered the problem of simultaneously scheduling the maximum number of links that can achieve a given signal to interference ratio (SIR). Using tools from stochastic geometry, we studied and maximized the medium access probability of a typical link. Our contributions are two-fold: (i) We showed that a simple modification to the RTS/CTS mechanism, viz., changing the receiver yield decision from an energy-level guard zone to an SIR guard zone, leads to performance gains; and (ii) We showed that this combined with a simple modification to the transmit power level – setting it to be inversely proportional to the square root of the link gain – leads to significant improvements in network throughput. Further, this simple power-level choice is no worse than a factor of two away from optimal over the class of all "local" power level selection strategies for fading channels, and further is optimal in the non-fading case. The analysis relies on an extension of the Matérn hard core point process which allows us to quantify both these SIR guard zones and this power control mechanism.

6.1.2.2. Opportunistic versions of CSMA/CA

In collaboration with Gustavo de Veciana and Yuchul Kim [UT Austin, ECE] we studied the benefits of channel-aware (opportunistic) scheduling of transmissions in ad-hoc networks using CSMA/CA [36]. The key challenge in optimizing the performance of such systems is finding a good compromise among three interdependent quantities, the density and channel quality of the scheduled transmitters, and the resulting interference at receivers. We propose two new channel-aware slotted CSMA protocols: opportunistic CSMA (O-CSMA) and quantile-based CSMA (QT-CSMA) and develop stochastic geometric models allowing us to quantify their performance in terms of spatial reuse and spatial fairness. When properly optimized these
Networks and Telecommunications - New Results - Project-Team TREC

protocols offer substantial improvements in terms of both of these metrics relative to CSMA - particularly when the density of nodes is moderate to high. Moreover, we show that a simple version of QT-CSMA can achieve robust performance gains without requiring careful parameter optimization. The paper supports the case that the benefits associated with channel-aware scheduling in ad hoc networks, as in centralized base station scenarios, might far outweigh the associated overhead, and this can be done robustly using a QT-CSMA like protocol.

6.1.3. Cognitive Radio Networks

We wrote a survey [22] on the probabilistic framework which can be used to model and analyze cognitive radio networks using various classes of MAC protocols (including carrier sensing based multiple access schemes and Aloha schemes). For each model, analytical results were derived for important performance metrics. This leads to a quantification of the interplay between primary and secondary users in such networks.

6.1.4. Generic Wireless Networks

6.1.4.1. Power Control in Wireless Networks

In [10], in collaboration with N. Bambos, [Stanford] and N. Gast [EPFL], we formulated a delay-power control (DPC) scheme for wireless networking, which balances delay against transmitter power on each wireless link. The DPC scheme is scalable, as each link autonomously updates its power based on the interference observed at its receiver; no cross-link communication is required. It is shown that DPC converges to a unique equilibrium power and several key properties are established, concerning the nature of channel bandwidth sharing achieved by the links. The DPC scheme is contrasted to the well-known Foschini-Miljanic (FM) formulation for transmitter power control in wireless networks, and some key advantages are established. Based on the DPC and FM schemes, two protocols are developed, which leverage adaptive tuning of DPC parameters. One of them is inspired by TCP and exhibits analogous behavior.

In [21], we studied the weighted sum rate maximization problem in wireless networks consisting of multiple source-destination pairs. The optimization problem is to maximize a weighted sum of data rates by adjusting the power of each user. The problem is in general a non-convex optimization problem that will lead to multiple local maxima. A Gauss-Seidel type iterative power control algorithm was presented. We showed by simulation that the proposed algorithm converges to the global maximum with very high probability, if we initialize the initial power allocation uniformly at random. The proposed algorithm also has the favorable properties that only simple operations are needed in each iteration, and the convergence is fast. Performance comparison under different user densities has also indicated its effectiveness. Finally, we discussed some simple and optimal power allocation strategies under special cases of the problem if the network can be represented by a certain approximation.

6.1.4.2. Simultaneous Decoding

In [15], in collaboration with A. El Gamal [Stanford, USA] and D. Tse [UC Berkeley, USA], we analyzed a network made of a collection of transmitter-receiver links where each link is considered to be part of a Multiple Access Channel (MAC) together with a collection of co-transmitters, rather than treating the messages of the latter as noise. This MAC extension is meant to improve the rate of the link and not to decode the messages of the co-transmitters. The necessary and sufficient condition for the feasibility of some rate when using successive interference cancellation and simultaneous decoding were provided. The reasons why simultaneous decoding is preferable to successive interference cancellation and simultaneous decoding were also given. The gain obtained when using this type of simultaneous decoding rather than treating interference as noise was then quantified in a network made of a large random collection of such links. The gains in coverage and in rate were analyzed in terms of ensemble averages, evaluated using stochastic geometry. Closed form or integral expressions were obtained for the outage/coverage probability in networks where nodes are randomly distributed like a Poisson point process on an infinite plane. In the CDMA limit (large bandwidth, low SINR per hertz, high density), the ensemble average of the link rates tends to 0 when interference is treated as noise whereas it tends to a positive constant when simultaneous decoding of infinite order is used. The whole analysis was conducted in the AWGN case.
6.2. Network Dynamics

This traditional research topic of TREC has several new threads like perfect simulation, active probing or Markov decision.

6.2.1. Network Calculus

Network calculus is a theory that aims at computing deterministic performance guarantees in communication networks. This theory is based on the \((\min,\plus)\) algebra. Flows are modeled by an \textit{arrival curve} that upper-bounds the amount of data that can arrive during any interval, and network elements are modeled by a \textit{service curve} that gives a lower bound on the amount of service offered to the flows crossing that element. Worst-case performances are then derived by combining these curves.

6.2.1.1. Performance bounds networks with static priorities

In cooperation with Aurore Junier [INRIA/IRISA], we present in [29] algorithms to compute worst-case performance upper bounds when the service policy is static priorities, using linear programming. Linear programming does not lead to tight bounds, but when combining this method with \((\min,\plus)\) methods, we obtain bounds that outperform the already known bounds. Also, we prove that in tandem networks, the the worst-case performance bound under arbitrary multiplexing can be obtain by a policy with static priorities, the “shortest-destination first” policy.

6.2.1.2. Feed-forward networks with wormhole routing discipline

In collaboration with Bruno Gaujal [INRIA Rhone Alpes] and Nadir Farhi [IFFSTAR] we are working on a model of performance bound calculus on feed-forward networks where data packets are routed under wormhole routing discipline. We are interested in determining maximum end-to-end delays and backlogs for packets going from a source node to a destination node, through a given virtual path in the network. Our objective is to give a “network calculus” approach to calculate the performance bounds. For this, we propose a new concept of curves that we call \textit{packet curves}. The curves permit to model constraints on packet lengths for data flows, when the lengths are allowed to be different. We used this new concept to propose an approach for calculating residual services for data flows served under non preemptive service disciplines. This notion also enabled us to differentiate different classes of service policies: those that are based on a packet count (like round-robin and its generalized version), where the packet curve will be useful to tighten the bounds computed, and those that are based on the amount of data served (FIFO, priorities), where it won’t be useful. These results can be found in [44] and have been presented in ILAS 2011.

6.2.1.3. Composition of service curves in Network Calculus

In envelope-based models for worst-case performance evaluation like Network Calculus or Real-Time Calculus, several types of service curves have been introduced to quantify some deterministic service guarantees. We compare those different classes of service curves regarding the composition (servers in tandem) and individual service curves (when several flows share a server, what service curve can be guaranteed to each of the flows?). In short, there are two main classes of service curves, simple and strict service curves. Individual service curve can not always be computed when simple service curves are considered, and strict service curves is not a stable class regarding the two operations described. We show that there can be no equivalence between the two main classes of service curves and that no notion of service curve in-between can be defined, that behaves well for the composition. We complete this study by studying other classes of service curves from this viewpoint. These results have been presented in [28]

6.2.1.4. Residuation in \((\max,\plus)\) automata

With Éric Badouel, Philippe Darondeau [INRIA/IRISA] and Jan Komenda [Institute of Mathematics, Brno], we study in [27] the decidability of existence and the rationality of delay controllers for systems with time weights in the tropical and interval semirings. Depending on the \((\max,+)\) or \((\min,+)\)-rationality of the series specifying the controlled system and the control objective, cases are identified where the controller series
defined by residuation is rational, and when it is positive (i.e., when delay control is feasible). When the control objective is specified by a tolerance, i.e. by two bounding rational series, a nice case is identified in which the controller series is of the same rational type as the system specification series.

6.2.2. Queueing Theory and Active Probing

6.2.2.1. Inverse Problems

Active probing began by measuring end-to-end path metrics, such as delay and loss, in a direct measurement process which did not require inference of internal network parameters. The field has since progressed to measuring network metrics, from link capacities to available bandwidth and cross traffic itself, which reach deeper and deeper into the network and require increasingly complex inversion methodologies. The thesis of B. Kauffmann [6] investigates this line of thought as a set of inverse problems in queueing theory. Queueing theory is typically concerned with the solution of direct problems, where the trajectory of the queueing system, and laws thereof, are derived based on a complete specification of the system, its inputs and initial conditions. Inverse problems aim to deduce unknown parameters of the system based on partially observed trajectories. A general definition of the inverse problems in this class was provided and the key variants were mapped out: the analytical methods, the statistical methods and the design of experiments. We also show how this inverse problem viewpoint translates to the design of concrete Internet probing applications.

Inverse problems in bandwidth sharing networks theory were also investigated. A bandwidth sharing networks allocates the bandwidth to each flow in order to maximize a given utility function (typically an $\alpha$-fairness), with the constraints given by the capacity of the different servers. In particular, it has been shown that the equilibrium distribution of the bandwidth allocated by TCP to many competing connections is oscillating around an $\alpha$-fair allocation. As such, the theory of bandwidth sharing network is a high-level viewpoint of networks. The meaning of inverse problems in this theory, and their relation to the active probing paradigm are analyzed. In two simple examples of network, the capacity of the different servers and the flow population can estimated, and an algorithm to perform this estimation was proposed.

6.2.2.2. Internet Tomography

Most active probing techniques suffer of the “Bottleneck” limitation: all characteristics of the path after the bottleneck link are erased and unreachable. we are currently investigating a new tomography technique, based on the measurement of the fluctuations of point-to-point end-to-end delays, and allowing one to get insight on the residual available bandwidth along the whole path. For this, we combined classical queueing theory models with statistical analysis to obtain estimators of residual bandwidth on all links of the path. These estimators were proved to be tractable, consistent and efficient. In [59] we evaluated their performance with simulation and trace-based experiments.

Lately this method has been generalized in [72] to a probing multicast tree instead of a single path. This work deals with the complexity of the combinatorials in trees, and gives an explicit formula for the iteration of the Expectation-Maximization (E-M) algorithm. The E-M algorithm is notoriously slow, and we provided three speed-up techniques which are effective in our case (up to a factor $10^3$ in the computation time). These techniques are general, and can be applied to other instances of E-M, or even several other iterative algorithms.

6.2.3. Perfect Sampling of Queueing Systems

Propp and Wilson introduced in 1996 a perfect sampling algorithm that uses coupling arguments to give an unbiased sample from the stationary distribution of a Markov chain on a finite state space $\mathcal{X}$. In the general case, the algorithm starts trajectories from all $x \in \mathcal{X}$ at some time in the past until time $t = 0$. If the final state is the same for all trajectories, then the chain has coupled and the final state has the stationary distribution of the Markov chain. Otherwise, the simulations are started further in the past. This technique is very efficient if all the events in the system have appropriate monotonicity properties. However, in the general (non-monotone) case, this technique requires that one consider the whole state space, which limits its application only to chains with a state space of small cardinality.
6.2.3.1. Piecewise Homogeneous Events

In collaboration with Bruno Gaujal [INRIA Grenoble - Rhone-Alpes], we proposed in [47] a new approach for the general case that only needs to consider two trajectories. Instead of the original chain, we used two bounding processes (envelopes) and we showed that, whenever they couple, one obtains a sample under the stationary distribution of the original chain. We showed that this new approach is particularly effective when the state space can be partitioned into pieces where envelopes can be easily computed. We further showed that most Markovian queueing networks have this property and we propose efficient algorithms for some of them. The envelope technique has been implemented in a software tool PSI2 (see Section 5.2).

6.2.3.2. Acceleration of Perfect Sampling by Skipping Events

In collaboration with Bruno Gaujal [INRIA Grenoble - Rhone-Alpes], we proposed a new method to speed up perfect sampling of Markov chains by skipping passive events during the simulation [38]. We showed that this can be done without altering the distribution of the samples. This technique is particularly efficient for the simulation of Markov chains with different time scales such as queueing networks where certain servers are much faster than others. In such cases, the coupling time of the Markov chain can be arbitrarily large while the runtime of the skipping algorithm remains bounded. This was further illustrated by several experiments that also show the role played by the entropy of the system in the performance of our algorithm.

6.2.3.3. Aggregated Envelopes

When the cardinality of the state space is so huge that even storing the state of the Markov chain becomes challenging, we propose to combine the ideas of bounding processes and the aggregation of Markov chains [30]. We illustrate the proposed approach of aggregated envelope bounding chains on queueing models with joint arrivals and joint services, often referred to in the literature as assemble-to-order systems. Due to the finite capacity, and coupling in arrivals and services, the exact solving techniques are inefficient for larger problem instances. For instance, for the service tools model proposed by Vliegen and Van Houtum (2009), the aggregated envelope method reduces exponentially the dimension of the state space and allows effective perfect sampling algorithms. We also provide bounds for the coupling time, under the high service rate assumptions.

6.2.4. Markov Chains and Markov Decision Processes

Solving Markov chains is in general difficult if the state space of the chain is very large (or infinite) and lacking a simple repeating structure. One alternative to solving such chains is to construct models that are simple to analyze and provide bounds for a reward function of interest. The bounds can be established by using different qualitative properties, such as stochastic monotonicity, convexity, submodularity, etc. In the case of Markov decision processes, similar properties can be used to show that the optimal policy has some desired structure (e.g. the critical level policies).

6.2.4.1. Stochastic Monotonicity

In collaboration with Jean-Michel Fourneau [PRiSM, Université de Versailles Saint-Quentin] we consider two different applications of stochastic monotonicity in performance evaluation of networks [18]. In the first one, we assume that a Markov chain of the model depends on a parameter that can be estimated only up to a certain level and we have only an interval that contains the exact value of the parameter. Instead of taking an approximated value for the unknown parameter, we show how we can use the monotonicity properties of the Markov chain to take into account the error bound from the measurements. In the second application, we consider a well known approximation method: the decomposition into submodels. In such an approach, models of complex networks are decomposed into submodels whose results are then used as parameters for the next submodel in an iterative computation. One obtains a fixed point system which is solved numerically. In general, we have neither an existence proof of the solution of the fixed point system nor a convergence proof of the iterative algorithm. Here we show how stochastic monotonicity can be used to answer these questions. Furthermore, monotonicity properties can also help to derive more efficient algorithms to solve fixed point systems.
6.2.4.2. Componentwise Bounds

In collaboration with Jean-Michel Fourneau [PRISM, Université de Versailles Saint-Quentin] we proposed an iterative algorithm to compute component-wise bounds of the steady-state distribution of an irreducible and aperiodic Markov chain [17]. These bounds are based on very simple properties of \((\max, +)\) and \((\min, +)\) sequences. We showed that, under some assumptions on the Markov chain, these bounds converge to the exact solution. In that case we have a clear tradeoff between computation and the tightness of bounds. Furthermore, at each step we know that the exact solution is within an interval, which provides a more effective convergence test than usual iterative methods.

6.2.4.3. Markov Reward Processes and Aggregation

In a joint work with I.M. H. Vliegen [University of Twente, The Netherlands] and A. Scheller-Wolf [Carnegie Mellon University, USA] [19], we presented a new bounding method for Markov chains inspired by Markov reward theory: Our method constructs bounds by redirecting selected sets of transitions, facilitating an intuitive interpretation of the modifications of the original system. We show that our method is compatible with strong aggregation of Markov chains; thus we can obtain bounds for an initial chain by analyzing a much smaller chain. We illustrated our method by using it to prove monotonicity results and bounds for assemble-to-order systems.

6.2.4.4. Critical Level Policies in Controlled Queuing Systems

In a joint work with Emmanuel Hyon [University of Paris Ouest Nanterre La Defense and LIP6] [39], we consider a single-item lost sales inventory model with different classes of customers. Each customer class may have different lost sale penalty costs. We assume that the demands follow a Poisson process and we consider a single replenishment hypoexponential server. We give a Markov decision process associated with this optimal control problem and prove some structural properties of its dynamic programming operator. This allows us to show that the optimal policy is a critical level policy. We also discuss some possible extensions to other replenishment distributions and give some numerical results for the hyperexponential server case.

6.2.5. Dynamic Systems with Local Interactions

Dynamic systems with local interactions can be used to model problems in distributed computing: gathering a global information by exchanging only local information. The challenge is two-fold: first, it is impossible to centralize the information (cells are indistinguishable); second, the cells contain only a limited information (represented by a finite alphabet \(A; A = \{0, 1\}\) in our case). Two natural instantiations of dynamical systems are considered, one with synchronous updates of the cells, and one with asynchronous updates. In the first case, time is discrete, all cells are updated at each time step, and the model is known as a Probabilistic Cellular Automaton (PCA) (e.g. Dobrushin, R., Kryukov, V., Toom, A.: Stochastic cellular systems: ergodicity, memory, morphogenesis, 1990). In the second case, time is continuous, cells are updated at random instants, at most one cell is updated at any given time, and the model is known as a (finite range) Interacting Particle System (IPS) (e.g. Liggett, T.M.: Interacting particle systems, 2005).

6.2.5.1. Density Classification on Infinite Lattices and Trees

In a joint work with N. Fatès [INRIA Nancy – Grand-Est], J. Mairesse and I. Marcovici [LIAFA, CNRS and Université Paris 7] [46] we consider an infinite graph with nodes initially labeled by independent Bernoulli random variables of parameter \(p\). We address the density classification problem, that is, we want to design a (probabilistic or deterministic) cellular automaton or a finite-range interacting particle system that evolves on this graph and decides whether \(p\) is smaller or larger than \(1/2\). Precisely, the trajectories should converge (weakly) to the uniform configuration with only 0’s if \(p < 1/2\), and only 1’s if \(p > 1/2\). We present solutions to that problem on \(\mathbb{Z}^d\), for any \(d \geq 2\), and on the regular infinite trees. For \(\mathbb{Z}\), we propose some candidates that we back up with numerical simulations.

6.2.6. Stochastic Stability

6.2.6.1. Ergodicity of Probabilistic Cellular Automata
In a joint work with J. Mairesse and I. Marcovici [LIAFA, CNRS and Université Paris 7] [31], we considered ergodicity properties of probabilistic cellular automata (PCA). A classical cellular automaton (CA) is a particular case of PCA. For a 1-dimensional CA, we proved that ergodicity is equivalent to nilpotency, and is therefore undecidable. We then proposed an efficient perfect sampling algorithm for the invariant measure of an ergodic PCA. Our algorithm does not assume any monotonicity properties of the local rule. It is based on a bounding process which is shown to be also a PCA. We then focused on the PCA Majority, whose asymptotic behavior is unknown, and performed numerical experiments using the perfect sampling procedure.

6.2.6.2. Spatial Queues

In a joint work with S. Foss [Heriot–Watt University, UK] [13], we considered a queue where the server is the Euclidean space, the customers are random closed sets of the Euclidean space arriving according to a Poisson rain and where the discipline is a hard exclusion rule: no two intersecting random closed sets can be served at the same time. We use the max plus algebra and Lyapunov exponents to show that under first come first serve assumptions, this queue is stable for a sufficiently small arrival intensity. We also discuss the percolation properties of the stationary regime of the random closed sets in the queue.

6.3. Economics of Networks

Participants: François Baccelli, Emilie Coupechoux, Marc Lelarge.

6.3.1. Diffusion and Cascading Behavior in Random Networks

The spread of new ideas, behaviors or technologies has been extensively studied using epidemic models. In [69], we considered a model of diffusion where the individuals’ behavior is the result of a strategic choice. We studied a simple coordination game with binary choice and give a condition for a new action to become widespread in a random network. We also analyze the possible equilibria of this game and identify conditions for the coexistence of both strategies in large connected sets. Finally we look at how can firms use social networks to promote their goals with limited information.

Our results differ strongly from the one derived with epidemic models. In particular, we showed that connectivity plays an ambiguous role: while it allows the diffusion to spread, when the network is highly connected, the diffusion is also limited by high-degree nodes which are very stable. In the case of a sparse random network of interacting agents, we computed the contagion threshold for a general diffusion model and showed the existence of (continuous and discontinuous) phase transitions. We also computed the minimal size of a seed of new adopters in order to trigger a global cascade if these new adopters can only be sampled without any information on the graph. We showed that this minimal size has a non-trivial behavior as a function of the connectivity. Our analysis extends methods developed in the random graphs literature based on the properties of empirical distributions of independent random variables, and leads to simple proofs.

6.3.2. Impact of Clustering on Diffusions and Contagions in Random Networks

In [33] we extend some results of the previous results to a model of random graphs having both a given degree distribution and a tunable clustering coefficient. This work shed new light on the impact of clustering on the spread of new ideas, technologies, viruses or worms. We consider two types of growth processes: the (classical SI) diffusion model, and the contagion model, which is inspired by a simple coordination game played on the network and is characterized by a threshold rule and a random seed. While clustering inhibits the diffusion process (on regular graphs), its impact for the contagion process is more subtle and depends on the connectivity of the graph: in a low connectivity regime, clustering also inhibits the contagion, while in a high connectivity regime, clustering favors the appearance of global cascades but reduces their size.

6.3.3. Economic Value of User Localization in Wireless Networks

The defining characteristic of wireless and mobile networking is user mobility, and related to it is the ability for the network to capture (at least partial) information on where users are located and how users change location over time. Information about location is becoming critical, and therefore valuable, for an increasingly larger number of location-based or location-aware services. A key open question, however, is how valuable exactly this information is. Our goal in this paper is to help understand and estimate the economics, or the value of location information.
In a joint work with J. Bolot [Sprint ATL, USA], we addressed in particular the value of different granularities of location information, for example how much more valuable is it to know the GPS location of a mobile user compared to only knowing the access point, or the cell tower, that the user is associated with. We made three main contributions. First, we presented novel models, which capture the location-based economic activity of mobile users. Second, we derived closed-form analytic solutions for the economic value generated by those users. Third, we augmented the models to consider uncertainty about the users’ location, and derived expressions for the economic value generated with different granularities of location information.

### 6.4. Point Processes, Stochastic Geometry and Random Geometric Graphs

**Participants:** François Baccelli, Bartłomiej Blaszcyszyn, Pierre Brémaud, Yogeshwaran Dhandapani, Kumar Gaurav, Mir Omid Haji Mirsadeghi, Justin Salez.

#### 6.4.1. Comparison of Clustering and Percolation of Point Processes and Random Graphs

Heuristics indicate that point processes exhibiting clustering of points have larger critical radius $r_c$ for the percolation of their continuum percolation models than spatially homogeneous point processes. It has already been shown in [64], [73] that the directionally convex (dcx) ordering of point processes is suitable to compare their clustering tendencies. Hence, it was tempting to conjecture that $r_c$ is increasing in dcx order. Some numerical evidences support this conjecture for a special class of point processes, called perturbed lattices, which are "toy models" for determinantal and permanental point processes. However the conjecture is not true in full generality. In 2011 we have prepared three publications on this subject.

**6.4.1.1. On comparison of clustering properties of point processes**

In [52] we provide a large class of perturbed lattice point processes, monotone in dcx order and comparable to Poisson point processes that is commonly considered as the reference model in the comparative study of clustering phenomena. We also introduce a weaker order based on the comparison of only void probabilities and factorial moment measures. We prove that determinantal and permanental processes, as well as, more generally, negatively and positively associated point processes are comparable in this weaker sense to the Poisson point process of the same mean measure.

**6.4.1.2. Clustering and percolation of point processes**

In [49] we show that simple, stationary point processes of a given intensity on $\mathbb{R}^d$, having void probabilities and factorial moment measures smaller than those of a homogeneous Poisson point process of the same intensity, admit uniformly non-degenerate lower and upper bounds on the critical radius $r_c$ for the percolation of their continuum percolation models. Examples are negatively associated point processes and, more specifically, determinantal point processes. More generally, we show that point processes dcx smaller than a homogeneous Poisson point processes (for example perturbed lattices) exhibit phase transitions in certain percolation models based on the level-sets of additive shot-noise fields of these point processes. Examples of such models are $k$-percolation and SINR-percolation models. We also construct a Cox point process with degenerate critical radius $r_c = 0$, that is dcx larger than a given homogeneous Poisson point process. This is a counterexample for the aforementioned conjecture in the full generality.

**6.4.1.3. Ordering of non-standard critical radii**

As explained above, heuristically one expects finiteness of the critical radii for percolation of sub-Poisson point processes. However, in [49] we have show that it is non-zero as well. In a more elaborate paper [50] we present a reasoning as to why this non-triviality is to be expected. Specifically, we defined two (nonstandard) critical radii for percolation of the Boolean model, called the lower and upper critical radii, and related, respectively, to the finiteness of the expected number of void circuits around the origin and asymptotic of the expected number of long occupied paths from the origin in suitable discrete approximations of the continuum model. These radii sandwich the usual critical radius $r_c$ for percolation of the Boolean model. We show that dcx order preserves the upper critical radii and reverses the lower critical radii.
6.4.1.4. Local weak convergence and stochastic comparison

Many random models are parametrized by the size of the model, and the essential properties of the model are the asymptotic ones as the size of the graph tends to infinity. In the master thesis [57] we show that the theory of local weak converge provides a natural setting to investigate stochastic (convex) ordering of such models. We consider both the geometric context of [71] and the discrete one of Galton-Watson branching process and Configuration Model, cf [5]. In this latter case we define and study a convex order in the context of random trees and graphs which converge in the local weak sense. In particular, we’re interested in the effect of ordering on percolation. It turns out that while in the case of Galton-Watson trees, convex ordering leads to the ordering of percolation probabilities, we cannot conclude this in the case of configuration model. In this case, we could only obtain the ordering of percolation thresholds.

6.4.1.5. AB random geometric graphs

We investigated percolation in the AB Poisson-Boolean model in d-dimensional Euclidean space, and asymptotic properties of AB random geometric graphs on Poisson points in $[0,1]^d$. The AB random geometric graph we studied is a generalization to the continuum of a bi-partite graph called the AB percolation model on discrete lattices. Such an extension is motivated by applications to secure communication networks and frequency division duplex networks. The AB Poisson Boolean model is defined as a bi-partite graph on two independent Poisson point processes of intensities $\lambda$ and $\mu$ in the $d$-dimensional Euclidean space in the same manner as the usual Boolean model with a radius $r$. We showed existence of AB percolation for all $d \geq 2$, and derived bounds for a critical intensity. Further, in $d = 2$, we characterize a critical intensity. The set-up for AB random geometric graphs is to construct a bi-partite graph on two independent Poisson point process of intensities $n$ and $cn$ in the unit cube. We provided almost sure asymptotic bounds for the connectivity threshold for all $c > 0$ and a suitable choice of radius cut-off functions $r_n(c)$. Further for $c < c_0$, we derived a weak law result for the largest nearest neighbor radius. This work, which was a part of the PhD thesis [73] will appear in [23].

6.4.2. Random Packing Models

Random packing models (RPM) are point processes (p.p.s) where points which "contend" with each other cannot be simultaneously present. These p.p.s play an important role in many studies in physics, chemistry, material science, forestry and geology. For example, in microscopic physics, chemistry and material science, RPMs can be used to describe systems with hard-core interactions. Applications of this type range from reactions on polymer chains, chemisorption on a single-crystal surface, to absorption in colloidal systems. In these models, each point (molecule, particle,···) in the system occupies some space, and two points with overlapping occupied space contend with each other. Another example is the study of seismic and forestry data patterns, where RPMs are used as a reference model for the data set under consideration. In wireless communications, RPMs can be used to model the users simultaneously accessing the medium in a wireless network using Carrier Sensing Medium Access (CSMA). In this context, each point (node, user, transmitter,···) does not occupy space but instead generates interference to other points in the network. Two points contend with each other if either of them generates too much interference to the other. Motivated by this kind of application, we studied in [70] the generating functionals of several models of random packing processes: the classical Matérn hard-core model; its extensions, the $k$-Matérn models and the $\infty$-Matérn model, which is an example of random sequential packing process. The main new results are: 1) A sufficient condition for the $\infty$-Matérn model to be well-defined (unlike the other two, the $\infty$-Matérn model may not be well-defined on unbounded space); 2) the generating functional of the resulting point process which is given for each of the three models as the solution of a differential equation; 3) series representation and bounds on the generating functional of the packing models; 4) moment measures and other useful properties of the considered packing models which are derived from their generating functionals.

6.4.3. Extremal and Additive Matérn Point Processes

In the simplest Matérn point processes, one retains certain points of a Poisson point process in such a way that no pairs of points are at distance less than a threshold. This condition can be reinterpreted as a threshold condition on an extremal shot–noise field associated with the Poisson point process. In a joint work with P.
Bermolen (Universidad de la República, Montevideo, Uruguay) [11], we studied extensions of Matérn point processes where one retains points that satisfy a threshold condition based on an additive shot–noise field of the Poisson point process. We provide an analytical characterization of the intensity of this class of point processes and we compare the packing obtained by the extremal and additive schemes and certain combinations thereof.

6.4.4. Spatial Birth and Death Point Processes

In collaboration with F. Mathieu [INRIA GANG] and Ilkka Norros [VTT, Finland], we started studying a new spatial birth and death point process model where the death rate is a shot noise of the point configuration [60]. We showed that the spatial point process describing the steady state exhibits repulsion. We studied two asymptotic regimes: the fluid regime and the hard–core regime. We derived closed form expressions for the mean (and in some cases the law) of the latency of points as well as for the spatial density of points in the steady state of each regime.

6.4.5. Information Theory and Stochastic Geometry

In a joint work with V. Anantharam [UC Berkeley], [58], we studied the Shannon regime for the random displacement of stationary point processes. Let each point of some initial stationary point process in $\mathbb{R}^n$ give rise to one daughter point, the location of which is obtained by adding a random vector to the coordinates of the mother point, with all displacement vectors independently and identically distributed for all points. The decoding problem is then the following one: the whole mother point process is known as well as the coordinates of some daughter point; the displacements are only known through their law; can one find the mother of this daughter point? The Shannon regime is that where the dimension $n$ tends to infinity and where the logarithm of the intensity of the point process is proportional to $n$. We showed that this problem exhibits a sharp threshold: if the sum of the proportionality factor and of the differential entropy rate of the noise is positive, then the probability of finding the right mother point tends to 0 with $n$ for all point processes and decoding strategies. If this sum is negative, there exist mother point processes, for instance Poisson, and decoding strategies, for instance maximum likelihood, for which the probability of finding the right mother tends to 1 with $n$. We then used large deviations theory to show that in the latter case, if the entropy spectrum of the noise satisfies a large deviation principle, then the error probability goes exponentially fast to 0 with an exponent that is given in closed form in terms of the rate function of the noise entropy spectrum. This was done for two classes of mother point processes: Poisson and Matérn. The practical interest to information theory comes from the explicit connection that we also establish between this problem and the estimation of error exponents in Shannon’s additive noise channel with power constraints on the codewords.

We currently investigate extensions of this approach to network information theoretic channels.

6.4.6. Navigation on Point Processes and Graphs

In [12], we studied optimal navigations in wireless networks in terms of first passage percolation on some space-time SINR graph. We established both “positive” and “negative” results on the associated the percolation delay rate (delay per unit of Euclidean distance, also called time constant in the classical terminology of percolation). The latter determines the asymptotics of the minimum delay required by a packet to progress from a source node to a destination node when the Euclidean distance between the two tends to infinity. The main negative result states that the percolation delay rate is infinite on the random graph associated with a Poisson point process under natural assumptions on the wireless channels. The main positive result states that when adding a periodic node infrastructure of arbitrarily small intensity to the Poisson point process, the percolation delay rate is positive and finite.

A new direction of research was initiated aiming at defining a new class of measures on a point process which are invariant under the action of a navigation on this point process. This class of measures has properties similar to Palm measures of stationary point processes; but they cannot be defined in the classical framework of Palm measures.

6.5. Random Graphs and Combinatorial Optimization

Participants: Hamed Amini, Emilie Coupechoux, Mathieu Leconte, Marc Lelarge, Justin Salez.
6.5.1. Rank of Large Random Graphs

In [16], with Charles Bordenave [CNRS-Université de Toulouse], we investigated the rank of the adjacency matrix of large diluted random graphs: for a sequence of graphs converging locally to a Galton-Watson tree, we provided an explicit formula for the asymptotic multiplicity of the eigenvalue 0 in terms of the degree generating function. In the first part, we showed that the adjacency operator associated with a Galton-Watson tree is self-adjoint with probability one; we analyzed the associated spectral measure at the root and characterize the distribution of its atomic mass at 0. In the second part, we established a sufficient condition for the expectation of this atomic mass to be precisely the normalized limit of the dimension of the kernel of the adjacency matrices of the sequence of graphs. Our proofs borrow ideas from analysis of algorithms, functional analysis, random matrix theory, and statistical physics.

6.5.2. Matchings in infinite graphs

In [43], we proved that for any sequence of (deterministic or random) graphs converging locally, the corresponding sequence of normalized matching numbers converges, and this limit depends only on the limit of the graph sequence. In the particular case where this limit is a unimodular Galton Watson tree, we were able to compute explicitly the value for the limit of the sequence of (normalized) matching numbers. This leads to an explicit formula that considerably extends the well-known one by Karp and Sipser for Erdős-Rényi random graphs.

We considered a natural family of Gibbs distributions over matchings on a finite graph, parameterized by a single positive number called the temperature. The correlation decay technique can be applied for the analysis of matchings at positive temperature and allowed us to establish the weak convergence of the Gibbs marginal as the underlying graph converges locally. However for the zero temperature problem (i.e. maximum matchings), we showed that there is no correlation decay even in very simple cases. By using a complex temperature and a half-plane property due to Heilmann and Lieb, we were able to let the temperature tend to zero and obtained a limit theorem for the asymptotic size of a maximum matching in the graph sequence.

6.5.3. Counting spanning subgraphs subject to local constraints

In [53], we use negative association and local weak convergence to establish the validity of the cavity method for counting spanning subgraphs subject to local constraints. Specifically, the normalized logarithm of the associated generating polynomial (or partition function) is shown to converge along any sequence of graphs whose random weak limit is a tree, and the limit is directly expressed in terms of the unique solution to a limiting cavity equation. On a Galton-Watson tree, the latter simplifies into a recursive distributional equation which can be solved explicitly. As an illustration, we provide an asymptotic formula for the maximal size of a spanning subgraph with maximal degree $b$ in the Erdős-Rényi model with fixed average degree and diverging size, for any $b \in \mathbb{N}$.

6.5.4. Bipartite graph structures for efficient balancing of heterogeneous loads

With Laurent Massoulié [Technicolor], we extend the results obtained previously on the asymptotic size of maximum matchings in random graphs converging locally to Galton-Watson trees to so-called b-matchings (with non-unitary capacity at vertices as well as constraints on individual edges). Compared to the matching case, this involves studying the convergence of a message passing algorithms which transmits vectors instead of single real numbers. We also look further into an application of these results to large scale distributed content service platforms, such as peer-to-peer video-on-demand systems. In this context, the density of maximum b-matchings corresponds to the maximum fraction of simultaneously satisfiable requests, when the service resources are limited and each server can only handle requests for a predetermined subset of the contents which it has stored in memory. An important design aspect of such systems is the content placement strategy onto the servers depending on the estimated content popularities; the results obtained allow to characterize the efficiency of such placement strategies and the optimal strategies in the limit of large storage capacity at servers are determined.
6.5.5. Flooding in Weighted Random Graphs

In a joint work [24] with Moez Draief [Imperial College London], we studied the impact of the edge weights on distances in diluted random graphs. We interpret these weights as delays, and take them as i.i.d exponential random variables. We analyzed the edge flooding time defined as the minimum time needed to reach all nodes from one uniformly chosen node, and the edge diameter corresponding to the worst case edge flooding time. Under some regularity conditions on the degree sequence of the random graph, we showed that these quantities grow as the logarithm of $n$, when the size of the graph $n$ tends to infinity. We also derived the exact value for the prefactors.

These allowed us to analyze an asynchronous randomized broadcast algorithm for random regular graphs. Our results show that the asynchronous version of the algorithm performs better than its synchronized version: in the large size limit of the graph, it will reach the whole network faster even if the local dynamics are similar on average.
TRIO Project-Team

6. New Results

6.1. Real-time services and protocols

In this area, we developed, on the one hand, policies for managing the quality of service of operating support (mainly, networks and protocols) in order to meet the properties required by real time applications (hard real time, weakly hard real time) and, on the other hand, strategies for scheduling activities and memory management.

6.1.1. Network-MAC cross-layer framework for differentiated QoS in wireless sensor networks

Participants: Bilel Nefzi, Ye-Qiong Song.

Self-adaptive QoS mechanism is preferable in large-scale wireless sensor networks because of frequent network condition changes and the difficulty to statically configure the network parameters. A network-MAC cross-layer framework has been developed for facilitating packet scheduling, congestion control and energy consumption minimization. The work is based on a very simple idea of “collecting-and-transmitting burst” scheme, called CoSenS (Collecting and Sending burst Scheme). The underlying MAC protocol is the widely adopted and deployed unslotted CSMA/CA of IEEE802.15.4. An algorithm is designed making the network self-adapts to the dynamic traffic changes. CoSenS provides a simple but efficient improvement of the MAC layer of IEEE 802.15.4 in terms of reliability, delay and throughput. Two extensions have been made: P-CoSenS for integrating priority management and S-CoSenS which adds dynamic sleeping period management.

6.1.2. QoS in UWB-based sensor networks

Participants: Jamila Ben Sliman, Mounir Frikha [INIT, SupCom, Tunisia], Anis Koubaa [ISEP-IPP-Politechnic Institute of Porto, Portugal], Ye-Qiong Song.

IEEE802.15.4a provides higher data rates with smaller energy consumption thanks to the UWB (Ultra Wide Band) technology. However there exist few solutions on how to optimally exploit the great potential of this new standard. Similar to the industrial wireless network initiatives (e.g. WirelessHART, ISA SP100, IEEE802.15.4e), we developed PMCMTP, a multi-channel multi-time slot MAC protocol, which dynamically assigns channels and time slots for dense and large-scale WSNs with QoS support. The most challenging issue is providing a tradeoff between the resource efficiency and the multi-constrained QoS support. For this purpose, we propose a cross-layer algorithm JSAR (Joint duty-cycle Scheduling, resource Allocation and multi-constrained QoS Routing algorithm), based on multi-channel multi-time slot PMCMTP MAC. JSAR simultaneously combines a duty-cycle scheduling scheme for energy saving, a resource allocation scheme for efficient use of frequency channels and time slots, and an heuristic for multi-constrained routing protocol. The performance of JSAR has been evaluated, showing that it is suitable for on-line implementation.

6.1.3. Wireless Networked control systems (WNCS)

Participants: Najet Boughanmi, Eric Rondeau [CRAN UMR 7039, Nancy], Ye-Qiong Song.

With recent technology progress, it is becoming attractive to use wireless solutions for industrial process monitoring and control. Our approach for developing wireless networked control systems (WNCS) is based on the application and network co-design principle. The idea is to adjust on-line the network parameters (QoS) according to the needs of the control loops or Quality of Control (QoC). For achieving this on a WSN (Wireless Sensor Network) which is based on CSMA/CA MAC protocol, several enhancements have been done. In the PhD work of N. Boughanmi [7], we proposed several QoS management mechanisms with priority (based on blackburst scheme) for both the beacon enabled mode and the non-beacon enabled mode of the IEEE 802.15.4 protocol. QoS online adaptation protocols have also been designed which take as parameter the QoC of the system. These proposals are validated through simulations (using TrueTime) and partially with fixed priority scheduling analysis approach.
6.1.4. Wireless networks and middleware for ambient assisted living systems

Participants: Claude Deroussent [MEDeTIC], Shahram Nourizadeh, Ye-Qiong Song, Jean-Pierre Thomesse.

Wireless sensor networks have a great potential for contributing to build the ambient assisted living environment for elderly people at home (PhD work of S. Nourizadeh under LORIA-MEDETIC contract). However several problems have to be addressed for the integration of WSN into the existing home automation networks. The PhD thesis of Shahram Nourizadeh addresses the problem of QoS in context-aware heterogeneous healthcare systems [9]. For providing real-time data collecting in a telehealthcare system composed of wireless sensor network and home automation network, a middleware called CodaQ is designed. It provides context data and takes into account QoS requirements of the applications. In [30], we showed how the data are modeled for including context information and how the QoS requirements are handled within a middleware. First measurements on a test bed have been carried out, showing the good performance of our design.

6.2. Evaluation and optimal dimensioning of real-time systems

6.2.1. Code analyses and advanced visualization of software in real-time

Participants: Damien Bodenes, Pierre Caserta, Olivier Zendra.

Last years, strong developments for our instrumentation, tracer and analyzer, had been performed, allowing us to really enter the experimental phase and getting first interesting results. A thorough state of the art had also been written. This year, in 2011, this state of the art paper was finally published in TVCG, a leading journal in computer visualization [10]. Thanks to the experimental setup efforts of previous years, we were in 2011 able to conduct good experiments. We designed and implemented a new way to visualize relations between software elements. These relations include static relations (is-a, direct heir, caller, callee, etc.) and dynamic ones (runtime caller, runtime callee). Our new relation visualization comprises a new way of placing way points so as to significantly decrease spatial and visual clutter when visualizing software systems with large numbers (thousands up to millions) of relations. This lead to a publication in VISSOFT, one of the most recognized conferences in the software visualization domain [23], as well as a Best Poster in ECOOP, one of the most recognized conferences in the object-oriented domain [46]. The important design and implementation work realized on the tracing and analysis software also lead to the publication of our method in ICOOOLPS 2011 [24].

Work is going onto analyze polymorphism in Java programs, answering an apparently simple yet so far unanswered question: how much polymorphism is there actually in Java programs. This is of paramount importance, since a lot of work occur around polymorphism, which is an important concept, but no one is currently able to tell how much it impact programs in real life. We have begun writing this paper in cooperation with the LIRMM lab in Montpellier. In addition, we are in the process of finishing work pertaining to analyzing program evolutions, looking at differences between versions, and analyzing how dynamic metrics and static metrics correlate to evolution rate.

6.2.2. Open Power and Energy Optimization PLatform and Estimator

Participants: Sophie Alexandre, Jonathan Ponroy, Kévin Roussel, Olivier Zendra.

Work in this domain was performed in the context of the ANR Open-PEOPLE (Open Power and Energy Optimization PLatform and Estimator) project, financed since the very end of 2008. INRIA Nancy Grand Est is responsible for the software part of the platform and is involved in memory management for low-power issues. Work in this project begun in April 2009 (kick-off meeting). We have finished setting up the very important infrastructure for the software part of the Open-PEOPLE platform. We have finished expressing the requirements for the platform, in order to start the actual developments and the actual integration of tools provided by the different partners. In 2011, we have finished expressing the platform architecture and user interface (GUI). We have also finished implementing the part of the software platform that is the remote control to the hardware platform. We finally have finished implementing the core of the software platform and canonical models handling. Several technical reports were written in relation to this work [38], [39], [40], [42], [43], [44].
We are now in the process of finishing the design and implementation of the PCMD (Power Consumption Model Development) and the PCAO (Power Consumption Analysis and Optimization) parts of the software platform, as well as the external tools integration work. The very first release of the whole Open-PEOPE platform is expected early 2012. This lead to the several presentations and posters in conferences [51], [47], [52].

6.2.3. Robustness evaluation for a critical distributed system

Participants: Adrien Guénard, Lionel Havet, Françoise Simonot-Lion.

Wireless Sensor and Actuator Networks (WSANs) combine sensors and actuators interconnected by wireless networks in order to perform distributed sensing and acting tasks. Closed-loop controllers can therefore be deployed on WSANs; such systems have to meet specific requirements in terms of performance, dependability, energy and cost which raises great challenges due to the unreliability of wireless communications. A way to ensure that a system meets the required properties is to model it and go through its analysis. Building a model requires both deep knowledge on the system as well as on the used framework. Therefore there is a need for frameworks well-suited to the targeted systems and to the properties to verify. We proposed an approach meeting these conditions and a simulation framework, Samovar, based on Matlab / Simulink, allowing the modeling of the network protocols (Mac and routing services) and the resources sharing policy thanks to the TrueTime toolbox. Several classes of components (application, nodes, networks and middleware) and a clear semantics for their composition are identified. Furthermore, the design of Samovar was also driven by the need to transfer easily software components model between the concrete systems and its simulated model. The modeling and simulation method as well as the Samovar framework were assessed on several case studies. This work is supported by INRIA through the ADT SAMOVAR.

6.3. Real-time scheduling

6.3.1. Scheduling of tasks in automotive multicore ECUs

Participants: Aurélien Monot, Nicolas Navet, Françoise Simonot-Lion.

As the demand for computing power is quickly increasing in the automotive domain, car manufacturers and tier-one suppliers are gradually introducing multicore ECUs in their electronic architectures. Additionally, these multicore ECUs offer new features such as higher levels of parallelism which ease the respect of safety requirements such as the ISO 26262 and the implementation of other automotive use-cases. These new features involve also more complexity in the design, development and verification of the software applications. Hence, car manufacturers and suppliers will require new tools and methodologies for deployment and validation. We address the problem of sequencing numerous elementary software components, called runnables, on a limited set of identical cores. We show how this problem can be addressed as two sub-problems, partitioning the set of runnables and building the sequencing of the runnables on each core, which problems cannot be solved optimally due to their algorithmic complexity. We then present low complexity heuristics to partition and build sequencer tasks that execute the runnable set on each core, and derive lower bounds on their efficiency (i.e., competitive ratio). Finally, we address the scheduling problem globally, at the ECU level, by discussing how to extend this approach in the case where other OS tasks are scheduled on the same cores as the sequencer tasks. An article providing a summary of this line of work will appear in IEEE TII [14].

6.3.2. Fine-grained hardware modeling in response time analyses

Participants: Dawood Khan, Nicolas Navet.

Early in the design cycle, the two main approaches for verifying timing constraints and dimensioning the networks are worst-case schedulability analysis and simulation. In [29], we advocate that both provide complementary results and that, most often, none of them alone is sufficient. In particular, it is shown on automotive case-studies that response time distributions that can be derived from simulations cannot replace worst-case analysis. On the other hand, it is shown on examples that the analytical models, as used in worst-case analyses, are error-prone and often much simplified abstractions of the real system, which might lead to optimistic (i.e., unsafe) results.
As an illustration of the latter point, the classical WCRT analysis of Controller Area Network (CAN) implicitly assumes an infinite number of transmission buffers which is not the case in practice. This might lead high priority messages to suffer from priority inversion if the buffers are already occupied by low priority messages. This gives rise to an additional delay for high priority messages, which, if not considered, may result in a deadline violation. In an earlier work, we explained the cause of this additional delay and have extended the existing CAN schedulability analysis to integrate it. We have then studied the case where low-priority transmissions cannot be aborted because the communication controller or the driver does not allow it. We show on two case studies that the impact on response times is important and cannot be neglected in most real-time systems. This work was published in [26].

6.3.3. **Probabilistically analysable real-time system**

**Participants:** Liliana Cucu-Grosjean, Codé Lo, Luca Santinelli, Dorin Maxim.

The adoption of more complex hardware to respond to the increasing demand for computing power in next-generation systems exacerbates some of the limitations of static timing analysis for the estimation of the worst-case execution time (WCET) estimation. In particular, the effort of acquiring (1) detail information on the hardware to develop an accurate model of its execution latency as well as (2) knowledge of the timing behaviour of the program in the presence of varying hardware conditions, such as those dependent on the history of previously executed instructions. These problems are also known as the timing analysis walls. The probabilistic timing analysis, a novel approach to the analysis of the timing behaviour of next-generation real-time embedded systems, provides answers to timing analysis walls. In [11] we have showed how the probabilistic timing analysis attacks the timing analysis walls. We have also presented experimental evidence that shows how probabilistic timing analysis reduces the extent of knowledge about the execution platform required to produce probabilistically-safe and tight WCET estimations.

6.3.4. **Optimal scheduling policies for real-time systems with probabilistic execution times**

**Participants:** Liliana Cucu-Grosjean, Luca Santinelli, Dorin Maxim, Olivier Buffet, Rob Davis [University of York].

We have investigated the problem of optimal priority assignment in fixed priority preemptive single processor systems where tasks have probabilistic execution times. We have identified three sub-problems which optimise different metrics related to the probability of deadline failures. For each sub-problem we have proposed an algorithm that is proved optimal. The first two algorithms are inspired by Audsley’s algorithm which is a greedy (lowest priority first) approach that is optimal in the case of tasks with deterministic execution times. Since we prove that such a greedy approach is not optimal for the third sub-problem, we have proposed a tree search algorithm in this case. These results were published in [27].

6.3.5. **Statistical analysis of real-time systems**

**Participants:** Liliana Cucu-Grosjean, Lu Yue, Thomas Nolte [Malardelan University], Ian Bate [University of York].

The response time analysis of real-time systems usually needs the knowledge of WCET estimation and this knowledge is not always available, e.g., because of intellectual property issues. This problem may be avoided by estimating statistically either the WCET of a task [18] or the response time of each task [37].

6.3.6. **Multiprocessor scheduling of real-time systems with probabilistic execution times**

**Participants:** Liliana Cucu-Grosjean, Joel Goossens [Université Libre de Bruxelles].

After providing exact feasibility tests for the case of arbitrary tasks on unrelated processor in [12], we have proposed feasibility tests for tasks with probabilistic execution times [34]. These tests are based on intervals that are proved to contain the highest probability of having tasks with deadline missed.

6.3.7. **Probabilistic Component-based Approaches**

**Participants:** Luca Santinelli, Patrick Meumeu Yomsi, Dorin Maxim, Liliana Cucu-Grosjean.
We have proposed a probabilistic component-based model which abstracts in the interfaces both the functional and non-functional requirements of such systems. This approach allows designers to unify in the same framework probabilistic scheduling techniques and compositional guarantees that go from soft to hard real-time. We have provided sufficient schedulability tests for task systems using such framework when the scheduler is either preemptive fixed-priority or earliest deadline first. These results were published in [35].

6.3.8. **Mixed-criticality problems for probabilistic real-time systems**

**Participants:** Bader Alahmad, Luca Santinelli, Liliana Cucu-Grosjean, Sathish Gopalakrishnan [University of British Columbia].

Critical embedded systems (CESs) face the need of new functionalities imposed by the end users. These new functionalities of CESs impose the utilization of complex architectures. The complex architectures increase the time variability of programs and this coupled with worst-case reasoning implies over-provisioned systems. Avoiding such over-provision became an important problem within CESs. One model answering such problem in the mixed-criticality problem. It is natural then to combine mixed-criticality with probabilistic approaches known to decrease the over-provision by taking into account the information that worst-case situations have low probability of occurrence. We have proposed and contrasted in [19] two probabilistic execution-behavior models for mixed-criticality independent job systems as they execute on a single machine. The models differ in both the system assumptions and the amount of job information they offer and exploit. While one model is compliant with the current standard practice of fixing jobs’ criticalities, the other is a proposal to treat job criticalities as random entities with predetermined probabilities of jobs being of certain criticalities throughout the lifetime of the system.

6.3.9. **Energy optimization for real-time systems**

**Participants:** Cristian Maxim, Liliana Cucu-Grosjean, Olivier Zendra.

Many embedded real-time systems integrate battery operated microprocessor systems with limited battery autonomy. Minimizing energy consumption is thus crucial. We have proposed in [28] an algorithm that improves energy consumption in real-time systems by combining Dynamic Voltage Scaling and a decrease in the number of preemptions. Our overall purpose is to focus on a specific part of the problem, namely selectively increasing frequency to lower the number of preemptions of a task to try and decrease the total energy consumption.

6.4. **National Initiatives**

6.4.1. **ANR Project “QUAlity of ServIce for wireless sensor networks and Mobile Objects – parameter aDaptatiOn (QUASIMODO)”**

**Participants:** Bilel Nefzi, François Despaux, Abdelkader Lahmadi, Adrien Guenard, Françoise Simonot-Lion, Ye-Qiong Song.

Quasimodo project (http://quasimodo.loria.fr/) is a joint “ANR Programme blanc international” project (March 2011 - February 2014) between LORIA laboratory- Nancy University and SKLICT - Zhejiang University, funded by ANR (n°ANR 2010 INTB 0206 01) and NSFC (n°NSFC 61061130563). The objective of the project is to provide an adaptive real-time quality of service (QoS) in wireless sensor and actuator networks (WSAN). The main QoS parameters are bounded delay and packet transmission success rate under stringent energy constraint and node mobility. The typical application scenario consists of a multi-robots tracking, coordination and cooperation through the WSAN. This first project year has been focused on the application scenario development, MAC layer design. A first scenario is the single mobile target tracking using mobile sensor nodes. Theoretic tracking algorithm has been developed based on Kalman filter estimation (an ellipse) and optimal sensor coverage. Its extension to including both communication delay and mobile node speed are under simulation using SAMOVAR simulator (http://samovar.loria.fr/). The MAC protocol will be based on the CoSenS framework with one enhancement for avoiding collisions during the waiting period of CoSenS.
6.4.2. PRST MISN / SSS Theme: Eco-Sûr2

Participants: Hugo Cruz Sanchez, Jamila Ben Sliman, Najet Boughanmi, Bilel Nefzi, Françoise Simonot-Lion, Ye-Qiong Song.

EcoSur2 aims at controlling and managing the energy production and consumption within a smart space. An important part of the system is the wireless sensor and actuator network (WSAN) which is used to sense devices and to activate actuators. The activities of TRIO team are focused on the design of wireless sensor network architectures that guarantee communication by optimizing the available resources of the WSAN, and the development of the interoperability solution aimed at linking the heterogeneous technologies used in the system. This activities include: 1) Implementation of a modified version of the Collection Tree Protocol (CTP) by using energy resources for routing decisions; 2) Implementation of asynchronous and periodical sensing applications on nodes; 3) The analysis of different platforms allowing to communicate with the available WSN equipment of previous projects and to facilitate the implementation of optimal communication mechanisms over different routing protocols (eg. Zigbee, RPL); 4) The implementation of the WSN system in the MPIGate to allow interoperability with other technologies (eg. building automation networks, WiFi, Ethernet); 5) The design of an energy oriented messaging system in a WSN; 6) The adaptation and the development of the QoS co-design approaches based on our previous results in networked control system co-design. This year we have focused on the network architecture design and the technical implementation. Contiki based sensor nodes have been chosen. Part of code of S-CoSenS protocol has been developed in Cooja simulator before the actual deployment on the sensor nodes.

6.4.3. PRST MISN / Thème IS: Smartroom for personal assisted living

Participants: Hugo Cruz Sanchez, Adrien Guenard, Lionel Havet, Bilel Nefzi, Shahram Nourizadeh, Ye-Qiong Song.

The aim of the smartroom project is to provide an open platform for developing and testing innovative solutions for personal assisted living. The main task of TRIO team is the definition of the communication architecture with interoperability and QoS support. MPIGate is the starting point for this project. The first phase is focused on the platform implementation. MPIGate has been extended to run on Web service platform [25, 45]. Further development will be around the auto-adaptive application-network middleware and the design of extra low-power and low duty-cycle protocols.

6.4.4. INRIA AEN PAL (Personal Assisted Living)

Participants: Hugo Cruz Sanchez, Shahram Nourizadeh, Ye-Qiong Song.

TRIO team has participated to the Large-scale initiative action AEN PAL project (http://pal.inria.fr/) which aims to provide technologies and services for improving the autonomy and quality of life for elderly and fragile persons. Communication is one of the key components for ensuring real-time data gathering and exchange between heterogeneous sensors and actuators (robots). TRIO team’s participation aims to design the most suitable communication architectures with guaranteed QoS. For this purpose the interface part of MPIGate has been revised in order to shift from a web server based gateway to a web service oriented architecture [36]. This part of work will mainly be supported via the upcoming ADT APL-PERCEE project which will start at the end of 2011.

6.5. European Initiatives

6.5.1. NOE High Performance Embedded Architectures and Compilation (HiPEAC)

Participant: Olivier Zendra.

The TRIO team is involved in the HiPEAC (High Performance Embedded Architecture and Compilation) European Network of Excellence (NoE). Olivier Zendra was initiator and leader in this context of a cluster of European Researchers “Architecture-aware compiler solutions for energy issues in embedded systems” from mid-2007 to mid-2009. A STREP proposal tentatively titled “Integrated and generic energy-aware adaptation for extreme computing systems” is currently being written, mostly in the context of this network of excellence, for submission in Call ICT 2011.9.8 FET Proactive: Minimising Energy Consumption of Computing to the Limit (MINECC).
6.5.2. PROARTIS - Probabilistically Analysable Real-Time Systems

Participants: Liliana Cucu-Grosjean, Luca Santinelli, Codé Lo, Dorin Maxim.

PROARTIS (http://www.proartis-project.eu/) is a STREP project within the FP7 call and it started on February 2010. It has six partners: Barcelona Supercomputing, University of York, University of Padova, INRIA and Airbus. The overarching objective of the PROARTIS project is to facilitate a probabilistic approach to timing analysis. The proposed approach will concentrate on proving that pathological timing cases can only arise with negligible probability, instead of struggling to eradicate them, which is arguably not possible and could severely degrade performance. This will be a major turn from previous approaches that seek analyzability by trying to predict with cycle accuracy the state of hardware and software through analysis.

The PROARTIS project will facilitate the production of analysable CRTE systems on advanced hardware platforms with features such as memory hierarchies and multi core processors. PROARTIS has the following overall strategic industrial goals:

- Increased performance, reliability and reduced costs by enabling critical real-time systems to take full advantage of advanced hardware like deep memory hierarchies and multi core processors. The use of these features will allow designers to schedule more tasks while reducing the weight, power consumption and the size of the whole system and maintaining the desired predictability. It will also reduce the risk of temporal budget overruns. Application-level tasks will have an execution behaviour free (with sufficient low probability) from pathological temporal overruns.
- Increased productivity by enabling software engineers to develop more complex real-time software systems through timing-aware systems that reveal crucial timing details while dramatically simplifying analysis. For example, memory latencies will be predicted with less effort, requiring knowledge only of the total number of memory accesses, rather than the exact memory addresses and memory access patterns.
- Reduced time-to-market by enabling trustworthy WCET and other analyses for large-scale real-time systems that will dramatically reduce testing time.

The work within this project during 2011 lead to the following two publications: [11] and [35].

6.5.3. TIMMO-2-USE - Timing Model - TOols, algorithms, languages, methodology, USE cases

Participants: Nicolas Navet, Françoise Simonot-Lion, Liliana Cucu-Grosjean, Ammar Oulamara, Luca Santinelli.

TIMMO-2-USE (http://timmo-2-use.org/) is an ITEA 2 European project and it started in November 2010. TIMMO-2-USE will address the specification, transition and exchange of different types of timing information throughout different steps of the development process. The general goal is to evaluate and enhance standards for different applications in the development by different technical use cases covering multiple abstraction levels and tools. For this, TIMMO-2-USE will bring the AUTOSAR standard, TADL and EAST-ADL2 into different applications like WCET analysis and in-the-loop scenarios. This will bring new algorithms and tools for the transition and conversion of timing information between different tools and abstraction level based on a new advanced methodology which, in turn, will be based on a combination of the TIMMO and the ATESST2 methodologies. The main impact of TIMMO-2-USE will be:

- Improved, predictable development cycle: An extended and further developed infrastructure for handling timing constraints, containing additional features, will increase the predictability and effectiveness of the development cycle even more. As a result, both development cost and development time are expected to go down due to fewer costly design iterations, while at the same time the resulting design will moreover be more reliable.
- Reduced time-to-market by massive reuse: Reusing components annotated with timing information for the construction of a new system will enable the derivation of more accurate system timing
behaviour at early development stages. Therefore the system can be developed with a reduced number of design iterations.

- More efficient communication and collaboration between different parties involved in development: This will support cooperative development scenarios and reduce the risk of mutual misunderstanding between different parties contributing to the design of the same system, for example OEMs and Tier-1 suppliers, and lead to safer and more accurate systems.

- Reduced development risk: A formal and unambiguous foundation for reasoning about time provides a steady basis and a common ground for better cooperation between tools with respect to timing information based on commonly agreed, industry-wide standards like AUTOSAR. The project will further develop methodologies and languages developed in ATESTT2 and TIMMO. TADL (Timing Augmented Description Language) and EAST-ADL2 were introduced as a major leap forward and will be further adapted and extended in TIMMO-2-USE.
6. New Results

6.1. Model Driven and Aspect Oriented Design

6.1.1. Requirements Engineering

Participants: Olivier Barais, Benoit Baudry, Benoit Combemale, Maha Driss, Jean-Marc Jézéquel, Emmanuelle Rouillé, Nicolas Sannier, Didier Vojisek.

Model-driven engineering can have a huge impact on the early design and analysis of complex systems. We have investigated modeling for requirements engineering in three areas:

- We use executable metamodeling techniques developed in the team to capture formal relationships between regulatory requirements and accepted practices in systems engineering [47], [42].
- We propose an approach for facilitating Web service selection according to user requirements. These requirements specify the needed functionality and expected QoS, as well as the composability between each pair of services. The originality of our approach is embodied in the use of Formal Concept Analysis (FCA) and its extension Relational Concept Analysis (RCA) [33] [25].
- We have analyzed a real industrial software process to illustrate the need for bridging the gap between software processes and software development tools to automate the development tools configuration, deployment, integration and adaptation [46].

6.1.2. Dynamically adaptive interactive systems

Participants: Arnaud Blouin, Jean-Marc Jézéquel, Grégory Nain.

Combining Aspect-Oriented Modeling with Property-Based Reasoning to Improve User Interface Adaptation: in this work we combined aspect-oriented modeling with an interactive system architecture to support dynamic adaptation of interactions and user interfaces [28].

6.1.3. Dynamically adaptive component-based systems

Participants: François Fouquet, Olivier Barais, Viet-Hoa Nguyen, Noël Plouzeau.

Continuous Design to Achieve Intelligent Reflection in Distributed Systems: we defined an intelligent reflection model to support fast adaptation of distributed systems by architecture modification without stopping the system. This adaptation mechanism is well suited to rapidly changing needs (continuous design of eternal systems) or fast paced modifications of the context of the running system (for instance for Internet of Things distributed systems) [34].

6.1.4. Architecture for Services-based applications

Participants: Olivier Barais, Johann Bourcier, Erwan Daubert, Jean-Marc Jézéquel.

The architecture of service-based applications can have a huge impact on their dynamic adaptability. We have investigated various framework for architecting service-based applications:

- Designing SAFDIS: a self adaptive framework for distributed applications based on services. SAFDIS includes facilities to support the coordination of distributed reconfigurations [24]. SAFDIS also takes benefit of the Infrastructure As A Service to dynamically reconfigure Software As A Service [44].
- Analyzing and improving consistency between functional and business view of telecom services architecture. This work is based on the definition of a strategic alignment of the target functional view with the target business view. Alignment is validated with a real case study implemented and deployed at Orange–France Telecom on their messaging service [22].
• Designing AutoHome: a service oriented framework to simplify the development and runtime adaptive support of autonomic pervasive applications. This includes the amalgamation of the two computing areas of Autonomics and Service Orientation, to produce a Component-based platform providing facilities. This infrastructure uniquely blends the advantages of distributed autonomic control with global conflict management in a management hierarchy [17].

6.2. Model V&V and Testing

6.2.1. Formal MDE Foundations

Participants: Benoit Baudry, Benoit Combemale.

• Formally Tracing Executions From an Analysis Tool Back to a Domain Specific Modeling Language’s Operational Semantics: in this work, we propose a formal and operational framework for tracing results back (e.g., a program crash log, or a counterexample returned by a model checker) from execution and verification tools to an original DSML’s syntax and operational semantics [31].
• A Proof Assistant Based Formalization of components in MDE: using the Coq proof assistant we propose a formalization of some operators for model fragment extraction and composition, as defined in the ReuseWare toolset [39].
• We have developed a methodology to explicitly model the context in which a temporal property must be verified. This contextual information is expressed in the requirements, and an explicit model allows to reduce the complexity of automated verification [41].

6.2.2. Pairwise testing for highly variable systems

Participants: Benoit Baudry, Aymeric Hervieu.

Variability management is a major concern for the development of software intensive systems. In particular, the explosion of variants is an issue for testing and analysis. Feature models allow to explicitly capture the variability in a formal model and get a complete view on all possible variants of the system. We have investigated pair-wise generation from feature models in order to test software product lines [36], and to evaluate QoS contracts in variable web service compositions [38].

6.2.3. Testing aspect-oriented programs

Participant: Benoit Baudry.

Aspect-oriented mechanisms introduce new risks for reliability that must be tackled by specific testing techniques in order to fully benefit from the use of this paradigm. We have investigated a monitoring mechanism of advices in an aspect-oriented program and use this information to build test cases that target faults in pointcut descriptors [18].

6.2.4. Modeling model quality metrics

Participants: Benoit Baudry, Jean-Marc Jézéquel.

We have developed a model-driven measurement approach to measure models of a domain specific modeling language. The approach uses models as unique and consistent metric specifications for the automated generation of a metric tool. The benefit from applying the approach is evaluated by four case studies [20]. In particular, we have evaluated the ability of the approach to build a tool for the measurement of requirements documents [21].
6.3. Meta-Modeling

6.3.1. Model Driven Language Engineering

Participants: Benoit Baudry, Arnaud Blouin, Juan-Jose Cadavid Gomez, Benoit Combemale, Clément Guy, Jean-Marc Jézéquel, Didier Vojtisek.

- Model-Driven Engineering and Optimizing Compilers: A bridge too far? In this work, we report and analyze an experience about the use of MDE technologies to build and evolve compiler infrastructures in the optimizing compiler domain. From this study, we highlight challenges and propose a roadmap for the cross-fertilization of the MDE and compiler domains [35], [45].
- Modeling Model Slicers: model slicing is a model operation that consists in extracting a subset of a model. Because the creation of a new DSL implies the creation from scratch of a new model slicer, we proposed the Kompren language that models and generates model slicers for any DSL [27].
- Empirical Evaluation of the Conjunct Use of MOF and OCL: we evaluate in this work the conjunct usage of MOF (Meta-Object Facility) and OCL (Object Constraint Language) in the development of Domain-Specific Modeling Languages. We observe the state of practice to understand how experts use them and find patterns on its usage, in order to provide techniques to improve the experience [29].

6.3.2. Model Transformation and Composition

Participants: Olivier Barais, Benoit Baudry, Arnaud Blouin, Mickaël Clavreul, Benoit Combemale, Xavier Dolques, Jean-Marc Jézéquel.

- Model operations such as transformation and composition declare source metamodels that are usually larger than the set of concepts and relations actually used by the operation. We have proposed and validated a static operation analyzer to retrieve the metamodel footprint of the operation [37].
- Service-Oriented Architecture Modeling: Bridging the Gap between Structure and Behavior: In this approach, we propose to detect divergences among structural and behavioral models to support a semi-automatic process of synchronization between class diagrams and workflow models [30].
- The paper propose a technique for discovering matchings between two model elements modeling the same system, but being instances of different metamodels. This is achieved by using property names and models structure thanks to the adaptation of a schema matching technique named Anchor-PROMPT [32].
- Specifying and implementing UI Data Bindings with Active Operations: based on the concept of active operations, this work proposes a framework to bind models at runtime and more precisely to bind data and their possible representations [26].
- We propose a requirement-centric approach for Web service composition which allows: (i) modeling users’ requirements with the MAP formalism and specifying required services using an Intentional Service Model (ISM); (ii) discovering and selecting relevant Web services and high QoS services; and (iv) generating automatically BPEL coordination processes by applying the model transformation technique [19].
6. New Results

6.1. Automatic Differentiation and parallel codes

Participants: Valérie Pascual, Laurent Hascoët, Hubert Alcin, Jean Utke [Argonne National Lab. (Illinois, USA)], Uwe Naumann [RWTH Aachen University (Germany)].

This research is an ongoing joint work between three teams working on AD. We study differentiation in reverse mode of programs that contain MPI communication calls. Instead of the commonly used approach that encapsulates the MPI calls into black-box subroutines that will be differentiated by hand, we are looking for a native differentiation of the MPI calls by the AD tool. The ultimate goal of this work is to generate the adjoint of MPI-parallel codes.

One issue is to reduce the variability of the available MPI procedures and parameters to a smaller number of elementary concepts. We then address the basic question of sends and receives, that may be blocking or nonblocking, individual or collective, and so on. Essentially the adjoint of a send is a recv, and vice-versa, but the possibility of nonblocking isend’s and irecv’s requires more subtlety. We continue adaptation of the tool’s static analysis to programs with message-passing communication. In the framework of flow-sensitive and context-sensitive data-flow analysis, we introduce new "channel" variables and modify the general static data propagation mechanism.

Implementation in TAPENADE is well advanced: the main MPI procedures are now correctly understood and all data-flow analyses are adapted. In 2011, we obtained a first valid tangent differentiated code of the team’s CFD code AIRONUM. Work is continuing to obtain the adjoint.

Our team focuses on AD based on program transformation. On the other hand, we closely follow the developments of operator-overloading AD tools towards message-passing communication. This requires a more complex definition of the overloaded communication primitives [33].

6.2. AD adjoints and Dynamic Memory

Participants: Laurent Hascoët, Jean Utke [Argonne National Lab. (Illinois, USA)].

Again in the adjoint mode, dynamic memory allocation and the associated pointer manipulations pose difficult problems. As the adjoint mode is bound to recover past values of variables, the need arises to recover past values of pointers too. However, these values are addresses often relative to some dynamically allocated memory. The original program often manages memory by allocating and deallocating memory on the run. Correspondingly, the adjoint program will have to reallocate memory as it walks backwards along the original allocation. If recovery of past values is implemented through storage, e.g. on a stack, the stored addresses refer to memory that has been deallocated, and do not correspond to the reallocated memory zones.

In 2011 we investigated this problem in two principal directions:

- We may consider not storing the address, but rather recompute it by repeating in the reverse sweep its calculation from the forward sweep. This is not always possible as pointer assignment and manipulation may be complex and distributed in the code. However, when possible, it is certainly a very efficient approach. We propose an data-flow algorithm to detect applicable cases.
- For the remaining cases where storage must be used, we study an address mapping mechanism, such that addresses inside some allocated memory can be dynamically converted into addresses inside the corresponding reallocated memory.
6.3. Resolution of linearised systems

**Participants:** Hubert Alcin, Olivier Allain [Lemma], Anca Belme, Marianna Braza [IMF-Toulouse], Alexandre Carabias, Alain Dervieux, Bruno Koobus [Université Montpellier 2], Carine Moussaed [Université Montpellier 2], Hilde Ouvrard [IMF-Toulouse], Stephen Wornom [Lemma].

The interaction between the sophisticated solution algorithm inside a program and the Automatic Differentiation of the program is a non-trivial issue. An iterative algorithm generally does not store the successive updates of the iterated solution vector. Furthermore, a modern iterative solution algorithm involves several nonlinear processes, like in:

- the evaluation of an optimal step, which results at least from a homographic function of the unknown,
- the orthonormalisation of the updates (Gram-Schmidt method, Hessenberg method).

Applying reverse AD to the iterative solution algorithm produces a linearised iterative algorithm which is transposed and therefore follows a reverse order, with exactly the same number of iterations, and needing exactly each of the iterated state solution vectors. This effect is considerably amplified in the case of the numerical simulation of unsteady phenomena with implicit numerical schemes. For example, the simulation of high Reynolds turbulent flows by a Large Eddy Simulation (LES) requires hundreds of thousands time steps, each of them involving a modern iterative solution algorithm.

In the 4-year ECINADS ANR project, we design more efficient solution algorithms and we examine the questions risen by their reverse differentiation. The application domain is the computation of high Reynolds turbulent flows with LES and hybrid RANS-LES models. The efficiency will be evaluated through the practical scalability on a large number of processors. This efficiency criterion also extends to the scalability of the reverse/adjoint algorithm. ECINADS also addresses the scalable solution of new approximations. ECINADS associates the university of Montpellier 2, the Institut de Mécanique des fluides de Toulouse and Lemma company. The kick off meeting of ECINADS was held at end of 2009.

In 2011, Hubert Alcin has performed a study of deflation and balancing coarse grid methods for a set of scalar models. The methods has been extended to the incompressible Navier-Stokes model in Lemma’s software ANANAS by Olivier Allain and to compressible Navier-Stokes by Bruno Koobus and Hubert Alcin. A collection of benchmark tests on these models has been performed and show a good scalability for the tested algorithms. An article is prepared on these results. Hubert Alcin has also studied a novel method for three-level preconditioning. The new method will be extended to compressible flows in cooperation with the Montpellier team (Carine Moussaed and Bruno Koobus).

6.4. Perturbation Methods

**Participants:** Alain Dervieux, Laurent Hascoët.

In the context of the European project NODESIM-CFD, the contribution of Tropics involved mainly the differentiation of perturbation methods and reduced order models for the management of uncertainties. These methods rely on Taylor series with second-order terms. The production of second derivative code is obtained through repeated application of Automatic Differentiation. Three strategies can be applied to obtain (elements of) the Hessian matrix, named Tangent-on-Tangent (ToT), Tangent-on-Reverse (ToR), and Reverse-on-Tangent (RoT). These new methods are disseminated through short courses, as those given by Alain Dervieux at ERCOFTAC sessions (Munich and Hampton). The application and extension of these methods have motivated a joint application from the Italian Aircraft company Alenia and Tropics in a FP7 proposal (Proposal CARDINA, nov. 2011).

6.5. Control of approximation errors

**Participants:** Frédéric Alauzet [GAMMA team, INRIA-Rocquencourt], Estelle Mbinky [GAMMA team, INRIA-Rocquencourt], Olivier Allain [Lemma], Anca Belme, Alexandre Carabias, Hubert Alcin, Alain Dervieux.
This is a joint research between three INRIA teams GAMMA (Rocquencourt), TROPICS, PUMAS and Lemma company. Roughly speaking, GAMMA brings mesh and approximation expertise, TROPICS contributes to adjoint methods, and CFD applications are developed in the context of PUMAS and Lemma.

The resolution of the optimum problem using the innovative approach of an AD-generated adjoint can be used in a slightly different context than the optimal shape design, namely the mesh adaptation. This will be possible if we can map the mesh adaptation problem into a differentiable optimal control problem. To this end, we have introduced a new methodology that consists in stating the mesh adaptation problem in a purely functional form: the mesh is reduced to a continuous property of the computational domain: the continuous metric. We minimize a continuous model of the error resulting from that metric. Thus the problem of searching an adapted mesh is transformed into the search of an optimal metric.

In 2011, a work on goal-oriented mesh adaptation for unsteady Euler flows has been extended, with further analysis, and a paper has been written and submitted to a journal. Its extension to the compressible Navier-Stokes model has been developed, [11] and a paper is being written. A further extension to Large Eddy Simulation is started. The method is being extended to a third-order approximation, the Vertex-CENO. This approximation was defined during a collaboration between university of Montpellier, IMM-Moscow and Tropics. A more accurate version has been studied by Alexandre Carabias and presented in Honom-Trento. A new theory involving error estimates and criteria has been developed by Gamma and Tropics. The extension of the multiscale adaptation method is considered by Estelle Mbinky at Rocquencourt. The extension of the goal-oriented method is considered by Alexandre Carabias at Sophia. Anisotropic mesh adaptation allows for better convergence to continuous solutions, and in particular more accurate a posteriori error estimates and correctors. The synergy between correctors and mesh adaptation is currently analysed and is the subject of a joint contribution (Gamma and Tropics) for the FP7 CARDINA proposal (nov. 2011).
6. New Results

6.1. Semantics of the Calculus of Inductive Constructions

**Participant:** Bruno Barras [Contact].

Bruno Barras has formalized the meta-theoretical study of strictly positive inductive types. This was built upon the previous work on specific instances: natural numbers and Brouwer ordinals. The main idea of the model construction is to use the property that every strictly positive inductive definition can be encoded in the parameterized type of trees (the so-called W-types). Such tree-types can themselves be encoded as partial functions from paths to labels. The soundness of this translation gives a way to build the closure ordinal of any strictly positive inductive definition.

Bruno Barras has then modelled the inductive families (also called inductive types with indices). He has been able to prove formally the previously known result that inductive family can be constructed in two steps: first build a carrier type (inductively) which is oblivious of the indices, and then define each member of the family as a subset of the carrier type by enforcing the constraints generated by the indices.

He also started to investigate advanced features of inductive definitions, like the possibility to have non-uniform parameters. When this feature was introduced in Coq, it was thought as a conservative one, but the formal analysis showed that this was not obvious. The consistency model could be extended (with one auxiliary result not yet encoded formally). This shows that non-uniform parameters do not extend much the expressivity of Coq, but the strict equivalence remained as an open problem.

6.2. Relative Strengths of set theory and type theory

**Participants:** Bruno Barras [Contact], Benjamin Werner.

Bruno Barras also formalized common translations in proof theory: negated translations and Friedman’s A-translation. This was used to build a model of (classical) ZF set theory in Coq extended with one axiom called TTDA (Type-Theoretical Description Axiom). This was done in two steps: first build a model of IZF_C (ZF with the collection axiom but not the excluded-middle) in Coq extended with TTDA, and then encode ZF in IZF_C, as shown by Friedman.

The converse result: an interpretation of Coq +TTDA in ZF (with one inaccessible cardinal!) seems not possible, as TTDA in a classical setting gives a (weaker) form of the axiom of choice. Bruno Barras as devised a new axiom (called the Type-Theoretical Collection Axiom) that still allow the ZF interpretation above, but he hopes that its consistency can be proved in ZF extended with one inaccessible cardinal.

Benjamin Werner has worked with Gyesik Lee on set-theoretical models of Coq’s type theory. This work is described in a paper published in the LMCS journal [18].

6.3. A Consistency model of Coq extended with decision procedures

**Participants:** Bruno Barras [Contact], Qian Wang.

Bruno Barras and Qian Wang are working on the construction of a model for the Calculus of Constructions extended with the type of natural numbers. The definitional equality has been extended to include all equations derivable in Presburger arithmetic. Compared to previous work, this model can support strong eliminations. Since strong eliminations and extensions of the definitional equality with non-satisfiable equations (for instance $0 = 1$) leads to non-normalizing terms, it was necessary to give a precise account of Presburger arithmetic, seen as a specific instance of first-order logic. This work is described in a paper published in the proceedings of the LICS conference [21].
6.4. Towards a concurrent architecture for the Coq kernel

**Participants:** Bruno Barras [Contact], Enrico Tassi.

In the context of the Paral-ITP ANR project, Bruno Barras and Enrico Tassi have started to implement a kernel of Coq where the process of constructing and checking the proof of a lemma can be executed in a parallel thread.

6.5. Physics of computation

**Participant:** Gilles Dowek.

Together with Pablo Arrighi, Gilles Dowek has extended Gandy’s theorem to quantum physics, by giving a new definition of the notion of finite density of information in this setting. This work has been presented at the congress QIPC [13].

6.6. Binders

**Participant:** Gilles Dowek.

Together with Jamie Gabbay, Gilles Dowek has given a translation of permissive nominal logic to Higher-order logic and proved its soundness and completeness. This work is described in a paper published in the Transactions on Computational Logic [15].

6.7. Interfacing Coq with SMT solvers

**Participants:** Germain Faure, Chantal Keller [Contact], Assia Mahboubi, Benjamin Werner.

This is work in close collaboration with the Marelle team (INRIA Sophia Antipolis). The starting point of this work is to note that SMT solvers, deciding the Satisfiability Modulo Theories, are in constant evolution to take into account new decision procedures as well as theories. These systems are rather complex and it is now clearly established that they all contain bugs. The standard approach is to ask the SMT solver to append to the decision result a certificate that can be checked by another tool.

In this context, we are using Coq to check the certificate. The approach is based on computational reflection. The checker is written in Coq, and its architecture is modular and extensible.

We are now able to check certificates coming from the ZChaff SAT solver and from the veriT SMT solver developed at INRIA Nancy – Grand - Est. Proofs established by the SMT tool for the theories of congruence closure and linear arithmetic are checked in short time, overtaking the state of the art in terms of time performance. We also use certificates to build a new Coq tactic that can safely call an external SMT solver, thus increasing Coq’s automation. This tactic is new since it is a decision procedure that combines both linear integer arithmetic and equality of uninterpreted functions. This work is described in a paper published in the proceedings of the CPP2011 conference [25].

6.8. SMT techniques for optimization problems

**Participant:** Germain Faure [Contact].

The TypiCal team has collaborated with the sysmo team at the Laboratoire d’Informatique de l’École Polytechnique in order to integrate the use of automated tools like SMT solvers in the resolution of optimization problems. The case study was a problem of large scale energy management with various constraints, proposed at the ROADEF 2010 challenge won by the sysmo team. We investigated how to delegate to the SMT tool part of the resolution of constraints. A first conclusion of this experiment is that solving optimization problems represents a more important part of the computation time than first expected. As SMT solvers are not geared toward this class of problems, their performance were not satisfactory. This nonetheless opens new perspectives for the development of SMT tools in order to adapt their internal decision procedures to this new kind of benchmarks. We consider that significant progress in that direction could be easily obtained.
6.9. Formal correctness of embedded programs

Participants: Gilles Dowek [Contact], Pierre Néron.

Pierre Néron is working on program transformations that remove the operations which create most of the approximations during the computation on floating point numbers, namely square roots and divisions. This kind of formal tool aims at increasing the confidence in embedded programs. The idea of this transformation comes from the elimination of the quantifier on real closed fields, hence the first task is to define a minimal but useful language on which the transformation will apply and then to extend this transformation on formulas to this whole language. Keeping the size of the code produced by this transformation in an acceptable range was a challenging issue in this work. The next objective is to write a formal proof ensuring that the transformation is correct. This work will be done in collaboration with the NASA Langley research center in the Formal Method team: Pierre Néron will visit this center for one month in January 2012.

This work is described in a submitted paper [30].

6.10. Formal proofs for convex optimization problems

Participants: Benjamin Werner [Contact], Victor Magron.

Victor Magron is working on the integration of tools that can deal with inequalities on semi-symbolic expressions with real numbers inside proof assistants like Coq.

In particular, he is working on new means to provide formally established bounds for multivariate inequalities, using methods inspired from the convex optimization literature like sums of squares (SOS) and the related semi-definite programming (SDP) relaxation.

He has implemented in OCaml a new algorithm which detects and computes automatically the possible bounds of a given expression. He has tested the approach using benchmarks largely built from inequalities issued from the formal proof of Kepler conjecture (by Thomas Hales). The algorithm computes approximation of transcendental functions by solving sum of squares problems, delegated to an external, dedicated tool. The next step of this project is to certify the correctness of these computations using the Coq system.

He has also improved a Coq tactic based on the external computation of decompositions into sums of squares originally developed by Frédéric Besson (INRIA Rennes - Bretagne Atlantique). The improvement consists in linking this tactic with a tool developed by David Monniaux (Verimag).

6.11. Formal proof in real algebraic geometry

Participants: Assia Mahboubi [Contact], Cyril Cohen.

Cyril Cohen and Assia Mahboubi have completed the first formal proof of quantifier elimination for the theory of real closed fields. This work includes a significant part of infrastructure code for ordered algebraic theories, intervals, and polynomials. This work is described in a submitted paper [29].

Cyril Cohen has implemented in Coq a construction of real algebraic numbers and proved it had a structure of discrete Archimedian real closed field, in the sense of the previous proof of quantifier elimination. Beside the computational interest of real algebraic numbers, this construction both legitimates the abstraction chosen for the proof of quantifier elimination and provides a basis for complex algebraic numbers needed for the completion of the formal proof of the Feit-Thompson theorem. This work is described in a paper to appear in the proceedings of the JFLA2011 conference.

6.12. Constructive mathematics

Participant: Cyril Cohen [Contact].

In collaboration with Thierry Coquand, Cyril Cohen has come up with a constructive proof of a generalization of the fundamental theorem of Algebra. This work show how to formalize the algebraic closure of an arbitrary real closed field. In particular, it can serve as a basis for the construction of complex algebraic numbers from the real algebraic numbers. This work is described in a submitted paper [28].
6.13. Intersection types

Participants: Alexis Bernadet [Contact], Stéphane Lengrand [(CNRS, Lix)].

Alexis Bernadet and Stéphane Lengrand have studied a typing system for the $\lambda$-calculus with non-idempotent intersection types. As it is the case in (some) systems with idempotent intersections, a $\lambda$-term is typable if and only if it is strongly normalizing. Non-idempotency brings some further information into typing trees, such as a bound on the longest $\beta$-reduction sequence reducing a term to its normal form. These results are presented in Klop’s extension of $\lambda$-calculus, where the bound that is read in the typing tree of a term is refined into an exact measure of the longest reduction sequence. This complexity result is, for longest reduction sequences, the counterpart of de Carvalho’s result for linear head-reduction sequences. This work is described in a paper published in the proceedings of the FOSSACS 2011 conference [22].

Alexis Bernadet and Stéphane Lengrand have also revisited models of typed $\lambda$-calculus based on filters of intersection types. By using non-idempotent intersections, they simplify a methodology that produces modular proofs of strong normalization based on filter models. Non-idempotent intersections provide a decreasing measure proving a key termination property, simpler than the reducibility techniques used with idempotent intersections. Such filter models are shown to be captured by orthogonality techniques: we formalize an abstract notion of orthogonality model inspired by classical realizability, and express a filter model as one of its instances, along with two term-models (one of which captures a now common technique for strong normalization). Applying the above range of model constructions to Curry-style System F describes at different levels of detail how the infinite polymorphism of System F can systematically be reduced to the finite polymorphism of intersection types. This work is described in a paper published in the proceedings of the CSL 2011 conference [23].

Participants: Alexis Bernadet [Contact], Stéphane Lengrand [(CNRS, Lix)].

We introduce here an alternative definition of Hyland’s effective topos, based on a realizability framework with two levels of abstraction: a low level and a high level. With this definition, the proof that this framework forms a topos is almost as simple as proving that the category of sets is a topos. Moreover, the high level of the framework can be directly used as a model of higher-order intuitionistic systems. We can then craft a programming language based on topos theory, which can be given a constructive semantics. In such a programming language, we can only write functions that terminate, as in proof assistants like Coq, so the language cannot be Turing-complete. The main advantage of having a programming language based on topos theory over more usual intuitionistic systems such as Martin-Loef type theory is the notion of equality: it is extensional, has proof-irrelevance, and allows the axiom of unique choice.

This work has been presented at the Chocola-Ens Lyon seminar in December 2011.

6.15. A formal proof of the Feit-Thompson theorem

Participant: Assia Mahboubi [Contact].

Assia Mahboubi has pursued her work in the Mathematical Component team lead by Georges Gonthier at the Microsoft Inria Joint Centre. She has finished the formalization of the Wielandt fixpoint theorem, which is one of the key results at the interface between the two components (local analysis and character theory) of the published revised proof of the Feit-Thompson theorem. The proof of the Wielandt theorem was difficult to formalize because it requires a challenging combination of advanced theories with sophisticated constructive formalization: group representation, module theory, linear algebra and characters.

The documentation of this formalization, as well as the current state of the whole formal proof can be found on the webpage of the Mathematical Components project.

6.16. A formal library for polynomial arithmetics

Participant: Assia Mahboubi [Contact].
Assia Mahboubi has worked on a modular formal library devoted to the divisibility theory of polynomials. The aim of this library is to provide a solid basis for further formal developments involving algorithms on polynomials, in particular to cover the cases when the coefficients of the polynomials involved are equipped with a structure weaker than the structure of field required by the standard Euclidean algorithm.

The documentation of this formalization can be found on the webpage of the Mathematical Components project.

**6.17. Weak Memory Models**

**Participant:** Assia Mahboubi [Contact].

Assia Mahboubi has collaborated with Jade Alglave (Oxford University) and has programmed a complete formalization in Coq of the semantic proposed by Jade Alglave in a PhD for weak memory models. This work is described in [27].
6. New Results

6.1. Models and Verification Techniques

6.1.1. The BCG Format and Libraries
Participants: Hubert Garavel, Frédéric Lang, Wendelin Serwe.

BCG (Binary-Coded Graphs) is both a file format for the representation of explicit graphs and a collection of libraries and programs dealing with this format. Version 1.0 of the BCG format was recently replaced by version 1.1, which can exploit the capabilities of 64-bit addressing.

In 2011, we continued to enhance the BCG libraries as follows:

- We extended the BCG_READ application programming interface with three new primitives so as to increase symmetry with the OPEN/CÆSAR application programming interface (see § 6.1.2).
- We fixed a memory corruption problem occurring with very long label strings; this problem would cause random crashes of the DISTRIBUTOR tool (see § 6.1.5).

6.1.2. The OPEN/CÆSAR and CÆSAR_SOLVE Libraries
Participants: Iker Bellicot, Hubert Garavel, Yann Genevois, Frédéric Lang, Radu Mateescu, Wendelin Serwe.

OPEN/CÆSAR is an extensible, modular, language-independent software framework for exploring implicit graphs. This key component of CADP is used to build simulation, execution, verification, and test generation tools.

In 2011, a bug in the CÆSAR_TABLE library has been corrected, which would cause segmentation faults when certain primitives of the Application Programming Interface were invoked on a bounded table.

CÆSAR_SOLVE is a generic software library based on OPEN/CÆSAR for solving boolean equation systems of alternation depth 1 (i.e., without mutual recursion between minimal and maximal fixed point equations) on the fly. This library is at the core of several CADP verification tools, namely the equivalence checker BISIMULATOR, the minimization tool REDUCTOR, and the model checkers EVALUATOR 3.5 and 4.0. The resolution method is based on boolean graphs, which provide an intuitive representation of dependencies between boolean variables, and which are handled implicitly, in a way similar to the OPEN/CÆSAR interface [4].

In 2011, we improved the parallel resolution algorithm of CÆSAR_SOLVE (see § 6.1.5).

6.1.3. The EVALUATOR Tool
Participants: Iker Bellicot, Hubert Garavel, Yann Genevois, Radu Mateescu.

EVALUATOR is a model checker that evaluates a temporal logic property on a graph represented implicitly using the OPEN/CÆSAR environment. EVALUATOR works on the fly, meaning that only those parts of the implicit graph relevant to verification are explored. The model checking problem is reformulated in terms of solving a boolean equation system. A useful feature of EVALUATOR is the generation of diagnostics (examples and counterexamples) explaining why a formula is true or false.

In version 3.5 of EVALUATOR, properties are described in regular alternation-free μ-calculus, a logic built from boolean operators, possibility and necessity modalities containing regular expressions denoting transition sequences, and fixed point operators without mutual recursion between least and greatest fixed points. The input language of the tool also enables the user to define parameterized temporal operators and to group them into separate libraries.
In version 4.0 of EVALUATOR (5,000 lines of SYNTAX code, 40,500 lines of Lotos NT code, and 13,100 lines of C code), properties are written in MCL (Model Checking Language) [18], an extension of the regular alternation-free $\mu$-calculus of EVALUATOR 3.5 with data-handling and fairness operators. In particular, EVALUATOR 4.0 can handle modalities and fixed point operators with data parameters, regular expressions extended with counters, operators inspired from programming languages (“if-then-else”, “for”, etc.), and operators (of alternation depth two) allowing to characterize complex infinite sequences.

In 2011, we continued the extensive testing of EVALUATOR 3.5 and 4.0 using our test base of 10,000 BCG graphs and 3,800 MCL formulas. This revealed three errors in EVALUATOR 4.0, which have been corrected. We also brought the following enhancements to MCL and EVALUATOR 4.0:

- We extended the set of MCL operators of alternation depth two with parameterized versions of the infinite looping and saturation operators, which allow to succinctly encode the presence (respectively, the absence) of accepting cycles in generalized Büchi automata. The evaluation of these parameterized operators is translated into parameterized boolean equation systems, which are instantiated into plain boolean equation systems and solved on the fly using the algorithms A3 and A4 (extended with marked cycle detection) of the CÆSAR_SOLVE library. This evaluation procedure has a complexity linear in the size of the degeneralized Büchi automaton, which is represented by the boolean equation system obtained after instantiation.
- We enhanced MCL by adding a data type for manipulating sets of natural numbers. This data type, equipped with the classical set operations (union, intersection, difference, insertion, deletion, membership, etc.), enables a succinct specification of temporal properties referring to the past, such as the fact that a certain set of events (represented by natural numbers) occurred on the transition sequences leading from the initial state to the current state.
- We added a new option to EVALUATOR 4.0 for displaying a set of regular expressions that over-approximate the set of visible actions (transition labels in the LTS) satisfying the action predicates occurring in the MCL formula. This feature enables to improve the efficiency of verification by hiding the set of actions other than those produced from the MCL formula, minimizing the LTS modulo a weak equivalence relation compatible with the formula, and then verifying the MCL formula on the minimized LTS. This may increase the efficiency of verification by one order of magnitude, as reported in [40].

EVALUATOR 4.0 was officially integrated in CADP in March 2011. MCL and EVALUATOR 4.0 were used successfully for analyzing mutual exclusion protocols (see § 6.3.1) and hardware architectures (see § 6.3.2).

6.1.4. Compositional Verification Tools

Participants: Frédéric Lang, Radu Mateescu.

The CADP toolbox contains various tools dedicated to compositional verification, among which EXP.OPEN 2.1, PROJECTOR 3.0, BCG_MIN 2.0, and SVL 2.2 play a central role. EXP.OPEN explores on the fly the graph corresponding to a network of communicating automata (represented as a set of BCG files). PROJECTOR implements behavior abstraction [58], [64] by taking into account interface constraints. BCG_MIN minimizes behavior graphs modulo strong or branching bisimulation and their stochastic extensions. SVL (Script Verification Language) is both a high level language for expressing complex verification scenarios and a compiler dedicated to this language.

In 2011, we corrected one bug in PROJECTOR, two bugs in EXP.OPEN, and four bugs in SVL. We also enhanced these tools as follows:

- The generalized parallel composition operator proposed in [13], including the support for “$m$ among $n$” synchronization, has been added to SVL, leading to version 2.3 of SVL.
- Together with Pepijn Crouzen (Saarland University), we pursued our work on the so-called “smart reduction” techniques for compositional verification. An article about smart reduction was published in an international conference [32].
We improved smart reduction for stochastic branching bisimulation so as to cut stochastic transitions (according to the “maximal progress” assumption) as early as possible in intermediate parallel compositions, thus yielding state space reductions. With this new optimization, EXP.OPEN detects when some action (usually, an output) offered by some process can synchronize with corresponding actions (usually, inputs) offered by the other processes in all their states; if so, all stochastic transitions in choice with this action can safely be cut in every intermediate composition. This situation occurs frequently with Input/Output Interactive Markov Chains.

Additionally, we studied an alternative compositional verification approach named partial model checking. Given a temporal logic formula \( \varphi \) to be evaluated on a set \( S \) of concurrent processes, partial model checking consists in transforming \( \varphi \) into another equivalent formula \( \varphi' \) to be evaluated on a subset of \( S \). Formula \( \varphi' \) is constructed incrementally by choosing one process \( P \) in \( S \) and incorporating into \( \varphi \) the behavioral information corresponding to \( P \)— an operation called quotienting. Simplifications must be applied at each step, so as to maintain formulas at a tractable size.

We developed a prototype implementation of this approach using the generic software components of CADP:

- We extended the definition of quotienting given by 47 to support all features of the input language of EXP.OPEN 2.1, which enables networks of labeled transition systems to be described using parallel composition operators borrowed from various process algebras such as CCS, CSP, and LOTOS, including also LOTOS NT parallel composition and “m among n” synchronisation operators 13.
- We gave an executable definition of quotienting in terms of a synchronous product between a graph representation (called formula graph) of the formula \( \varphi \) and the process \( P \), thus enabling quotienting to be implemented efficiently in EXP.OPEN. We extended EVALUATOR 3.5 to automatically generate the formula graph corresponding to a temporal logic formula.
- We proposed and implemented efficient formula simplifications by combining reductions modulo bisimulations and partial formula evaluation computed using boolean equation systems.

We used this prototype implementation to verify 28 temporal logic properties on the TFfP avionics protocol 14. For several of these properties, partial model checking uses hundreds of times less memory than on-the-fly model checking using EVALUATOR. This work led to a publication in an international conference 38.

6.1.5. Parallel and Distributed Verification Tools

Participants: Iker Bellicot, Hubert Garavel, Rémi Hérilier, Radu Mateescu.

The CADP toolbox contains several components designed to take advantage of distributed computing facilities (such as clusters of machines) to perform large-scale verifications, namely: CÆSAR_NETWORK, a network communication library used by the other tools, DISTRIBUTOR and BCG_MERGE, two companion tools 10 that perform reachability analysis using a distributed state space exploration algorithm, and BES_SOLVE 35, a tool that solves boolean equations systems using the various resolution algorithms provided by the CÆSAR_SOLVE library (see § 6.1.2), including a distributed on-the-fly resolution algorithm.

In 2011, we continued enhancing these tools, taking advantage of the valuable feedback provided by Eric Madelaine (INRIA Sophia Antipolis) who used CADP on the PACAGRID cluster. We brought the following improvements:

- We performed careful code reviews of the CÆSAR_NETWORK library, and corrected nine bugs. We equipped this library with logging primitives that proved to be helpful for debugging distributed algorithms programmed above the CÆSAR_NETWORK library.
- We fixed three bugs in DISTRIBUTOR and two bugs in BCG_MERGE.
- We pursued the intensive testing campaign undertaken in 2010 for BES_SOLVE, using up to 100 concurrent processes running on the PIPOl and GRID5000 platforms. We focused our efforts on the distributed resolution algorithm for boolean equation systems of CÆSAR_SOLVE/BES_SOLVE,
which was tested extensively on examples of boolean equation systems represented explicitly as text files or generated randomly according to various parameters, the resolution results being cross-checked against the sequential resolution algorithms provided by $\text{CAESAR\_SOLVE/\text{BES\_SOLVE}}$.

Several bugs (affecting memory leaks, handling of early termination, diagnostic generation, collecting of statistical information about the resolution) were fixed. Changes were also carried out on the code to simplify its structure, increase modularity, and improve readability. The convergence of the distributed resolution algorithm was accelerated by backward propagation of constants as soon as they have been discovered.

- The EVALUATOR 4.0 tool was extended with a new prototype algorithm allowing the distributed verification of an MCL formula on a graph using several machines connected by a network. This functionality was implemented by connecting the tool to the distributed resolution algorithm for boolean equation systems and experimented out on clusters of machines.

- Finally, we added to C\textsc{adp} four new tools named $\text{PBG\_CP}$, $\text{PBG\_INFO}$, $\text{PBG\_MV}$, and $\text{PBG\_RM}$. These tools respectively enable to copy, query, move, and delete the $\text{PBG}$ (Partitioned BCG Graph) collection of files generated and used by DISTRIBUTOR and BCG\_MERGE.

### 6.1.6. Other Tool Developments

**Participants:** Hubert Garavel, Yann Genevois, Rémi Hérilier, Frédéric Lang, Radu Mateescu, Wendelin Serwe.

To support the usage of C\textsc{adp} in industry and academia, we pursued our efforts to master the software quality of C\textsc{adp}:

- We added support for Mac OS X 10.7 (“Lion”) and enhanced the documentation for Mac OS X.
- We corrected one bug in the INSTALLATOR installation assistant, two bugs in the TST platform-checking command, and brought two bug fixes and one usability enhancement in the EUCALYPTUS graphical user-interface. We also provided a workaround for supporting recent versions of UBUNTU.
- We continued building a comprehensive validation framework, based on non-regression testing and semantical checking for the C\textsc{adp} tools. This framework allows functional testing of individual tools as well as integration testing for several C\textsc{adp} tools used together to perform complex verification scenarios on various computing platforms and using various compilers.

Other research teams took advantage of the software components provided by C\textsc{adp} (e.g., the BCG and OPEN/CAESAR environments) to build their own research software. We can mention the following developments:

- the KMELIA tools for component-based systems [50], developed at the University of Nantes (France);
- the VERCORS tool for unifying architectural and behavioral specifications of distributed components [52], developed at INRIA Sophia-Antipolis;
- the DAMASCO (Discovery, Adaptation and Monitoring of Context-Aware Services and Components) framework for composition and adaptation based on model transformation [54], developed at the University of Málaga (Spain);
- the SCOOP tool for composition and adaptation based on model transformation [54], developed at RWTH Aachen (Germany);
- the SLCO (Simple Language of Communicating Objects) environment [49], developed at Eindhoven University of Technology (The Netherlands);
- the MOTOR tool for probabilistic analysis of embedded systems [68], developed at the Embedded Systems Institute (Eindhoven, The Netherlands);
- the ALVIS modeling language for design and verification of embedded systems [72], developed at the AGH University of Science and Technology (Krakow, Poland).
6.2. Languages and Compilation Techniques

6.2.1. Compilation of LOTOS

Participants: Hubert Garavel, Wendelin Serwe.

The CADP toolbox contains several tools dedicated to the LOTOS language, namely the CÆSAR.ADT compiler [3] for the data type part of LOTOS, the CÆSAR compiler [11] for the process part of LOTOS, and the CÆSAR.INDEPT pretty-printer.

In 2011, in addition to fixing four bugs in the CÆSAR and CÆSAR.ADT compilers, we improved the LOTOS-dedicated tools of CADP as follows:

- We revised the predefined type libraries and C code generated by CÆSAR and CÆSAR.ADT to suppress warnings emitted by recent versions of GCC.
- We enhanced the format in which values of singleton and tuple types are displayed to end users.
- We modified the predefined libraries for natural (unsigned) and integer (signed) types so that users can now indicate the precise number of bits (between 1 and 64) to be used for the machine representation of these types, and can also determine the precise range (lower and upper bound) to be used for values of these types.
- We further modified these two libraries to enable (optional) overflow and underflow checking during arithmetic operations on the natural and integer types.

6.2.2. Compilation of LOTOS NT

Participants: Hubert Garavel, Frédéric Lang, Christine McKinty, Vincent Powazny, Wendelin Serwe.

Regarding the LOTOS NT language — a variant of E-LOTOS created by the VASY project team — we worked along two directions:

- We continued enhancing the TRAIAN compiler (see § 5.2), which generates C code from LOTOS NT data type and function definitions. TRAIAN is distributed on the Internet and used intensively within the VASY project team as a development tool for compiler construction [8].

In 2011, TRAIAN was essentially in maintenance mode. We updated its documentation and added to its predefined library a conversion function that was missing.

- The LNT2LOTOS, LNT.OPEN, and LPP tools convert LOTOS NT code to LOTOS, thus allowing the use of CADP to verify LOTOS NT descriptions. These tools are officially part of CADP since 2010 and have been used successfully for many different systems (see § 6.3.1, § 6.3.2, § 6.3.5, § 6.3.5, and § 6.3.3).

In 2011, we continued enhancing these tools, of which we delivered four new releases. In addition to 13 bug fixes, the following enhancements have been brought:

- The LOTOS NT language was extended with range types (which are interval subtypes of character, integer, or natural types) and predicate types (which are subtypes of existing types, a boolean predicate being used to determine the domain of each subtype).

- The LOTOS NT language was enriched with the concept of “module pragmas”, which specify implementation constraints for predefined types such as naturals, integers, and strings. Also, the predefined operations “first” and “last” have been added for enumerated types.

- The LNT2LOTOS translator was made semantically stricter by adding checks for overflow and underflow when doing natural and integer arithmetics, checking that range type bounds and array type bounds belong to the domain of admissible values for their parent types, and adding additional checks for type pragmas.
– The LOTOS code generated by the LNT2LOTOS translator was optimized by handling equation premises (in the data part) and boolean guards (in the behavior part) that are always false or always true. Other optimizations have been added for process definitions whose bodies are empty or only contain a call to another process, for "case" statements that are followed by no instruction or only a "null" instruction, and for "while" loops with an empty body.

– The speed of processing LOTOS NT specifications containing several modules has been made between two and three times faster.

– The error and warning messages issued by the LOTOS NT tools have been enhanced.

– The reference manual has been corrected, reorganized and comprehensively edited. Two new appendices have been added, one that lists all the predefined functions, and another one (20 pages) giving the formal semantics of LOTOS NT.

6.2.3. Source-Level Translations between Concurrent Languages

Participants: Hubert Garavel, Rémi Hérilier, Frédéric Lang, Radu Mateescu, Gwen Salaün, Wendelin Serwe, Damien Thivolle.

Although process algebras are, from a technical point of view, the best formalism to describe concurrent systems, they are not used as widely as they could be. Besides the steep learning curve of process algebras, which is traditionally mentioned as the main reason for this situation, it seems also that the process algebra community scattered its efforts by developing too many languages, similar in concept but incompatible in practice. Even the advent of two international standards, such as LOTOS (in 1989) and E-LOTOS (in 2001), did not remedy this fragmentation. To address this problem, we started investigating source-level translators from various process algebras into LOTOS or LOTOS NT, so as to widen the applicability of the CADP tools.

In 2011, in addition to the LNT.OPEN tool suite (see § 6.2.2), we worked on the following translators:

- We continued our work on the FLAC tool, which translates a FIACRE program into a LOTOS program automatically, for verification using CADP. In 2011, 2 bugs reported by users of FLAC were corrected. Those corrections led to revisions 74 and 75 of the FLAC code, which is available on the development forge dedicated to FIACRE compilers. We collected new examples of FIACRE code to enhance our test suite, which now comprises 79 examples.

- BPEL (Business Process Execution Language) [61] is a language inspired by the $\pi$-calculus [67] and standardized by the OASIS consortium (led by IBM and Microsoft) to describe the orchestrations of Web services. BPEL depends on other W3C standard XML-related languages: XML Schema for data types, XPATH for data expressions, and WSDL for declaring the interfaces (communication links and link functions) of a Web service.

Following interest expressed by research teams at MIT and the Polytechnic University of Bucharest, we designed translation rules from BPEL to LOTOS NT in order to formally verify BPEL services with CADP. We began to develop an automated translator.

In 2011, following a remark by Charles Pecheur (Université Catholique de Louvain, Belgium) who spotted an error in the translation of BPEL processes into LOTOS NT, we corrected the translation of exception handling so that it no longer interferes with the atomicity mechanism. The complete translation algorithm is given in Damien Thivolle’s PhD thesis [23]. We pursued the implementation of our BPEL to LOTOS NT translator and finalized the translation of XML Schema types and WSDL definitions.

- We considered the $\pi$-calculus [67], a process algebra based on mobile communication. We proposed a general method for translating the finite control fragment of the $\pi$-calculus (obtained by forbidding recursive invocations of an agent through parallel composition operators) into LOTOS NT. The mobile communication is encoded using the data types of LOTOS NT, each channel name

\[ http://gforge.enseeiht.fr/projects/fiacre-compil \]
being represented as a value of an enumerated data type. The binary synchronization of $\pi$-calculus is enforced by associating a LOTOS NT gate to each parallel composition operator present in the $\pi$-calculus specification and by tagging each synchronization with the unique identifiers of the sender and receiver agents. The translation preserves the operational semantics by mapping each transition of a $\pi$-calculus agent to a single transition of the resulting LOTOS NT term.

In 2011, we have extended the $\pi$-calculus with data-handling features, with the goal of widening its possible application domains. This was done by extending the language grammar and the translation to support typed variables and data expressions. As language for describing data, we chose LOTOS NT: indeed, the data types and functions used in the $\pi$-calculus specification can be described in LOTOS NT and directly incorporated to the LOTOS NT code produced by translation. This results in an applied $\pi$-calculus, such as the variant of the calculus proposed in [45] for the verification of security properties.

The $\text{Pic2LNT}$ translator was extended accordingly. It now consists of 2,100 lines of $\text{SYNTAX}$ code, 3,100 lines of LOTOS NT code, and 500 lines of C code. The tool was tested on 234 examples of $\pi$-calculus specifications, including most of the examples provided in the Mobility Workbench distribution.

6.3. Case Studies and Practical Applications

6.3.1. Mutual Exclusion Protocols

Participants: Radu Mateescu, Wendelin Serwe.

Mutual exclusion protocols are an essential building block of concurrent systems to ensure proper use of shared resources in the presence of concurrent accesses. Many variants of mutual exclusion protocols exist for shared memory, such as Peterson’s or Dekker’s well-known protocols. Although the functional correctness of these protocols has been studied extensively, relatively little attention has been paid to their performance aspects.

In 2011, we considered a set of 27 mutual exclusion protocols for up to sixteen processes with a shared memory and coherent local caches. We specified each protocol in LOTOS NT, using a set of generic modules to describe shared variables, the cache protocol, and the overall architectures (in total, 13,600 lines of LOTOS NT code). Then, we compositionally added Markov delays modeling the latencies of read/write accesses on shared variables, so as to obtain the Interactive Markov Chain ($\text{IMC}$) corresponding to each protocol (up to 1.6 billion states and 2.7 billion transitions for the black-white bakery protocol [73] for four processes).

We verified functional properties using the same set of $\text{MCL}$ [18] formulas for each protocol (in total, 380 lines of $\text{MCL}$). The mutual exclusion property was easy to express as an $\text{MCL}$ formula, but other properties (livelock and starvation freedom, independent progress, and unbounded overtaking) turned out to be quite involved because they belong to the $\mu$-calculus fragment of alternation depth two; fortunately, we succeeded in expressing them using the infinite looping operator of $\text{MCL}$, which can be checked in linear time. In particular, it was challenging to express these properties using a parameter $N$ for the number of processes.

Finally, using the performance evaluation tools of CADP (i.e., $\text{BCG\_STEADY}$ for small numbers of processes and $\text{CUNCTATOR}$ for larger numbers of processes), we computed the steady-state throughputs of critical section accesses by varying several parameters (relative speeds of processes, ratio between the time spent in critical and non-critical sections, etc.).

These experiments enabled us to compare the protocols according to their efficiency (steady-state throughputs) and study also their scalability for an increasing number of processors. We observed that symmetric protocols are more robust when the difference in execution speed between processes is large, which confirms the importance of the symmetry requirement originally formulated by Dijkstra [56]. The quantitative results corroborated those of functional verification: the presence of (asymmetric) starvation of processes, detected using temporal formulas, was clearly reflected in their steady-state throughputs. Our results also corroborate experimental measures found in the literature [48].
6.3.2. The Platform 2012 Architecture

Participant: Wendelin Serwe.

In the context of the MULTIVAL contract (see § 7.1), STMicroelectronics studied PLATFORM 2012, a many-core programmable multi-cluster platform fabric targets a range of emerging video, imaging, and next-generation immersive multimodal applications. Configurability options include the number of clusters, the number and type of processing elements (PE) per cluster, specialization of the architecture and instruction-set of the PEs, and finally, support of hardware-accelerated PEs. The platform is supported by a rich programming environment which embodies a range of platform programming models.

In 2011 we focused on the DTD (Dynamic Task Dispatcher) hardware block that assigns a set of application tasks on a set of PEs. It is called dynamic because each task itself might add tasks to the set of those to be dispatched by the DTD. The DTD is synthesized from a C++ model, optimized to generate an efficient hardware block. Due to the intrinsic complexity of the DTD, STMicroelectronics was interested in the co-simulation of this C++ code with a formal model of the DTD.

In a first step, we generalized the LOTOS NT model of the DTD developed in 2010 to allow the handling of an arbitrary number of PEs (1, 200 lines of LOTOS NT). We also modeled as LOTOS NT processes the different sets of tasks corresponding to various applications. To express the operations provided by the DTD, we had to include a call-stack in the model of each PE, as a means of circumventing the static-control constraints of CÆSAR forbidding recursion over parallel composition. STMicroelectronics judged LOTOS NT to be essential in modeling the DTD, because using LOTOS instead would have been extremely difficult, requiring complex continuations with numerous parameters. We also wrote twelve scenarios (1, 000 lines of LOTOS NT) describing applications to be dispatched by the DTD. For each scenario and for up to six PEs, we generated the corresponding LTS (up to 100 million states and 500 million transitions).

Then, for each generated LTS, we verified several properties, such as the correctness of assertions inserted in the model (by checking the set of transition labels), the termination of the scenario, or that each task is executed exactly once. We expressed the latter properties using the MCL language [18] and verified them using the EVALUATOR 4 model checker. This allowed us to point out a difference between our implementation and the one from the architect, highlighting a high sensibility on the order of terms in an equation, revealing an under-specified mechanism. We also verified the correctness of a complex optimization.

Having gained confidence in the LOTOS NT model, we applied the EXEC/CÆSAR framework to co-simulate the C++ and LOTOS NT models of the DTD, a challenge being the connection of the asynchronous LOTOS NT model with the synchronous C++ model, because one step of the C++ model corresponds, in general, to several transitions of the LOTOS NT model.

This case study enabled us to discover and correct a few bugs in CADP and led to a publication in an international conference [39].

6.3.3. The Self-configuration Protocol

Participant: Gwen Salaün.

Cloud computing emerged a few years ago as a major topic in modern programming. It leverages hosting platforms based on virtualization, and promises to deliver resources and applications that are faster and cheaper with a new software licensing and billing model based on the pay-per-use concept.

Distributed applications in the cloud are composed of a set of virtual machines (VMs) running a set of interconnected software components. However, the task of configuring distributed applications is complex as each VM includes many parameters either for local configuration (e.g., pool size, authentication data) or remote interconnection (e.g., IP address and port to access a server). Existing deployment solutions are often specific to certain applications and rarely take into account these configuration parameters, which are usually managed by dedicated scripts that do not work fully automatically.
Together with Xavier Etchevers, Thierry Coupaye (Orange labs), Fabienne Boyer, and Noël de Palma (INRIA Grenoble), we worked on the verification of an innovative self-configuration protocol [34] that automates the configuration of distributed applications in the cloud without requiring any centralized server nor a scripting effort. The high degree of parallelism involved in this protocol making its design difficult and error-prone, we decided to specify the protocol using LOTOS NT and to verify it with CADP. So doing, we detected a major bug, which was corrected in the reference JAVA implementation. The LOTOS NT specification also served as a workbench to experiment with several possible communication models, which helped us to avoid an erroneous design.

These results have been published in [44].

### 6.3.4. Realizability of Choreographies

**Participants:** Matthias Güdemann, Gwen Salaün.

The specification and the analysis of interactions among distributed components play an important role in service-oriented computing. In order to facilitate the integration of independently developed components (named *peers*) that may reside in different organizations, it is necessary to provide a global contract that the peers participating in a service composition should adhere to. Such a contract is called *choreography*. One important problem in a top-down development process is figuring out whether a choreography specification can be implemented by a set of peers that communicate via message passing. Given a choreography specification, it would be desirable to generate peers automatically by projecting the global choreography specification to each peer ignoring all messages that are not sent or received by that peer. However, generation of peers that precisely implement a choreography specification is not always possible, i.e., there are choreographies that are not implementable by a set of distributed peers. This problem is known as *realizability*.

In 2011, we considered the following aspects of the realizability problem:

- In collaboration with Gregor Gössler (INRIA Grenoble) we studied the realizability of choreographies for peers interacting asynchronously through message buffers. Although this problem is generally undecidable for unbounded buffers, we proposed techniques to check whether peers interacting asynchronously with finite buffers can realize a choreography, and if so, for which buffer sizes. These results have been published in [36].

- In collaboration with Pascal Poizat (LRI, Orsay), we proposed an approach to check the realizability of choreographies using the interaction model of BPMN (*Business Process Modeling Notation*) 2.0. While being a standard for the abstract specification of business workflows and collaboration between services, BPMN has only been recently extended into BPMN 2.0 to support choreographies. Our approach is based on a model transformation into LOTOS NT and the use of equivalence checking. We implemented a prototype of our approach using the ECLIPSEBPMN 2.0 editor and CADP. These results have been published in [43].

- In collaboration with Meriem Ouederni (LINA, Nantes), we studied the automatic synthesis of monitors to enforce realizability, using CADP to check equivalence between the choreography and an automatically obtained distributed implementation.

### 6.3.5. Other Case Studies

**Participants:** Hubert Garavel, Frédéric Lang, Radu Mateescu, Gwen Salaün, Wendelin Serwe, Damien Thivolle.

- In the context of the TOPCASED project (see § 7.2), we studied how CADP can be used to verify avionics protocols. In 2011, we prepared two lectures summarizing our prior results on four avionic protocols, namely a ground/plane communication protocol based on TFTP (*Trivial File Transfer Protocol*) [14], the BITE (*Built In Test Equipment*)/CMS (*Central Maintenance Function*), the ATC (*Air Traffic Control*) system, and the AFN (*Air Traffic System Facilities Notification*).

- Our prior work (2009–2010) with Fabienne Boyer and Olivier Gruber (Université Joseph Fourier Grenoble) on modeling and verification using LOTOS NT and CADP of the SYNERGY reconfiguration protocol led to a publication in an international conference [31].
Other teams also used the CADP toolbox for various case studies. To cite only recent work not already described in previous VASY activity reports, we can mention:

- behavior analysis of malware by rewriting-based abstraction \[ 51 \];
- safety verification of fault-tolerant distributed components \[ 46 \];
- verification of mobile ad hoc networks \[ 57 \];
- model checking ERLANG applications \[ 59 \];
- model-checking dataflow in service compositions \[ 63 \];
- verification of a key chain based TTP transparent CEM protocol \[ 65 \];
- semantics tuning of UML/SYSML \[ 69 \];
- atomicity maintenance in EPCREPORT of ALE \[ 70 \];
- cost analysis of semantic composability validation \[ 71 \];
- rigorous development of prompting dialogs \[ 75 \];
- scalably verifiable cache coherence \[ 76 \].
6. New Results

6.1. Algebraic methods for geometric problems

6.1.1. New bivariate system solver and topology of algebraic curves

We present in [22] a new approach for solving polynomial systems of two bivariate polynomials with rational coefficients. The tools used in our algorithm are classical (subresultants, Groebner basis, triangular systems, regular chains, RUR (rational univariate representations), modular computation) but they are combined in a new way. We first use a classical approach based on subresultant sequences for decomposing a system into subsystems according to the number of roots (counted with multiplicities) in vertical lines. We then show how the resulting triangular subsystems can be efficiently solved by computing lexicographic Gröbner bases and Rational Univariate Representations (RURs) of these systems. We eventually show how this approach can be performed using modular arithmetic, while remaining deterministic, yielding an algorithm that can take advantage of a parallel implementation. We apply our solver to the problem of computing the topology of algebraic curves using the algorithm Isotop [31]. We show that, on generic curves, our algorithm performs similarly as classical resultant-based algorithms and, on non-generic curves, it performs significantly better than all non-GPU based implementations (it outperforms the curve arrangement of CGAL with factors up to several hundreds). Preliminary experiments also hint that the recent GPU-based approach of Berberich et al. [29] and the multi-thread version of our implementation perform similarly on a standard machine, although our implementation naturally depends on the number of threads.

We also started to work on a generalization of these results to real algebraic curves embedded in dimension 3 and higher.

6.1.2. Counting the number of embeddings of a given rigid graph

We addressed the problem of counting the number of embeddings of a given rigid graph (a graph with edges labeled by distances). Such graphs are still not well understood and appear in several applications such as robot kinematics and structural biology. By modeling the problem as a sparse system of polynomial equations, we could bound the maximal number of embeddings from above with the algebraic mixed volume theory, and bound it from below with stochastic optimization methods. This work submitted in 2010 was accepted and published in the proceedings of the IFToMM 2011 conference [21].

6.1.3. Description of singularities of a parameterized mechanism

Kinematic design can be seen as an application of rigid graph theory. In collaboration with the IRCCyN laboratory, we worked on the design of parallel mechanisms. We studied in particular the cable robots, a new kind of architecture, which is difficult to understand. The problem is to describe the set of parameters such that the robot doesn’t break or lose control. Using tools from algebra, we can describe rigorously the working space of a simple planar cable robot [19]. Work on this subject is promising, and some theory developed for rigid graphs could give other interesting results in kinematic design.

6.1.4. Distance between 3-dimensional terrains

We addressed the problem of computing efficiently the distance between two piecewise-linear bivariate functions $f$ and $g$ defined over a common domain $M$. We focus on the distance induced by the $L_2$-norm, that is $\|f - g\|_2 = \sqrt{\int_M (f - g)^2}$. If $f$ is defined by linear interpolation over a triangulation of $M$ with $n$ triangles, while $g$ is defined over another such triangulation, the obvious naïve algorithm requires $\Theta(n^2)$ arithmetic operations to compute this distance. We show that it is possible to compute it in $O(n \log(n^3))$ arithmetic operations, by reducing the algebraic problem to multi-point evaluation of a certain type of polynomials [24].
6.1.5. Invariant-based predicate evaluation strategies

We have worked on formalizing polynomial evaluation strategies of geometric predicates using algebraic invariant theory. Let \( \mathcal{P} \) be a typical predicate that one encounters in (non-linear) computational geometry. The general approach has three main steps:

1. Identify the symmetries of the problem, i.e. the transformations on the entries \( X \) of \( \mathcal{P} \) that leave invariant the output of the predicate. These transformations can be modeled by the action \( \psi \) of a group \( G \) operating on \( X \).

2. Use appropriate techniques or known theorems to obtain polynomial invariants for \( \psi \). In particular, we have investigated the use of an effective invariant construction method due to Grosshans et al. based on a symbolic representation of invariants.

3. Build a polynomial evaluation strategy for \( \mathcal{P} \) by determining those orbits of \( \psi \) that are discriminated by the invariants obtained above.

We have applied this general approach to two problems: determining the number of real lines piercing four given lines and determining when two quadrics have no real point in common. For the first problem we essentially reproduce the results obtained previously by Devillers et al. through a direct manipulation of equations. For the second we only have partial results so far.

This work is part of Guillaume Batog’s PhD thesis (defended in December 2011) [12].

6.2. 3D visibility, theory and applications

6.2.1. Calibration for linear cameras

The linear camera is a fairly general geometric model of imaging devices proposed by Jean Ponce and based on linear line congruences, two-dimensional sections of the Klein quadric (a classical model for the space of lines). In a previous work, in collaboration with Jean Ponce, we explored properties of this model. We established in particular the equivalence of linear camera with another model proposed by Tomas Pajdla (which we generalized along the way). The complementarity of these models allowed to extend standard computer vision techniques, such as stereo-reconstruction, to any imaging system modeled by a linear camera. We went one step further and explored how the notion of “calibration” extends to linear cameras. We enriched the usual “intrinsic” parameters used for central cameras by additional parameters that encode the geometry of linear line congruences. This required to investigate the Euclidean aspects of linear line congruences, objects that are usually studied in a projective setting.

This work is part of Guillaume Batog’s PhD thesis (defended in December 2011) [12] and a journal version is in preparation.

6.3. Discrete and computational geometry

6.3.1. On Point-sets that Support Planar Graphs

A set of points is said universal if it supports a crossing-free drawing of any planar graph. For a planar graph with \( n \) vertices, if bends on edges of the drawing are permitted, universal point-sets of size \( n \) are known, but only if the bend-points are in arbitrary positions. If the locations of the bend-points must also be specified as part of the point-set, no result was known, and we prove that any planar graph with \( n \) vertices can be drawn on a universal set \( S \) of \( O(n^2 / \log n) \) points with at most one bend per edge and with the vertices and the bend points in \( S \). If two bends per edge are allowed, we show that \( O(n \log n) \) points are sufficient, and if three bends per edge are allowed, \( \Theta(n) \) points are sufficient. When no bends on edges are permitted, no universal point-set of size \( o(n^2) \) is known for the class of planar graphs. We show that a set of \( n \) points in balanced biconvex position supports the class of maximum-degree-3 series-parallel lattices [20].
6.3.2. Helly numbers of acyclic families

The nerve of a family of sets is a simplicial complex that records the intersection pattern of its subfamilies. Nerves are widely used in computational geometry and topology, because the nerve theorem guarantees that the nerve of a family of geometric objects has the same topology as the union of the objects, if they form a good cover.

We relaxed the good cover assumption to the case where each subfamily intersects in a disjoint union of possibly several homology cells, and we proved a generalization of the nerve theorem in this framework, using spectral sequences from algebraic topology. We then deduced a new topological Helly-type theorem that unifies previous results of Amenta, Kalai and Meshulam, and Matoušek. This Helly-type theorem is applied to (re)prove, in a unified way, bounds on Helly numbers of sets of lines in geometric transversal theory [25].

6.4. National Initiatives

6.4.1. ANR Blanc - PRESAGE

This project brings together computational geometers (from the VEGAS and GEOMETRICA projects of INRIA) and probabilistic geometers (from Universities of Rouen, Orléans and Poitiers) to tackle new probabilistic geometry problems arising from the design and analysis of geometric algorithms and data structures. We focus on properties of discrete structures induced by or underlying random continuous geometric objects.

This is a four year project, with a total budget of 400kE, that will start on Dec. 31st, 2011. It is coordinated by X. Goaoc (VEGAS).

6.4.2. PEPS Rupture - INS2I: Manifold

The aim of this project is to initiate a collaboration to investigate algebraic/numeric methods for the analysis of manifolds, considering also singularities, that arise in robotics and biological models. Researchers specialized in interval analysis (LINA) and symbolic methods (LORIA) evaluate the relevance of their approaches to applications in robotics (IRCCyN) and biology (LINA). The outcome of this evaluation will be a proposal for a hybridization of both methods that will be worked out in a longer term project.

This is a one year project with a budget of 10 kE. Two one day workshops have been funded with invitations of potential partners for a followup.

6.5. International Initiatives

6.5.1. Visits of International Scientists

- William J. Lenhart, Williams College (USA), one year (sabbatical) from September 2011.
- Andreas Holmsen, KAIST (South Korea), June, 1 week.
- Martin Tancer, Charles University (Prague), April 1 week.
- Pavel Patak, Charles University (Prague), April 1 week.
- Zuzana Safernova, Charles University (Prague), April 1 week.
- Jinsan Cheng, Chinese academy of science (Beijing), November, 1 week.
- Luis Peñaranda, University of Athens, December, 1 week.

6.5.2. Participation In International Programs

- Sylvain Petitjean collaborates with Pr. Gert Vegter of the University of Groningen on “Certified Geometric Approximation”. This collaboration is funded by the Netherlands Organization for Scientific Research (NWO) - 2008–2012.
6. New Results

6.1. Using symmetries in SMT

Participants: David Déharbe, Pascal Fontaine, Bruno Woltzenlogel Paleo.

Methods exploiting problem symmetries have been very successful in several areas including constraint programming and SAT solving. We propose a similar technique for enhancing the performance of SMT-solvers by detecting symmetries in the input formulas and using them to prune the search space of the SMT algorithm. This technique is based on the concept of (syntactic) invariance by permutation of constants. An algorithm for solving SMT by taking advantage of such symmetries is presented. The implementation of this algorithm in the SMT-solver veriT results in an impressive improvement of veriT’s performances on the SMT-LIB benchmarks that places it ahead of the winners of the last editions of the SMT-COMP contest in the QF_UF category. This technique has immediately been adopted by the SMT community. For instance, we are aware that Z3 (Microsoft) and CVC3 (University of New-York and University of Iowa) implemented this technique for the 2011 competition.

6.2. Compression of SMT proofs

Participants: Pascal Fontaine, Stephan Merz, Bruno Woltzenlogel Paleo.

Integrating an SMT solver in a certified environment such as an LF-style proof assistant requires the solver to output proofs. Unfortunately, those proofs may be quite large, and the overhead of rechecking the proof may account for a significant fraction of the proof time. In previous work, we proposed a technique for reducing the sizes of propositional proofs based on the analysis of resolution graphs, which were justified in an algebra of resolution. Unfortunately, the complexity of these techniques turned out to be prohibitive. In a paper published at CADE 2011 [11], we give practical algorithms for more restricted compression techniques and validate them on standard benchmarks. Our algorithms significantly improve state-of-the-art proof compression algorithms and achieve better reduction of proof sizes, often by 30%.

6.3. Combination of decision procedures

Participant: Pascal Fontaine.

We investigate the theoretical limits of combining decision procedures and reasoners, as these are important for the development of the veriT solver (see section 5.1). It has long been known that it is possible to extend any decidable language (subject to a minor requirement on cardinalities) with predicates described by a Bernays-Schönfinkel-Ramsey theory (BSR). A formula belongs to the BSR decidable fragment if it is a conjunction of universal, function-free formulas. As a consequence of this theoretical result, it is possible to extend a decidable quantifier-free language with sets and set operators, relations, orders and similar concepts. This can be used to significantly extend the expressivity of SMT solvers. In previous work, we had generalized this result to the decidable first-order class of monadic predicate logic, and to the two-variable fragment. In 2011, in cooperation with Carlos Areces from Universidad Nacional de Córdoba, Argentina, we showed that two other important decidable fragments (namely the Ackermann fragment, and several guarded fragments) are also easily combinable. This result was presented at the FroCoS Conference 2011 [8], as well as at the SMT’2011 workshop (joint with the Conference on Computer Aided Verification, CAV 2011).

6.4. Encoding TLA+ proof obligations for SMT solvers

Participants: Stephan Merz, Hernán-Pablo Vanzetto.
The TLA\textsuperscript{+} proof system TLAPS (see \refsec{5.2}) is being developed within a project at the MSR-INRIA Joint Centre in which we participate. The original release of TLAPS contained an SMT backend that handled quantifier-free proof obligations in linear arithmetic and that was occasionally useful, given that the other backends perform quite poorly on formulas involving arithmetic. However, TLA\textsuperscript{+} proof obligations usually mix arithmetic with other theories, in particular set theory, functions, records, and tuples. We propose a new encoding of TLA\textsuperscript{+} sequents in SMT-LIB, the generic input language of SMT solvers. The main challenge has been to design a sound translation from untyped TLA\textsuperscript{+} to the multi-sorted first-order logic that underlies SMT-LIB. We have developed a type system and a type inference algorithm that assigns SMT-LIB sorts to symbols and terms in the input formula, based on “typing assumptions” among the hypotheses present in the proof obligation.

The translation has been validated over several existing examples, yielding significant reductions in proof sizes. For example, the new backend can automatically verify the main invariant of a parameterized version of the Bakery algorithm, which previously required a few hundred lines of interactive proof. Similarly, an existing proof about a security architecture \cite{33} has been reduced by about 90\%. The backend has been integrated in TLAPS and has been presented at a workshop \cite{19}.

\subsection*{6.5. Model checking within SimGrid}

\textbf{Participants:} Stephan Merz, Martin Quinson [of project team AlGorille], Cristián Rosa.

For several years we have cooperated with Martin Quinson from the AlGorille project team on adding model checking capabilities to the simulation platform SimGrid for message-passing distributed C programs. The expected benefit of such an integration is that programmers can complement simulation runs by exhaustive state space exploration in order to detect errors such as race conditions that would be hard to reproduce by testing. Indeed, a simulation platform provides a controlled execution environment that mediates interactions between processes, and between processes and the environment, and thus provides the basic functionality for implementing a model checker. The principal challenge is the state explosion problem, as a naive approach to the systematic generation of all possible process interleavings would be infeasible beyond the most trivial programs. Moreover, it is impractical to store the set of global system states that have already been visited: the programs under analysis are arbitrary C programs with full access to the heap, making it difficult and costly to store global states and to determine if two states are equal.

We have implemented a stateless model checker within the SimGrid platform, for verifying safety properties of distributed C programs that communicate by message passing. The visible actions correspond to the communication events, at which points programs can be interrupted by the simulation core. In order to mitigate state explosion, the exploration relies on Dynamic Partial-Order Reduction (DPOR) that avoids exploring redundant interleavings corresponding to the same global happens-before relation. We have identified four primitive communication actions, in terms of which the different message-passing libraries provided by SimGrid can be implemented, and have proved independence theorems for these primitives that underly our DPOR exploration algorithm. We thus obtain a small kernel that supports different communication APIs; nevertheless, practical evaluations yield similar reductions as those obtained by Li et al. \cite{30} for a much more detailed analysis of a fragment of the MPI library.

The model checker SimGridMC is now part of the SimGrid platform and allows programmers to either perform simulation or model checking runs based on the same source code. It has allowed us to discover a non-trivial bug in an implementation of the Chord algorithm for realizing a distributed hashtable over a P2P network. A conference paper has been published at FORTE 2011 \cite{13}. Cristián Rosa successfully defended his PhD thesis \cite{7} in October 2011, which also proposes efficient techniques for parallelizing simulation runs in SimGrid. Marion Guthmuller has explored extensions of our model checking algorithm for verifying liveness properties, and has started working on her PhD thesis in this area in the fall of 2011.

\subsection*{6.6. A new version of PlusCal}

\textbf{Participants:} Sabina Akhtar, Stephan Merz, Martin Quinson [of project team AlGorille].
In cooperation with Martin Quinson of the AlGorille team of INRIA Nancy we have defined and implemented a high-level language for the description of concurrent and distributed algorithms. Our work is inspired by Lamport’s PlusCal [29], but extends it for the modeling and verification of distributed algorithms. In particular, processes can be nested and variables are properly scoped; this is useful for modeling concurrent execution at different levels of a hierarchy (such as threads versus processes).

In 2011, the main effort has gone into designing partial-order reduction techniques for model checking PlusCal algorithms, which exploit the locality information present in the models. In particular, we have defined predicates that ensure the independence of two (blocks of) statements and adapted the TLC model checker to implement static partial-order reduction. Sabina Akhtar prepares her PhD thesis manuscript, and the thesis defense is planned for spring 2012.

6.7. Verification of distributed algorithms in the Heard-Of model

**Participants:** Henri Debrat, Stephan Merz.

Distributed algorithms are often quite subtle, both in the way they operate and in the assumptions required for their correctness. Formal models are important for unambiguously understanding the hypotheses and the properties of a distributed algorithm. We focus on the verification of round-based algorithms for fault-tolerant distributed systems expressed in the Heard-Of model of Charron-Bost and Schiper [26], for which we had already proved a reduction theorem in previous work.

In 2011, we have extended our previous results to the case of Byzantine errors where values may be received that do not correspond to those that should have been computed by the sender process (for example because of an intermittent fault in the sender process, a malicious process, or a value-changing error in the transmission channel). We have formalized a corresponding extension of the Heard-Of model in Isabelle/HOL, and have verified three Byzantine Consensus algorithms (EIG, ATE and UTE) within this framework. These results have been presented at SSS 2011 [9].

6.8. Modeling and verifying the Pastry routing protocol

**Participants:** Tianxiang Lu, Stephan Merz.

As a significant case study for the techniques that we are developing within VeriDis, we are modeling and verifying the routing protocol of the Pastry algorithm [25] for maintaining a distributed hash table in a peer-to-peer network. As part of his PhD work (under the joint supervision of Stephan Merz and Christoph Weidenbach from MPI-INF Saarbrücken), Tianxiang Lu has developed a TLA+ model of the Pastry routing protocol, which has uncovered several issues in the existing presentations of the protocol in the literature, and in particular a loophole in the join protocol that had been fixed by the algorithm designers in a technical report that appeared after the publication of the original protocol.

In 2011, we have worked towards a correctness proof of the routing protocol. We have in particular identified a number of candidate invariants that have been validated by extensive model checking over finite instances and for which we have formally proved that their validity would imply the correctness of the protocol. Our proofs are carried out in TLAPS (section 5.2) and represent a sizable case study for the different proof tools of the proof system. Our results have been presented at FORTE 2011 [12].

6.9. Incremental development of distributed algorithms

**Participants:** Dominique Méry, Manamiary Andriamiarina.

The development of distributed algorithms and, more generally, of distributed systems, is a complex, delicate, and challenging process. The approach based on refinement helps to gain formality by using a proof assistant, and proposes to apply a design methodology that starts from the most abstract model and leads, in an incremental way, to the most concrete model, for producing a distributed solution. Our works help to formalize pre-existing algorithms, develop new algorithms, as well as develop models for distributed systems.
Our research, carried out with Mohammed Mosbah and Mohammed Tounsi from the LABRI laboratory, was supported by the ANR project RIMEL until 2010 and we are maintaining a joint project B2VISIDIA with LABRI on these topics. More concretely, we aim at an integration of the correct-by-construction refinement-based approach into the local computation programming model. The team of LABRI develops an environment called VISIDIA that provides a toolset for developing distributed algorithms expressed as a set of rewriting rules of graph structures. The simulation of rewriting rules is based on synchronization algorithms and we have developed these algorithms by refinement.

Synchronization algorithms [14] are mandatory for simulating local computation models of distributed algorithms. Therefore, correctness of these algorithms becomes crucial, because it gives confidence that local computations are simulated as designed and do not behave harmfully. However, these algorithms are often very complex to prove correct since they integrate both distributed and probabilistic aspects. We derive proofs of synchronization algorithms upon which the correct-by-construction paradigm depends; the latter is supported by a progressive and incremental process controlled by the refinement techniques. We illustrate our approach by examples such as the Handshake and the LC1 algorithms. These algorithms are designed for an asynchronous distributed network of anonymous processes that communicate by message passing.

A second contribution is related to the integration of probabilistic arguments when reasoning about the design of distributed programs. We particularly focus [20] on probabilistic aspects of distributed algorithms related to termination, e.g. the choice between two delays in the case of communication protocols like IEEE 1394 (FireWire), or the choice between several colors for vertex coloring algorithms. We have in particular applied this approach to developing probabilistic distributed graph coloring algorithms (also called vertex coloring algorithms), based on an algorithm developed by Métivier et al. [32], using the Event B and probabilistic Event B methods.

A third contribution takes into account the modification of links between nodes in a graph modelling a network. We present [15] an incremental formal development of the Dynamic Source Routing (DSR) protocol in Event-B. DSR is a reactive routing protocol, which finds a route for a destination on demand, whenever communication is needed. Route discovery is an important task of any routing algorithm and its formal specification is a challenging problem in itself. The specification is performed in a stepwise manner by introducing more advanced routing components between the abstract specification and topology. It is verified through a series of refinements. The specification includes safety properties as a set of invariants, and liveness properties that characterize when the system reaches stable states. We establish these properties by proof of invariants, event refinement and deadlock freedom. The consequence of this incremental approach helps us achieve a high degree of automatization. Our approach can be useful for formalizing and developing other kinds of reactive routing protocols such as AODV.

6.10. Bounding message length in attacks against security protocols

Participant: Marie Duflot-Kremer.

Security protocols are short programs that describe communication between two or more parties in order to achieve security goals. Despite the apparent simplicity of such protocols, their verification is a difficult problem and has been shown to be undecidable in general. This undecidability comes from the fact that the set of executions to be considered is of infinite depth (an infinite number of protocol sessions can be run) and infinitely branching (the intruder can generate an unbounded number of distinct messages). Several attempts have been made to tackle each of these sources of undecidability. Together with Myrto Arapinis, we have shown [22] that, under a syntactic and reasonable condition of “well-formedness” on the protocol, we can get rid of the infinitely branching part. More precisely we proved that as far as the secrecy property is considered and for a well-formed protocol, we just need to consider well-typed attacks, with a strong typing system. This result directly implies that the messages to be considered are of bounded length. We are currently working on a journal version of this result that extends the set of security properties to which the result is applicable, in particular including authentication properties.
6.11. Formally verified decision procedures for finite automata

Participants: Stephan Merz, Julien Perugini, Hernán Ponce de Leon, Pierre Savonitto.

Decision problems in the theory of finite automata underly verification algorithms in model checking and decision procedures for fragments of arithmetic. We are interested in developing a certified library of automata-theoretic constructions within a trusted interactive proof assistant such as Isabelle. In 2011, two student projects addressed such problems.

Julien Perugini and Pierre Savonitto formalized a decision procedure for the universality problem of finite automata based on the antichain technique suggested by Doyen et al. [27] and verified its correctness in Isabelle/HOL. They then verified a list-based implementation of that algorithm, using the Isabelle Collections Framework, which provides pre-proved data structures for generating executable implementations. Future work should address efficiency issues by adopting better suited data structures.

During his internship, Hernán Ponce de Leon formalized and verified an automaton-based decision procedure for Presburger arithmetic over the integers, based on a previous encoding of a similar procedure restricted to natural numbers.
6. New Results

6.1. Verification

6.1.1. Analysis of partially observed recursive discrete-event systems

**Participants:** Sébastien Chédor, Thierry Jéron, Hervé Marchand, Christophe Morvan.

Monitoring of recursive discrete-event systems under partial observation is an important issue with major applications such as the diagnosability of faulty behaviors and the detection of information flow. We consider regular discrete-event systems, that is recursive discrete-event systems definable by deterministic graph grammars. This setting is expressive enough to capture classical models of recursive systems such as the pushdown systems. Hence they are infinite-state in general and standard powerset constructions for monitoring do not apply anymore. We exhibit computable conditions on these grammars together with non-trivial transformations of graph grammars that enable us to construct a monitor. This construction is applied to diagnose faulty behaviors, to detect information flow in regular discrete-event systems, and to generate tests.

6.1.2. Analysis of timed systems

6.1.2.1. Approximate determinization of timed automata

**Participants:** Nathalie Bertrand, Thierry Jéron, Amélie Stainer.

Timed automata are frequently used to model real-time systems. Their determinization is a key issue for several validation problems. However, not all timed automata can be determinized, and determinizability itself is undecidable. In [18], we propose a game-based algorithm which, given a timed automaton, tries to produce a language-equivalent deterministic timed automaton, otherwise a deterministic over-approximation. Our method subsumes two recent contributions: it is at once more general than an existing (non terminating) determinization procedure by Baier et al. (2009) and more precise than the approximation algorithm of Krichen and Tripakis (2009). Moreover, an extension of the method allows to deal with invariants and \( \epsilon \)-transitions, and to consider other useful approximations: under approximation, and combination of under- and over-approximations which are particularly useful in testing (see 6.2.1).

6.1.2.2. Frequency analysis for timed automata

**Participants:** Nathalie Bertrand, Amélie Stainer.

The languages of infinite timed words accepted by timed automata are traditionally defined using Büchi-like conditions. These acceptance conditions focus on the set of locations visited infinitely often along a run, but completely ignore quantitative timing aspects. In [15] we propose a natural quantitative semantics for timed automata based on the so-called frequency, which measures the proportion of time spent in the accepting states. We study various properties of timed languages accepted with positive frequency, and in particular the emptiness and universality problems.

6.1.3. Petri nets reachability graphs

**Participant:** Christophe Morvan.

Petri nets are a general model for concurrency, the structure of their reachability graph is mostly unknown. In [19] we have investigated the decidability and complexity status of model-checking problems on unlabelled reachability graphs of Petri nets by considering first-order, modal and pattern-based languages without labels on transitions or atomic propositions on markings. We consider several parameters to separate decidable problems from undecidable ones. These results illustrate the intrinsic complexity of the structure of these graphs.
6.2. Active and passive testing

6.2.1. Off-line test selection with test purposes for non-deterministic timed automata

Participants: Nathalie Bertrand, Thierry Jéron, Amélie Stainer.

In [17], we propose novel off-line test generation techniques for non-deterministic timed automata with inputs and outputs (TAIOs) in the formal framework of the tioco conformance theory. In this context, a first problem is the determinization of TAIOs, which is necessary to foresee next enabled actions, but is in general impossible. The determinization problem is addressed in [18] thanks to an approximate determinization using a game approach (see 6.1.2.1). We adapt this procedure here to over- and under-approximation, in order to preserve tioco and guarantee the soundness of generated test cases. A second problem is test selection for which a precise description of timed behaviors to be tested is carried out by expressive test purposes modeled by a generalization of TAIOs. Finally, using a symbolic co-reachability analysis guided by the test purpose, test cases are generated in the form of TAIOs equipped with verdicts.

6.2.2. Test generation using pushdown automata

Participant: Puneet Bhateja.

IOLTS (input output labeled transition system) is a versatile model and is frequently used in model based testing to model the functional behavior of an IUT (implementation under test). However when a system is tested remotely, its observed behavior can be different from its actual functional behavior. In a previous paper, we defined a notion of remotely observed behavior of an IOLTS in terms of its actual behavior. Paper [14] contributes by proposing a methodology to simulate a PDA (pushdown automaton) from the given IOLTS such that the simulated PDA precisely expresses the remotely observed behavior of the IOLTS. The simulated PDA can be thought of as an automatic test generator for remote testing.

6.2.3. Test case selection in asynchronous testing

Participants: Puneet Bhateja, Thierry Jéron.

Conformance testing has a rich underlying formal theory called IOLTS-based conformance testing. Depending upon whether the implementation-under-test (IUT) interacts with its environment directly, or indirectly through a medium, IOLTS-based conformance testing can be classified as synchronous testing or asynchronous testing, respectively. So far the problem of test case selection has been addressed mostly in the context of synchronous testing. In this work we contribute by addressing this problem in the context of asynchronous testing. Though an asynchronously communicating process can be simulated by a synchronously communicating process, the fact that the simulating process is infinite state even if the simulated process is finite state made the problem challenging.

6.2.4. A tagging protocol for asynchronous testing

Participant: Puneet Bhateja.

Conformance testing has a rich underlying theory popularly called IOCO-test theory. In the realm of IOCO-test theory, this paper addresses the issue of testing a component of an asynchronously communicating distributed system. Testing a system which communicates asynchronously (i.e., through some medium) with its environment is more difficult than testing a system which communicates synchronously (i.e., directly without any medium). What impedes asynchronous testing is that the actual behavior of the implementation under test (IUT) appears distorted and infinite to the tester. This impediment consequently renders the problem of generating a complete test suite, from the given specification of the IUT, infeasible. To this end, paper [13] proposes a tagging protocol which when implemented by the asynchronously communicating distributed system will enable the generation of a complete test suite, from the specification of any of its component. Further, this paper describes how to generate the test suite from the given specification of the component.

6.2.5. Abstracting time and data for conformance testing of real-time systems

Participants: Thierry Jéron, Hervé Marchand.
Current approaches to model-based conformance testing of real-time systems are mostly based either on finite state machines/transition systems or on timed automata. However, most real-time systems manipulate data while being subjected to time constraints. The usual solution consists in enumerating data values (in finite domains) while treating time symbolically, thus leading to the classical state explosion problem. Paper [12] with W.L. Andrade and P. Machado (Fed. Univ. Campina Grande) proposes a new model of real-time systems as an extension of both symbolic transition systems and timed automata, in order to handle both data and time requirements symbolically. We then adapt the tioco conformance testing theory to deal with this model and describe a test case generation process based on a combination of symbolic execution and constraint solving for the data part and symbolic analysis for timed aspects.

6.2.6. Ensuring security properties

6.2.6.1. Runtime enforcement monitors: composition, synthesis, and enforcement abilities

**Participant:** Yliès Falcone.

Runtime enforcement is a powerful technique to ensure that a program will respect a given set of properties. In [9] we extend previous work on this topic in several directions. Firstly, we propose a generic notion of enforcement monitors based on a memory device and finite sets of control states and enforcement operations. Moreover, we specify their enforcement abilities w.r.t. the general Safety-Progress classification of properties. Furthermore, we propose a systematic technique to produce a monitor from the automaton recognizing a given safety, guarantee, obligation or response property. Finally, we show that this notion of enforcement monitors is more amenable to implementation and encompasses previous runtime enforcement mechanisms.

6.2.6.2. What can you verify and enforce at runtime?

**Participant:** Yliès Falcone.

The underlying property, its definition and representation play a major role when monitoring a system. Having a suitable and convenient framework to express properties is thus a concern for runtime analysis. It is desirable to delineate in this framework the sets of properties for which runtime analysis approaches can be applied to. [8] presents a unified view of runtime verification and enforcement of properties in the Safety-Progress classification. Firstly, we extend the Safety-Progress classification of properties in a runtime context. Secondly, we characterize the set of properties which can be verified (monitorable properties) and enforced (enforceable properties) at runtime. We propose in particular an alternative definition of ”property monitoring” to the one classically used in this context. Finally, for the delineated sets of properties, we define specialized verification and enforcement monitors.

6.3. Control synthesis

6.3.1. Controllers for probabilistic systems

**Participant:** Nathalie Bertrand.

*Partially Observable Markov Decision Processes (POMDP for short)* have been extensively studied in several research communities, among which AI and model-checking. In [16] we address the problem of the *minimal information* a user needs at runtime to achieve a simple goal, modeled as reaching an objective with probability one. More precisely, to achieve her goal, the user can either choose at each step to use partial information only, or pay a fixed cost and receive full information. The natural question is then to minimize the cost the user needs to fulfill its objective. This optimization question gives rise to two different problems, whether we consider to minimize the *worst case cost*, or the *average cost*. On the one hand, concerning the worst case cost, we show that efficient techniques from the model checking community can be adapted to compute the optimal worst case cost and give optimal strategies for the users. On the other hand, we show that the optimal average price (a question typically considered in the AI community) cannot be computed in general, nor can it be approximated in polynomial time even up to a large approximation factor.
6.3.2. Supervisory control for synchronous systems

6.3.2.1. Controller synthesis and programming language

Participant: Hervé Marchand.

In [24], we define a mixed imperative/declarative programming language: declarative contracts are enforced upon imperatively described behaviors. We rely on the notion of Discrete Controller Synthesis (DCS), a formal technique stemming from control theory and the supervisory control of discrete event systems. We target the application domain of adaptive and reconfigurable computing systems: our language can serve programming closed-loop adaptation controllers, enabling flexible execution of functionalities w.r.t. changing resource and environment conditions. We give a synthetic presentation of the language, its semantics and compilation, and we illustrate its use with the example of a robot system.

6.3.2.2. Symbolic supervisory control of infinite transition systems under partial observation using abstract interpretation

Participant: Hervé Marchand.

In [11], we propose algorithms for the synthesis of state-feedback controllers with partial observation of infinite discrete state systems modeled by Symbolic Transition Systems. We provide models of safe memoryless controllers both for potentially deadlocking and deadlock free controlled systems. The termination of the algorithms solving these problems is ensured using abstract interpretation techniques which provide an overapproximation of the transitions to disable. We then extend our algorithms to controllers with memory and to online controllers. We also propose improvements in the synthesis of controllers in the finite case which, to our knowledge, provide more permissive solutions than what was previously proposed in the literature. Our tool SMACS gives an empirical validation of our methods by showing their feasibility, usability and efficiency.

6.3.2.3. Decentralized control of infinite systems

Participant: Hervé Marchand.

In [10], we propose algorithms for the synthesis of decentralized state-feedback controllers with partial observation of infinite state systems, which are modeled by Symbolic Transition Systems. We first consider the computation of safe controllers ensuring the avoidance of a set of forbidden states and then extend this result to the deadlock free case. The termination of the algorithms solving these problems is ensured by the use of abstract interpretation techniques, but at the price of overapproximations, in particular, in the computation of the states which must be avoided. We then extend our algorithms to the case where the system to be controlled is given by a collection of subsystems (modules). This structure is exploited to locally compute a controller for each module. Our tool SMACS gives an empirical evaluation of our methods by showing their feasibility, usability and efficiency.

6.3.2.4. Polychronous controller synthesis from MARTE CCSL timing specifications

Participant: Hervé Marchand.

The UML Profile for Modeling and Analysis of Real-Time and Embedded systems (MARTE) defines a mathematically expressive model of time, the Clock Constraint Specification Language (CCSL), to specify timed annotations on UML diagrams and thus provides them with formally defined timed interpretations. Thanks to its expressive capability, the CCSL allows for the specification of static and dynamic properties, of deterministic and non-deterministic behaviors, or of systems with multiple clock domains. Code generation from such multicked specifications (for the purpose of synthesizing a simulator, for instance) is known to be a difficult issue. We address it in [23] by using the approach of controller synthesis. In our framework, a timed CCSL specification is regarded as a property whose satisfaction should be enforced for any UML diagram carrying it as annotation. To do so, CCSL statements are first translated into dynamical polynomial systems. Such systems can be manipulated using the model-checker Sigali to synthesize an executable property (a controller) which enforces the satisfaction of the specified timing constraints on the UML diagram with which it is executed.
6.3.3. Control of distributed systems

Participant: Hervé Marchand.

In this work, we consider the control of distributed systems composed of subsystems communicating asynchronously; the aim is to build local controllers that restrict the behavior of a distributed system in order to satisfy a global state avoidance property. We model our distributed systems as communicating finite state machines with reliable unbounded FIFO queues between subsystems. Local controllers can only observe the behavior of their local subsystem and do not see the queue contents. To refine their control policy, the controllers can use the FIFO queues to communicate by piggybacking extra information (some timestamps and their state estimates) to the messages sent by the subsystems [21]. We provide an algorithm that computes, for each local subsystem (and thus for each controller), during the execution of the system, an estimate of the current global state of the distributed system. The local estimate is updated at each message reception. We then define synthesis algorithms allowing to compute the local controllers. Our method relies on the computation of (co)reachable states. Since the reachability problem is undecidable in our model, we use abstract interpretation techniques to obtain regular overapproximations of the possible FIFO queue contents, and hence of the possible current global states. An implementation of our algorithms provides an empirical evaluation of our method [22].
5. New Results

5.1. Analysis of structures resulting from meristem activity

5.1.1. Acquisition and design of plant geometry

Participants: Chakkrit Preuksakarn, Frédéric Boudon, Christophe Pradal, Christophe Godin.

This research theme is supported by RTRA and ARC projects named PlantScan3D.

Virtual 3D model of plants are required in many areas of plant modeling. They can be used for instance to simulate physical interaction of real plant structures with their environment (light, rain, wind, pests, ...), to set up initial conditions of growth models or to assess their output against real data. In the past decade, methods have been developed to digitize plant architectures in 3D [42], [33]. These methods are based on direct measurements of position and shape of every plant organ in space. Although they provide accurate results, they are particularly time consuming. More rapid and automated methods are now required in order to collect plant architecture data of various types and sizes in a systematic way. In this aim, we explore the use of pictures, video, laser scanner and direct sketching.

• Reconstruction of plant architecture from 3D laser scanner data. (Chakkrit Preuksakarn, Mathilde Balduzzi, Frédéric Boudon, Jean-Baptiste Durand, Christophe Godin, Xinghua Song [INRIA, Galaad], Bernard Mourrain [INRIA, Galaad], Dobrina Boltcheva [INRIA, Imagine], Franck Hetroy [INRIA, Morpheus], Marie-Paule Cani [Inria, Imagine], Pascal Ferraro [Labri, Bordeaux] )

We investigate the possibility to use 3D laser scanners to automate plant digitizing. We are developing algorithms to reconstruct branching systems without leaves or foliage from scanner data or from scan simulated on plant mock-up obtained using different digitizing method. For this we collaborate with the EPI Galaad from Sophia-Antipolis, the EPI Imagine from Grenoble, different INRA teams, UMR PIAF in Clermont Ferrand, UMR LEPSE and AFEF team in Montpellier and Lusignan, the University of Helsinki, Finland and the CFCC in England.

We developed a reconstruction pipeline composed of several procedures. A contraction procedure, first aggregates points at the center of the point cloud. The team proposed a simple adaptive scheme to contract points. In parallel, the Galaad team explored uses of detection of circular patterns to be contracted toward their center. Comparison of these approaches has been carried out. In a second step, a skeleton procedure uses a Space Colonization Algorithm [41] to build the skeleton of the shape from the contracted point set. This method is adaptive to the local density of the point set. Then a pipe-model based procedure makes it possible to estimate locally diameters of the branches. Finally, an evaluation procedure has been designed to assess the accuracy of the reconstruction. Results Publication of this work is in progress.

• Sketching of plants. (Frédéric Boudon, Christophe Godin, Steven Longuay [University of Calgary, Canada], Przemyslaw Prusinkiewicz [University of Calgary, Canada])

Modeling natural elements such as trees in a plausible way, while offering simple and rapid user control, is a challenge. In a first collaboration with the EPI Evasion we developed a method based on the design of plants from silhouettes [43]. This sketching paradigm allows quick and intuitive specification of foliage at multiple scales. On this topic, we started a collaboration with S. Longuay and P. Prusinkiewicz who develop iPad tools to design plants based on SCA. Combination of multitouch interface, sketching paradigm and powerful adaptive procedural model that generate realistic trees offer intuitive and flexible design tools. This work is part of the INRIA associated team with the University of Calgary.

• Reconstruction of vineyards from video. (Frédéric Boudon, Jerome Guenard [IRIT, Toulouse], Geraldine Morin [IRIT, Toulouse], Pierre Gurdjos [IRIT, Toulouse], Vincent Charvillat [IRIT, Toulouse])
In this work, we investigate the reconstruction of constrained plant geometry of a vineyard from a set of pictures coming from video. Pictures are segmented to identify the different trees of a same row in the yard. From this segmentation, a number of parameters are estimated, which makes it possible to instantiate a virtual model of a vine tree. In particular, paths of main branches and leaf volumes and densities are estimated. A preliminary version of this work has been presented to the AFIG conference [21].

- **Reconstruction of virtual fruits from pictures.** (Mik Cieslak, Nadia Bertin [Inra, Avignon], Frédéric Boudon, Christophe Godin, Christophe Pradal, Michel Genard [Inra, Avignon], Christophe Goz-Bac [Université Montpellier 2])

This research theme is supported by the Agropolis project Fruit3D.

Understanding the controlling factors of fruit quality development is challenging, because fruit quality is the result of the interplay between physical and physiological processes that are under the control of genes and the environment. Although process-based models have been used to make significant progress in understanding these factors, they to a large extent ignore the shape and internal structure of the fruit. To help characterizing effects of fruit shape and internal structure on quality, the creation of a 3D virtual fruit model that integrates fruit structure and function with growth governed by environmental inputs has been investigated. For this purpose, a modelling pipeline has been created that includes the following steps: creation of a 3D volumetric mesh of the internal and external fruit structure, calculation of the fruit’s physical properties from the resulting mesh, and integration of aspects of fruit physiology into the 3D structure. This pipeline has been applied to study tomato fruit (Solanum lycopersicum) by constructing 3D volumetric meshes from two images of perpendicular fruit slices and from MRI data, and integrating water and carbon transport processes into one of these meshes. To illustrate the tomato model, a simulation of one season’s of the fruit’s growth has been performed and its results compared with an already published process-based tomato fruit model. The results of the two models were in general agreement, but our model provided additional information on the internal properties of the fruit, such as a gradient in sugar concentration. Once the model is calibrated and evaluated, our approach will be suitable for studying the effects of internal fruit heterogeneity and overall shape on fruit quality development [18].

### 5.1.2. Modeling the plant ontogenic programme

**Participants:** Christophe Godin, Yann Guédon, Evelyne Costes, Jean-Baptiste Durand, Pascal Ferraro, Anaëlle ambreville, Christophe Pradal, Catherine Trottier, Jean Peyhardi, Yassin Refahi, Etienne Farcot.
This research theme is supported by two PhD programmes.

The remarkable organization of plants at macroscopic scales may be used to infer particular aspects of meristem functioning. The fact that plants are made up of the repetition of many similar components at different scales, and the presence of morphological gradients, e.g. [23], [35], [36], [32], provides macroscopic evidence for the existence of regularities and identities in processes that drive meristem activity at microscopic scales. Different concepts have been proposed to explain these specific organizations such as "morphogenetic programme" [38], "age state" [31] or "physiological age" [24]. All these concepts state that meristem fate changes according to position within the plant structure and during its development. Even though these changes in meristem fate are specific to each species and lead to the differentiation of axes, general rules can be highlighted [31], [24]. Here we develop computational methods to decipher these rules.

- **Branching and axillary flowering structures of fruit tree shoots.** (Yann Guédon, Evelyne Costes, David Da Silva [UC Davis], Anna Davidson [UC Davis], Ted DeJong [UC Davis], Claudia Negron [UC Davis]).

  In the context of a collaboration with Claudia Negron, Anna Davidson, David Da Silva and Ted DeJong, stochastic models (hidden semi-Markov chains) for the branching and axillary flowering structures of different categories of peach and almond shoots corresponding to different genetic backgrounds, environment conditions and horticultural practices were built. These stochastic models have been integrated in simulation systems which combine stochastic models with different mechanistic models of biological function, in particular carbon partitioning models. This collaboration extends the work initiated on apple trees [40], [3]; see 5.1.3.

- **Genetic determinisms of the alternation of flowering in apple tree progenies.** (Jean-Baptiste Durand, Jean Peyhardi, Baptiste Guitton [DAP, AFEF team], Catherine Trottier, Evelyne Costes, Yann Guédon)

  Previous approaches for a statistical quantification of the effect of factors on tree architecture were mainly oriented toward the structure of main axes, and environmental explanatory variables (see [34], [27]). To characterize genetic determinisms of the alternation of flowering in apple tree progenies at annual shoot (AS) scale, a model of the transitions between ASs was built. The ASs were of two types: flowering or vegetative. Two replications of each genotype were available. Our model operated on tree-structured data and relied on a second-order Markov tree. Generalized Linear Mixed Models (GLMMs) were used to model the effect of year, replications and genotypes (with their interactions with year or memories of the Markov model) on the transition probabilities. This work was the continuation of the Master 2 internship of Jean Peyhardi (Bordeaux 2 University) and was carried out in the context of the PhD thesis of Baptiste Guitton.

  This PhD thesis also comprised the study of alternation in flowering at individual scale, with annual time step. To relate alternation of flowering at AS and individual scales, indices were proposed to characterize alternation at individual scale. The difficulty is related to early detection of alternating genotypes, in a context where alternation is often concealed by a substantial increase of the number of flowers over consecutive years. To separate correctly base effect from alternation in flowering, our model relied on a parametric hypothesis on the base effect (random slopes specific to genotype and replications), which translated into mixed effect modeling. Different indices of alternation were then computed on the residuals. Clusters of individuals with contrasted patterns of bearing habits were identified. Our models highlighted significant correlations between indices of alternation at AS and individual scales. The roles of local alternation and asynchronism in regularity of flowering were assessed using an entropy-based criterion, which characterized asynchronism.

  As a perspective of this work, patterns in the production of children ASs (numbers of flowering and vegetative children) depending on the type of the parent AS must be analyzed using branching processes and different types of Markov trees, in the context of Pierre Fernique’s PhD Thesis.

- **Modeling branching patterns in fruit tree shoots through the characterization of their demographic properties** (Pierre Fernique, Jean-Baptiste Durand, Yann Guédon).
To test the effect of some properties of a given parent shoot on the properties of its children shoots, statistical models based on multitype branching processes were developed. This kind of dependence between parent and children shoots is frequently at stake in fruit trees, for which the number of flowering or vegetative children of a parent shoot depends on its nature, with potential interactions with other factors. Thus, controlling demographic patterns of the shoots (through varietal selection or crop management strategies) is expected to bring substantial improvements in the quantity and quality of yields.

Formally, the shoot properties are summed up using the notion of shoot state. The number of children shoots in each state is modeled through discrete multivariate distributions. Model selection procedures are necessary to specify parsimonious distributions. We developed an approach based on probabilistic graphical models to identify and exploit properties of conditional independence between numbers of children in different states, so as to simplify the specification of their joint distribution. The graph building stage was based on a Poissonian Generalized Linear Model for the contingency tables of the counts of joint children state configurations. Then, parametric families of distributions were implemented and compared statistically to provide probabilistic models compatible with the estimated independence graph.

This work was carried out in the context of Pierre Fernique’s Master 2 internship (Montpellier 2 University and AgroParisTech). It was applied to model dependencies between short or long, vegetative or flowering shoots in apple trees. The results highlighted contrasted patterns related to the parent shoot state, with interpretation in terms of alternation of flowering. This work will be continued during Pierre Fernique’s PhD thesis, with extensions to other fruit tree species (mango trees) and other strategies to build probabilistic graphical models and parametric discrete multivariate distributions including covariates and mixed effects.

- **Analyzing fruit tree phenology** (Anaëlle Dambreville, Jean-Baptiste Durand, Yann Guédon, Christophe Pradal, Pierre-Eric Lauri [UMR AGAP], Frédéric Normand [UPR HortSys], Catherine Trottier)

Mango is a tropical tree characterized by strong asynchronisms within and between trees. Causation networks explaining the vegetative and reproductive growths within and between growing cycles were studied on the basis of generalized linear models. We highlighted in this way marked interplays between structural and temporal components of tree structure development at three scales. At growth unit scale, a growth unit appeared early in the growing cycle had higher rate of burst compared to late appeared growth units. At growing cycle scale, a growth unit which flowered delayed its future vegetative growth compared to a vegetative growth unit. At tree scale, a fruiting tree delayed further vegetative growth and flowering compared to a non-fruiting tree. These results evidenced that tree phenology is strongly affected by structural components and not only by the environment.

- **Self-nested structure of plants.** (Christophe Godin, Pascal Ferraro)

To study the redundancy of structures embedded at various levels in tree architectures, we investigated the problem of approximating trees by trees with particular self-nested structures. Self-nested trees are such that all their subtrees of a given height are isomorphic. We show that these trees present remarkable compression properties, with high compression rates. In order to measure how far a tree is from being a self-nested tree, we introduced a quantitative measure of the degree of self-nestedness for any tree. For this, we want to find a self-nested tree that minimizes the distance of the original tree to the set of self-nested trees that embed the initial tree:

$$NEST(T) = \arg \min_{S \in S^+(T)} D(T, S),$$

where $T$ is a tree, $D(\cdot, \cdot)$ is a distance on the set of trees (chosen so as to preserve certain structural properties between the compared trees) and $S^+(T)$ is the set of self-nested trees that contain $T$, i.e. that can be obtained from $T$ by inserting nodes only. In a previous work we showed that this problem can be solved in polynomial time and gave the corresponding algorithm [6].
Now, we continue this work along different directions:

- **Approximate compression including geometry** (Anne-Laure Gaillard, Pascal Ferraro, Frédéric Boudon, Christophe Godin)

  We now investigate how to include branch geometry in the compression schemes. This problem constitutes a part of the PhD thesis of Anne-Laure Gaillard co-supervised with P. Ferraro. First results show that any tree architecture can be compressed at different degrees with a varying loss in the geometric information. A publication on this topic is currently in progress.

- **Search for the NST** (Farah Ben-Naoum, Christophe Godin, Pascal Ferraro)

  The NEST algorithm constructs a closest self-nested tree that embeds a given tree \( T \). This means in particular that \( T \in NEST(T) \). For some trees this definition might be too restrictive and one may want to get rid of the latter constraint. In this case, the closest self-nested tree (NST) to a tree \( T \) would be defined by:

  \[
  NST(T) = \arg \min_{S \in S(T)} D(T, S),
  \]

  where \( S(T) \) is now the set of all self-nested trees. Although it has not yet been demonstrated, the computation of \( NST(T) \) is likely to be a NP-complete problem. Therefore we decided to develop a heuristic algorithm to carry out this optimization. This algorithm is based on evolutionary optimization algorithms. First results obtained at the University of Sidi Bel Abbes by Farah Ben Naoum are very encouraging. They should contribute to define a general method to compress tree-like structures based on self-similarity.

- **Stochastic NESTs** (Jean-Baptiste Durand, Christophe Godin, Pascal Ferraro, Yann Guédon)

  One of the limits of the original NEST algorithm in defining a compressed structure is that it does not take into account possible small variations in the identification of similar tree patterns in the global tree structure. In real trees, it is however seldom the case that similar tree parts are exactly isomorphic. They may differ by small details while keeping globally similar. A general compression technique should account for such variations from a theoretical point of view. This is what we intend to do here by developing a stochastic NEST approach. The idea is to extend the definition of tree compression to include the notion of tree distribution in compressed representations of trees. A first formalism has been designed for stochastic tree compression.

  - **Statistical characterization of the branching properties of trees at individual scale – application to the quantification of approximate self-nestedness.** (Jean-Baptiste Durand, Yann Guédon, Christophe Godin)

    To test different hypotheses related to the role of apical control on local branching properties within tree architecture, statistical models of the fates of the apical meristem and its production at a given scale were specified. They extend the hidden Markov tree models \([29]\) to variable number of children of a given entity, and provide a model for their dependencies. Moreover, they allow for the comparison of different hypotheses regarding the relevance of the children ordering (absence of ordering, partial or total ordering). In the next years, these models will be used on mango and apple tree cultivars. Particularly, they will found new approaches to compare the effect of various strategies of culture.

    These models are based on a notion of state that extends the concept of equivalence classes for tree isomorphism used in the above paragraph, to the notion of classes of approximate isomorphism (i.e. isomorphism as a stochastic process). As a consequence, the hidden Markov tree models offer new insight for lossy compression of trees, which will be investigated in future work.

  - **Analyzing perturbations in Arabidopsis thaliana phyllotaxis.** (Yann Guédon, Yassin Refahi, Etienne Faricot, Christophe Godin, Fabrice Besnard [RDP, Lyon], Teva Vernoux [RDP, Lyon])
The cytokinin hormones are known to play a significant role in the regulation of phyllotaxis. To investigate this, Fabrice Besnard and Teva Vernoux are studying Arabidopsis thaliana ahp6 mutants, AHP6 being a protein known for its inhibitory effect in the cytokinin signaling pathway. At the macroscopic scale, this mutation induces perturbations of the phyllotaxis, barely sensible on single plants. In order to characterize these perturbations, we designed a pipeline of models and methods [20] which decompose into three steps: (i) identification of perturbation patterns, (ii) characterization of perturbation patterns using hidden variable-order Markov chains and combinatorial mixture models both with von Mises observation distributions (Gaussian-like periodic distribution for circular variables), (iii) classification of plant phyllotaxis among wild-type and ahp6 mutant phyllotaxies.

Using this pipeline of methods, we have shown that the perturbation patterns in both wild-type and mutant plants can be explained by permutations in the order of insertion along the stem of 2 or 3 consecutive organs. The number of successive synchronized organs between two permutations reveals unexpected patterns that depend on the nature of the preceding permutation (2- or 3-permutation). We identified significant individual deviations of the level of baseline segments with reference to 137.5°, which confirms theoretical model predictions. Finally, we highlighted a marked relationship between permutation of organs and defects in the elongation of the internodes in between these organs. All these results can be explained by the absence of a strict coupling between the timing of organ development and their angular and longitudinal position on the stem. A paper about these results is in revision for the journal Science. Another more methodological paper is in progress.

5.1.3. Analyzing the influence of the environment on the plant ontogenic programme

Participants: Jean-Baptiste Durand, Damien Funey, Frédéric Boudon, Christophe Godin, Yann Guédon, Jean Peyhardi, Pierre Fernique, Christian Cilas, Evelyne Costes, Pascal Ferraro, Catherine Trottier.

This research theme is supported by a CIFRE contract and two PhD programmes.

The ontogenetic programme of a plant is actually sensitive to environmental changes. If, in particular cases, we can make the assumption that the environment is a fixed control variable (see section 5.1.2), in general the structure produced by meristem results from a tight interaction between the plant and its environment, throughout its lifetime. Based on observations, we thus aim to trace back to the different components of the growth (ontogenetic development and its modulation by the environment). This is made using two types of approaches. On the one hand, we develop a statistical approach in which stochastic models are augmented with additional time-varying explanatory variables that represent the environment variations. The design of estimation procedures for these models make it possible to separate the plant ontogenetic programme from its modulation by the environment. On the other hand, we build reactive models that make it possible to simulate in a mechanistic way the interaction between the plant development and its environment.

- Analyzing growth components in trees. (Yann Guédon, Jean-Baptiste Durand, Jean Peyhardi, Yves Caraglio [AMAP], Emilie Lebarbier [AgroParisTech], Catherine Trottier, Olivier Taugourdeau [AMAP])

Observed growth, as given for instance by the length of successive annual shoots along a forest tree trunk, is assumed to be mainly the result of three components: (i) an endogenous component assumed to be structured as a succession of roughly stationary phases separated by marked change points that are asynchronous between individuals [34], (ii) a time-varying environmental component assumed to take the form of fluctuations that are synchronous between individuals, (iii) an individual component corresponding to the local environment of each tree. This environmental component is thus assumed to be a "population" component as opposed to the individual component. In order to identify and characterize these three components, we proposed to use Markov and semi-Markov switching linear mixed models [27] [2]. The underlying Markov or semi-Markov chain represents the succession of growth phases (endogenous component) while the linear mixed model attached to each state of the underlying Markov or semi-Markov chain represents - in the corresponding growth phase - both the influence of time-varying climatic explanatory variables (environmental component) as fixed effects, and inter-individual heterogeneity (individual component) as random effects. We
investigated the estimation of Markov and semi-Markov switching linear mixed models in a general framework using MCEM-like algorithms. These integrative statistical models were in particular applied in a forest ecology context to characterize the opportunistic development of understory samplings in relation to light environment [15]. Concerning the application to forest trees, the proposed statistical modeling approach relies on the availability of climatic data. In the case where climatic data are not available, we are studying Markov and semi-Markov switching linear mixed models with year random effects common to all the trees to model the synchronous part of the growth fluctuations. With Markov and semi-Markov switching linear mixed models, the response variable is constrained to be approximately normally distributed. We are now studying the statistical methodology for Markov and semi-Markov switching generalized linear mixed models to take into account non-normally distributed response variables (e.g. number of growth units, apex death/life, non-flowering/flowering character). It should be noted that the estimation algorithms proposed for Markov switching linear mixed models can be directly transposed to other families of hidden Markov models such as, for instance, hidden Markov tree models; see Section 5.1.2.

- **Coupling stochastic models with mechanistic models for plant development simulation.** (Damien Fumey, Yann Guédon, Christophe Godin, Thomas Cokelaer, Evelyne Costes, Pierre-Eric Lauri [UMR AGAP])

Arboricultural practices such as pruning, artificial bending or fruit thinning are crucial interventions in orchard management and are used for controlling tree size, penetration of light into the canopy and the equilibrium between vegetative and reproductive growth. In the PhD of Damien Fumey we explored the possibility of integrating such practices in a model of apple tree development. To this end, a field experiment was designed to study the effects of pruning (thinning or heading cuts) on two apple cultivars with contrasted architecture, ‘Fuji’ and ‘Braeburn’. Results of this experiment [30] showed that thinning cuts of laterals tended to be compensated by an increase in lateral branching. Based on these field experiments, a model is currently being developed to account for pruning practices on fruit trees. This model relies on a formalization of the competition of meristems by combining a carbon allocation strategy and a competition mechanism in a stochastic manner. The resulting model is reactive to human interventions and should enable us to capture plant reactions to pruning practices in a robust way [28]. A paper describing this model is currently in progress.

5.2. Meristem functioning and development

In axis 2 work focuses on the creation of a virtual meristem, at cell resolution, able to integrate the recent results in developmental biology and to simulate the feedback loops between physiology and growth. The approach is subdivided into several sub-areas of research.

5.2.1. Data acquisition and design of meristem models

**Participants:** Frédéric Boudon, Christophe Godin, Vincent Mirabet, Jan Traas, Grégoire Malandain, Jean-Luc Verdeil.

*This research theme is supported by the ATP CIRAD Meristem and the ANR GeneShape and FlowerModel projects.*

Studies on plant development require the detailed observation of the tissue structure with cellular resolution. In this context it is important to develop methods that enable us to observe the inner parts of the organs, in order to analyze and simulate their behavior. Here we focus on the apical meristems, that have been extensively studied using live imaging techniques and confocal microscopy. An important limitation of the confocal microscope lies in the data anisotropy. To overcome this limitation, we designed new protocols to achieve an accurate segmentation of the cells. Using these segmentations, a geometrical and topological representation of the meristem is built. Such representations may be used to analyze the meristem structure at cell level, to support the description of gene expression patterns and to initiate and assess virtual meristem simulations.

- **Microscopy image reconstruction and automatic lineage tracking of the growing meristem cells**
Participants: Romain Fernandez, Christophe Godin, Grégoire Malandain, Jan Traas, Pradeep Das, Vincent Mirabet.

In previous work [5], we studied the tracking of meristem cells using time-lapse confocal microscopy acquisition on early stages flowers of Arabidopsis shoot apical meristems. We designed a reconstruction method (MARS, Figure 4) and a tracking algorithm (ALT) in order to map the segmentations of the same meristem at different times, based on a network flow representation in order to solve the cell assignment problem. We validated the MARS-ALT pipeline on a four-steps time course of an early stage floral bud. In 2011, we worked to improve the robustness of the MARS-ALT pipeline. The software pipeline was completely re-engineered so as to be easily available in OpenAlea with documentation. We also designed new tests to improve the method and get high-quality results on different types of organisms.

Figure 4. Surface view of a flower meristem automatically segmented using MARS at cell resolution and a transversal cut showing the inner segmented tissues

- Design of 3D virtual maps for specifying gene expression patterns (Jérôme Chopard, Christophe Godin, Jan Traas, Françoise Monéger [ENS Lyon])

This research theme is supported the ANR GeneShape and FlowerModel projects.

To organize the various genetic, physiological, physical, temporal and positional informations, we build a spatialized and dynamic database. This database makes it possible to store all the collected information on a virtual 3D structure representing a typical organ. Each piece of information has to be located spatially and temporally in the database. Tools to visually retrieve and manipulate the information, quantitatively through space and time are being developed. For this, the 3D structure of a typical organ has been created at the different stages of development of the flower bud. This virtual structure contains spatial and temporal information on mean cell numbers, cell size, cell lineages, possible cell polarization (transporters, microtubules), and gene expression patterns. Such 3D virtual map is mainly descriptive. However, like for classical databases, specific tools make it possible to explore the virtual map according to main index keys, in particular spatial and temporal keys. Both a dedicated language and a 3D user interface are being designed to investigate and query the 3D virtual map.
A prototype version of this 3D virtual map is currently being built and is integrated in V-Plants, see figure 5 where a cell-based volumic tissue that can contain different types of information (cell lineage, cell size, cell identity, etc...).

![3D virtual map prototype](image)

*Figure 5. A 3D database represented as a cell-based map that can contain different types of information (cell lineage, cell size, cell identity, ...), from [14].*

Using this 3D virtual map prototype, along with piecewise-linear models of gene networks, and optimization techniques, our colleagues from ENS/Lyon have been able to develop a model of the gene network regulating sepal polarization in *A. thaliana*. This model, which is consistent with a very comprehensive literature data set, also include new predictions for certain gene interactions, and will appear next year in Plant Cell. [14]

5.2.2. Shape analysis of meristems

(Jean-Baptiste Durand, Frederic Boudon, Yann Guedon, Francois Mankessi [BURST, DAP], Olivier Monteuxis [BURST, DAP], Jean Luc Verdeil [PHIV, DAP])

Plants that grow several forms or type of leaves along a shoot, depending on age or shoot length, are called heteroblastic. The influence of heteroblasty on morphological and histocytological characteristics of *Acacia mangium* shoot apical meristems (SAMs) was assessed comparing materials with mature and juvenile leaf morphology in natural and in vitro conditions. For this we introduced a workflow for characterizing dome shape with few parameters (SAM dome heigh (H), basal diameter (D) and shape factor (S)) and their joint
statistical analysis to assess influence of conditions on SAM shape. In particular, a new statistical test is introduced here for multivariate analysis. This is a generalization of univariate ANOVA that takes into account statistical dependencies between the shape parameters. As a result, we found that SAM dome height (H) and basal diameter (D) were highly correlated. The joint analysis revealed that H, D, and shape (S) varied significantly according to the four plant origins investigated, with the higher scores for the outdoor mature source “Mat”. Overall, heteroblasty induced more conspicuous differences of SAM characteristics for the outdoor than for the in vitro materials.

5.2.3. Transport models

Participant: Michael Walker.

*This research theme is supported by the ANR GeneShape and ERASysBio+ iSAM projects.*

Active transport of the plant hormone auxin has been shown to play a key role in the initiation of organs at the shoot apex, and vein formation in both leaves and the shoot apical meristem. Polar localized membrane proteins of the PIN1 and AUX/LAX family facilitate this transport and observations and models suggest that the coherent organization of these proteins in the L1 layer is responsible for the creation of auxin maxima (surrounded by a depletion zone), which in turn triggers organ initiation close to the meristem center \[39\] \[1\]. Furthermore, canalized PIN allocations are thought to play a crucial role in vein formation in the leaf and in the L2.

Previous studies have typically modeled the L1 and L2 with different models to explain their different PIN allocations. For example \[25\] used the so-called ‘up-the-gradient’ model in the L1 to recreate the depletion zone around a maximum, and a ‘flux-mediated’ model to produce the midvein growing through the L2. A more unified approach was that of Stoma *et.al.* \[10\] who used the flux-mediated model in both tissues, but with different powers of the auxin flux, *i.e.* with a linear function in the L1 and a quadratic one in the L2.

We seek a completely unified model with no difference in the PIN allocation model. Our approach is based on inherent differences between the L1 and L2, specifically their dimensionality and the distribution of sources and sinks. We also use a flux-feedback function whose power is intermediate between one and two. For powers close to but slightly higher than one, the diffuse PIN distribution is retained in the L1 but a canalized one is formed in the L2.

We are also comparing two and three dimensional simulations to test the common approximation of three-dimensional tissues being modeled as two-dimensional. We find that source-sink models are well-approximated in two dimensions while sink- and source-driven systems show qualitatively different behavior.

A paper on this unified model is being written. This work is done in the context of the Geneshape and iSAM projects.

5.2.4. Mechanical model

Participants: Jérôme Chopard, Christophe Godin, Frédéric Boudon, Jan Traas, Olivier Hamant [ENS-Lyon], Arezki Boudaoud [ENS-Lyon].

*This research theme is supported by the ANR VirtualFlower and Geneshape projects.*

The rigid cell walls that surround plant cells is responsible for their shape. These structures are under constraint due to turgor pressure inside the cell. To study the overall shape of a plant tissue and morphogenesis, its evolution through time, we therefore need a mechanical model of cells. We developed such a model, in which walls are characterized by their mechanical properties like the Young modulus which describes the elasticity of the material. Wall deformation results from forces due to turgor pressure. Growth results from an increase in cell wall synthesis when this deformation is too high. The final shape of the tissue integrates mechanically all the local deformations of each cell.
To model this process, we used a tensorial approach to describe both tissue deformation and stresses. Deformations were decomposed into elementary transformations that can be related to underlying biological processes. However, we showed that the observed deformations does not map directly local growth instructions given by genes and physiology in each cell. Instead, the growth is a two-stage process where genes are specifying by their activity a targeted shape for each cell (or small homogeneous region) and the final cell shape results from the confrontation between this specified shape and the physical constraints imposed by the cell neighbors. Hence the final shape of the tissue results from the integration of all these local rules and constraints at organ level. This work is being described in a paper which will be submitted for publication at the beginning of 2011.

5.2.5. Gene regulatory networks

Modeling gene activities within cells is of primary importance since cell identities correspond to stable combination of gene level activity.

- **The auxin signaling pathway** (Etienne Farcot, Yann Guédon, Christophe Godin, Yassin Refahi, Jonathan Legrand, Jan Traas, Teva Vernoux)

  The auxin signalling network involves about 50 potentially interacting factors. We applied a graph clustering method [16] that relies on 0/1 interactions between factors deduced from yeast two-hybrid (Y2H) data. The Y2H analysis involves two independent tests (X-gal and HIS3 tests). Each possible interaction was tested in the two possible configurations, where each protein was alternatively the bait and the prey protein. A binary interaction is thus a summary of the four outputs of the X-gal and HIS3 tests. In order to limit the loss of information, we designed a standardization procedure to summarize the outputs of the X-gal and HIS3 tests as a distance defined on a continuous scale. This opens the possibility to studies the influence of phylogenetic distances between factors on their interactions using an extension of the mixture model for random graphs that incorporate explanatory variables. This work is the object of a collaboration with Jean-Benoist Leger and Stéphane Robin (MIA, AgroParisTech/INRA).

  As an output to this interaction extraction, it was possible to apply a clustering procedure (work of Y. Guédon and J. Legrand), based on a mixture model of random graphs. This allowed us to determine a well-founded simplified network, which was then used to develop a differential equation model. This model showed that the meristem could present well differentiated buffering abilities in its role of auxin perception, a prediction that was corroborated by experiments using a newly developed auxin sensor. The combination of computational techniques and novel experimental tools and data that were developed in this project have led to a new view of the meristem behavior, where auxin signaling, and not only its transport, plays a crucial role. These results have appeared in a systems biology journal with wide readership [16].

  As a follow up, extensions of the differential equation model are under study, with the aim of better understanding this system in more general contexts than the shoot apical meristem development.

- **Complex dynamics and spatial interactions in gene networks** (Yassin Refahi, Etienne Farcot, Christophe Godin)

  Complex computational and mathematical questions arise in the study of gene networks at two levels: (i) the single cell level, due to complex, nonlinear interactions, (ii) the tissue level, where multiple cells interact through molecular signals and growth, so that even simple local rules can challenge our intuition at higher scales.

  At the single cell level, new results were obtained in the framework of piecewise-linear models. Since their introduction in the late 1960’s, these models have been believed to present chaotic behavior in some parameter regimes. However, this was mostly observed numerically, based on intensive generation of random networks. In a collaboration between E. Farcot and R. Edwards (Univ. Victoria, Canada), with recent input from one of his students, E. Foxall, we have introduced a method to explicitly build piecewise affine models having a return map which is conjugate to a topological horseshoe. A paper presenting these results is currently in revision.
At a higher scale, we have also continued the study of gene regulation in meristematic tissues. Numerical tools for the simulation of gene network models have been further developed, in the context of Y. Refahi’s thesis. Using realistic 3D and 4D structures, reconstructed from microscopy data using the methods in [5], we have defined putative gene expression patterns in collaboration with biologist colleagues in Lyon (P. Das). We then have constructed an adimensional model with only 3 parameters, based on the existing literature [37]. Using standard optimization procedures to fit these parameters we were able to reproduced the in silico patterns with great accuracy. Moreover, alternative patterns were found, based on hypotheses of continuous deformation of gene patterns under tissue growth. These predictions remain to be tested, and this will constitute a large part of Y. Refahi’s post-doctoral project (INRA/INRIA CJS fund), in collaboration with ENS Lyon and the team of Henrik Jönsson in Lund, Sweden.

A related study has been initiated during a visit of E. Farcot at the Memorial University of Newfoundland, funded by the INRIA "Explorateur" program (see international relations section). This visit has allowed to initiate a mathematical study of gene regulated patterning in plants, with the aid of tools from equivariant dynamical systems theory, and more generally by relying on symmetry properties. Some first results have been obtained concerning homogeneous patterns in regular tissues, and their bifurcations.

5.2.6. Model integration

Participants: Mikaël Lucas, Michael Walker, Jérôme Chopard, Frédéric Boudon, Christophe Godin, Laurent Laplaze, Jan Traas, François Parcy.

This research theme is supported by the ANR/BBSRC project iSam.

Our approach consists in building a programmable tissue which is able to accept different modeling components. This includes a central data structure representing the tissue in either 2-D or 3-D, which is able to grow in time, models of gene activity and regulation, models of signal exchange (physical and chemical) between cells and models of cell cycle (which includes cell division). For each modeling component, one or several approaches are investigated in depth, possibly at different temporal and spatial scales, using the data available from the partners (imaging, gene networks, and expression patterns). Approaches are compared and assessed on the same data. The objective of each submodel component will be to provide plugin components, corresponding to simplified versions of their models if necessary, that can be injected in the programmable tissue platform.

- **Development of a computer platform for the 'programmable tissue'.** (Jérôme Chopard, Michael Walker, Frédéric Boudon, Etienne Farcot, Christophe Godin)
  
  One key aspect of our approach is the development of a computer platform dedicated to programming virtual tissue development. This platform will be used to carry out integration of the different models developed in this research axis. The platform is based on OpenAlea. Partner models can be integrated in the platform in a non-intrusive way (the code of their model need not be rewritten). In this context, model integration will i) consist of designing adequate data-structures at different levels that will be exchanged and reused among the different plug-in models and ii) defining control flows at adequate levels to avoid the burden of excessive interaction between components.

- **Design of a genetic model of inflorescence development.** (Etienne Farcot, Christophe Godin, François Parcy)
  
  At a scale involving organs and their geometric arrangement, we have developed a first model of the control of floral initiation by genes, and in particular the situation of cauliflower mutants, in which the meristem fails in making a complete transition to the flower. This work couples models at different scales, since gene regulation is described by a minimal gene network, which is used as a decision module in an L-system model of the inflorescence architecture. This coupled model has led us to hypothesize some interactions between genes and a particular plant hormone, and experiments are currently being made to verify this prediction.
VIGNES Project-Team

6. New Results

6.1. Image Segmentation, Registration and Analysis

6.1.1. Quantitative Analysis of Open Curves in Brain Imaging: Applications to White Matter Fibers and Sulci

Participants: Meena Mani, Christian Barillot.

Shape, scale, orientation and position, the four physical features associated with open curves, have different properties so the usual approach has been to design different metrics and spaces to treat them individually. We took an alternative approach using a comprehensive Riemannian framework where joint feature spaces allow for analysis of combinations of features. We can compare curves by using geodesic distances, which quantify their differences. We validated the metrics we used, demonstrated practical uses and applied the tools to important clinical problems. To begin, specific tract configurations in the corpus callosum are used to showcase clustering results that depend on the Riemannian distance metric used. This nicely argues for the judicious selection of metrics in various applications, a central premise in our work. The framework also provides tools for computing statistical summaries of curves. We represented fiber bundles with a mean and variance, which describes their essential characteristics. This is both a convenient way to work with a large volume of fibers and is a first step towards statistical analysis. Next, we designed and implemented methods to detect morphological changes, which can potentially track progressive white matter disease. With sulci, we addressed the specific problem of labeling. An evaluation of physical features and methods such as clustering leads us to a pattern matching solution in which the sulcal configuration itself is the best feature.

6.1.2. Trimmed-likelihood estimation for focal lesions and tissue segmentation in multisequence MRI for multiple sclerosis

Participants: Sylvain Prima, Christian Barillot.

Following Daniel Garcia-Lorenzo’s PhD, we proposed a new automatic method for segmentation of multiple sclerosis (MS) lesions in magnetic resonance images. The method performs tissue classification using a model of intensities of the normal appearing brain tissues. In order to estimate the model, a trimmed likelihood estimator is initialized with a hierarchical random approach in order to be robust to MS lesions and other outliers present in real images. The algorithm was first evaluated with simulated images to assess the importance of the robust estimator in presence of outliers. The method was then validated using clinical data in which MS lesions were delineated manually by several experts. Our method obtains an average Dice similarity coefficient (DSC) of 0.65, which is close to the average DSC obtained by raters (0.66) [15].

6.1.3. Segmentation of Multimodal Brain Images using Spectral Gradient and Graph Cut

Participants: Camille Maumet, Jean-Christophe Ferré, Christian Barillot.

Following Jeremy Lecoeur’s PhD, we have introduced a new and original scale-space approach for segmenting normal and pathological tissue from multidimensional images. This method can perform a joint segmentation of three complementary imaging volumes at the same time by embedding a scale-space color invariant edge detector - i.e. the spectral gradient - as the boundary term in a graph cut optimization framework. Finally, we have proposed to extend this new scheme to more than three channels. We focussed the contribution onto the segmentation of tissues or structures of interest from multi-dimensional / multi-sequences brain MRI. This new multidimensional segmentation framework has been validated on simulated data and on clinical data (both pathological and healthy brains). We have exhibited the performances of this new method on various combinations of MRI sequences for the segmentation of normal and pathological tissues and showed how it is able to out perform competitive works. This work is under submission to an international journal.
6.1.4. Adaptive pixon represented segmentation for 3D MR brain images based on mean shift and Markov random fields

Participant: Christian Barillot.

Following Lei Lin and Daniel Garcia Lorenzo’s PhDs, we proposed an adaptive pixon represented segmentation (APRS) algorithm for 3D magnetic resonance (MR) brain images. Different from traditional method, an adaptive mean shift algorithm was adopted to adaptively smooth the query image and create a pixon-based image representation. Then K-means algorithm was employed to provide an initial segmentation by classifying the pixons in image into a predefined number of tissue classes. By using this segmentation as initialization, expectation-maximization (EM) iterations composed of bias correction, a priori digital brain atlas information, and Markov random field (MRF) segmentation were processed. Pixons were assigned with final labels when the algorithm converges. The adoption of bias correction and brain atlas made the current method more suitable for brain image segmentation than the previous pixon based segmentation algorithm. The proposed method was validated on both simulated normal brain images from BrainWeb and real brain images from the IBSR public dataset. Compared with some other popular MRI segmentation methods, the proposed method exhibited a higher degree of accuracy in segmenting both simulated and real 3D MRI brain data. The experimental results were numerically assessed using Dice and Tanimoto coefficient [18].

6.1.5. EM-ICP strategies for joint mean shape and correspondences estimation: applications to statistical analysis of shape and of asymmetry

Participant: Sylvain Prima.

In collaboration with B. Combès, we proposed a new approach to compute the mean shape of unstructured, unlabelled point sets with an arbitrary number of points. This approach can be seen as an extension of the EM-ICP algorithm, where the fuzzy correspondences between each point set and the mean shape, the optimal non-linear transformations superposing them, and the mean shape itself, are iteratively estimated. Once the mean shape is computed, one can study the variability around this mean shape (e.g. using PCA) or perform statistical analysis of local anatomical characteristics (e.g. cortical thickness, asymmetry, curvature). To illustrate our method, we performed statistical shape analysis on human osseous labyrinths and statistical analysis of global cortical asymmetry on control subjects and subjects with situs inversus [29]. This work was led within the ARC 3D-MORPHINE (http://3dmorphine.inria.fr).

6.1.6. Surface-based method to evaluate global brain shape asymmetries in human and chimpanzee brains

Participant: Sylvain Prima.

Following PhD and PostDoc works from Benoit Combès and Marc Fournier, in this work we used humans and chimpanzees brain MRI databases to develop methods for evaluating global brain asymmetries. We performed brain segmentation and hemispheric surface extraction on both populations. The human brain segmentation pipeline was adapted to chimpanzees in order to obtain results of good quality. To alleviate the problems due to cortical variability we proposed a mesh processing algorithm to compute the brain global shape. Surface-based global brain asymmetries were computed on chimpanzee and human subjects using individual mid-sagittal plane evaluation and population-level mean shape estimation. Asymmetry results were presented in terms of axis-wise components in order to perform more specific evaluation and comparison between the two populations [35]. This work was led within the ARC 3D-MORPHINE (http://3dmorphine.inria.fr).

6.1.7. Computational techniques for the analysis of endocranial cast and endocranial structures

Participant: Sylvain Prima.
Following PhD and post-doc works from Benoît Combès and Marc Fournier, a series of studies were led within the ARC 3D-MORPHINE (http://3dmorphine.inria.fr) and were presented at the 1836th Journées de la Société d’Anthropologie de Paris (January 26-28) and at the 80th annual meeting of the American Association of Physical Anthropologists (April 12-16). These include: a method to assess 3D endocranial asymmetries in extant and fossil species: new insights into paleoneurology [48]; a method to map the distance between the brain and the inner surface of the skull [51], [34]; a method to compare bony labyrinths in humans, chimpanzees and baboons [28]; a method to compare endocranial shape and its relationship with ectocranial structures [41]; a new reconstruction of the frontal lobe and temporal pole of the Taung (Australopithecus africanus) endocast [32].

6.1.8. Evaluation of Registration Methods on Thoracic CT: The EMPIRE10 Challenge

Participant: Olivier Commowick.

We participated, as part of a collaboration with the Asclepios team, to the EMPIRE10 challenge on registration. EMPIRE10 (Evaluation of Methods for Pulmonary Image REGistration 2010) is a public platform for fair and meaningful comparison of registration algorithms which are applied to a database of intra-patient thoracic CT image pairs. Evaluation of non-rigid registration techniques is a non-trivial task. This is compounded by the fact that researchers typically test only on their own data, which varies widely. For this reason, reliable assessment and comparison of different registration algorithms has been virtually impossible in the past. In this work we present the results of the launch phase of EMPIRE10, which comprised the comprehensive evaluation and comparison of 20 individual algorithms from leading academic and industrial research groups. All algorithms are applied to the same set of 30 thoracic CT pairs. Algorithm settings and parameters are chosen by researchers expert in the configuration of their own method and the evaluation is independent, using the same criteria for all participants. All results are published on the EMPIRE10 website (http://empire10.isi.uu.nl). The challenge remains ongoing and open to new participants. Full results from 24 algorithms have been published at the time of writing. This article details the organisation of the challenge, the data and evaluation methods and the outcome of the initial launch with 20 algorithms. More details are available in [20].

6.2. Image processing on Diffusion Weighted Magnetic Resonance Imaging

6.2.1. Diffusion Directions Imaging (DDI)

Participants: Aymeric Stamm, Christian Barillot.

Diffusion magnetic resonance imaging (dMRI) is the reference in vivo modality to study the connectivity of the brain white matter. Images obtained through dMRI are indeed related to the probability density function (pdf) of displacement of water molecules subject to restricted diffusion in the brain white matter. The knowledge of this diffusion pdf is therefore of primary importance. Several methods have been devised to provide an estimate of it from noisy dMRI signal intensities. They include popular diffusion tensor imaging (DTI) as well as higher-order methods. These approaches suffer from important drawbacks. Standard DTI cannot directly cope with multiple fiber orientations. Higher-order approaches can alleviate these limitations but at the cost of increased acquisition time. We have proposed, in the same vein as DTI, a new parametric model of the diffusion pdf with a reasonably low number of parameters, the estimation of which does not require acquisitions longer than those used in clinics for DTI. This model also accounts for multiple fiber orientations. It is based on the assumption that, in a voxel, diffusing water molecules are divided into compartments. Each compartment is representative of a specific fiber orientation (which defines two opposite directions). In a given compartment, we further assume that water molecules that diffuse along each direction are in equal proportions. We then focus on modeling the pdf of the displacements of water molecules that diffuse only along one of the two directions. Under this model, we derive an analytical relation between the dMRI signal intensities and the parameters of the diffusion pdf. We exploit it to estimate these parameters from noisy signal intensities. We carry out a cone-of-uncertainty analysis to evaluate the accuracy of the estimation of the fiber orientations and we evaluate the angular resolution of our method. Finally, we show promising results on real data and propose a visualization of the diffusion parameters which is very informative to the neurologist. This work was conducted in collaboration with Patrick Perez from Technicolor [56].
6.2.2. **Anatomy of the corticospinal tracts: evaluation of a deterministic tractography method**  
**Participants:** Romuald Seizeur, Nicolas Wiest-Daesslé, Sylvain Prima, Camille Maumet, Jean-Christophe Ferré, Xavier Morandi.

In this work, anatomical, diffusion-weighted and functional 3T MRI were acquired on 15 right-handed healthy subjects to analyse the portions of the corticospinal tract (CST) dedicated to hand motor and sensory functions. The three MR images were then registered and regions of interest were delineated i) in the mid-brain using 3D T1-weighted MRI, and ii) in the cortex using fMRI using hand motor and sensory tasks. Deterministic tractography was then performed using these two ROIs from diffusion-weighted MRI after the diffusion tensors were computed. The ventrolateral tract fibers of the CST were generally not properly identified, due to fiber crossing in the corona radiata [55].

6.2.3. **Tracking of the Hand Motor Fibers within the Corticospinal Tract Using Functional, Anatomical and Diffusion MRI**  
**Participants:** Romuald Seizeur, Nicolas Wiest-Daesslé, Olivier Commowick, Sylvain Prima, Aymeric Stamm, Christian Barillot.

In this work, we proposed to compare three diffusion models to track the portion of the corticospinal tract dedicated to the hand motor function (called hand motor fibers hereafter), using diffusion, functional and anatomical MRI. The clinical diffusion data have few gradient directions and low b-values. In this context, we show that a newly introduced model, called diffusion directions imaging (DDI) outperforms both the DTI and the ODF models. This new model allows to capture several diffusion directions within a voxel, with only a low number of parameters. Two important results are that i) the DDI model is the only one allowing consistent tracking from the mesencephalon to the most lateral part of the cortical motor hand area, and that ii) the DDI model is the only model able to show that the number of hand motor fibers in the left hemisphere is larger than in the contralateral hemisphere for right-handed subjects; the DDI model, as the other two models, fails to find such a difference for left-handed subjects. To the best of our knowledge, this is the first time such results are reported, at least on clinical data. [44].

6.2.4. **Multifiber Deterministic Streamline Tractography Based on a New Diffusion Model**  
**Participants:** Olivier Commowick, Romuald Seizeur, Nicolas Wiest-Daesslé, Sylvain Prima, Aymeric Stamm, Christian Barillot.

In this work, we have built upon a new model, describing the random motion of water molecules in fibrous tissues, to develop a multifiber deterministic tractography algorithm. We apply this algorithm to track the corticospinal tract of the human brain, in both controls and patients with tumors. [31].

6.2.5. **Automated detection of white matter fiber bundles**  
**Participant:** Olivier Commowick.

This work is part of a collaboration with the Computational Radiology Laboratoy headed by Simon Warfield in Boston, USA. For this topic, we have studied how white matter fiber bundles can be extracted in a reproducible way from diffusion tensor MRI. Usually, white matter (WM) fiber bundles of the brain can be delineated by diffusion tractography utilizing anatomical regions-of-interest (ROI). These ROIs can specify seed regions in which tract generation algorithms are initiated. Interactive identification of such anatomical ROIs enables the detection of the major WM fiber tracts, but suffers from inter-rater and intra-rater variability, and is time consuming. We developed and compared three techniques for automated delineation of ROIs for the detection of two major WM fiber tracts in 12 healthy subjects. Tracts identified automatically were compared quantitatively to reference standard tracts derived from carefully hand-drawn ROIs. Based on comparative performance of the experimental techniques, a multi-template label fusion algorithm was found to generate tracts most consistent with the reference standard. More details on this work are available in [43].
6.3. Management of Information and Semantic Processing

6.3.1. NeuroLOG project: Sharing of data and sharing of processing tools in neuroimaging

Participants: Bernard Gibaud, Bacem Wali.

The NeuroLOG project (ANR ANR-06-TLOG-024) came to its end in December 2010. However, we managed to maintain the NeuroLOG platform in operation, which is important with regards to publication. Several papers are in preparation. A lot of efforts were devoted in 2011 to submit a new proposal to ANR, building on NeuroLOG’s achievements. A NeuroLOG2 project was submitted in March to the ANR TECSAN program (health technology). This new project aimed both at going on developing the technology for sharing data and processing tools, while being more involved in neuroimaging applications. Two application fields were proposed, concerning research on Alzheimer Disease, on the one hand, and epilepsy, on the other hand. The consortium was enlarged accordingly, with the integration of new partners such as the EDELWEISS project (INRIA, Sophia), the U642 LTSI (INSERM, Rennes) and U1028 CNRL (INSERM, Lyon). A new submission is envisaged in 2012, taking into account the recommendations of ANR.

6.3.2. Semantic annotation of anatomic images in neuroimaging

Participants: Bernard Gibaud, Tristan Moreau, Xavier Morandi.

This project aims at exploring the feasibility of relying on symbolic knowledge provided by ontologies to assist the annotation of anatomical images. The basic assumption underlying this work is that ontologies not only can provide a reference vocabulary to annotate images, but they can also provide useful prior knowledge that may help the annotation process itself, an assumption supported by the interesting results obtained by Ammar Mechouche in his PhD work. The current study, initiated in 2010 in the context of the Master student work of Elsa Magro (analysis of intra-precentral connections and of the U-fibers connecting the precentral and postcentral gyri) was pursued in 2011 (PhD work of Tristan Moreau). Our most recent works try to establish a parcellation of the grey-matter white matter surface based on the connectivity profiles of individual points of this surface, valid for a population of subjects. This is a prerequisite before identifying the more salient fiber bundles to be modelled in our ontology.

6.3.3. Semantic annotation of models and simulated medical images

Participants: Bernard Gibaud, Germain Forestier.

This project is carried out in the context of the Virtual Imaging Platform (VIP) project, an ANR project aiming at setting up a platform for facilitating the use of image simulation software in medical imaging, and coordinated by Creatis (Lyon). The platform will integrate simulation software to generate image of different modalities (i.e. MR, CT, PET, US). In this project, VISAGES is in charge of coordinating the development of an application ontology to support the annotation of the data shared in this platform (simulated images, anatomical models and physiological models used in simulations), as well as the annotation of simulation software components, in order to facilitate their interoperability within the platform. The work completed in 2011 is a continuation of what was started in 2010. Our major result in 2011 is an ontology allowing to annotate the models used for medical image simulations. Actually models are composed of files containing images (3D voxel maps) or surfaces (meshes). Our ontology includes entities called model layers associated with those files and depicting the model contents in terms of: anatomical structures, pathological structures, foreign bodies, contrast agents etc. Each individual object present in the model is referred to by an object layer part to which physical parameter distributions can be associated, that are used by simulation software. The ontology was modelled as OntoSpec documents (a methodology defined by Gilles Kassel in Amiens), then implemented in OWL. A preliminary version of this model was presented at a workshop organized by EBI in Cambridge in March 2011 (in the context of the VPH/RICORDO project). A more complete version was presented at the CBMS’2011 Conference in Bristol. VIP is a collaborative project, supported by ANR (Agence National de la Recherche), through grant ANR-AA-PPPP-000. The partners with whom we have the tightest relations are: Creatis (Lyon), I3S (Sophia), CEA-LETI (Grenoble).
6.4. Image Guided Intervention

6.4.1. Classification of Surgical Process using Dynamic Time Warping

**Participants:** Pierre Jannin, Germain Forestier, Florent Lalys, Brivael Trelhu.

Toward the creation of new computer-assisted intervention systems, Surgical Process Models (SPMs) are more and more used as a tool for analyzing and assessing surgical interventions. SPMs represent Surgical Process (SPs) which are defined as symbolic structured descriptions of surgical interventions, using a pre-defined level of granularity and a dedicated terminology. In this context, an important challenge is the creation of new metrics for the comparison and the evaluation of SPs. Thus, correlations between these metrics and pre-operative data allow to classify surgeries and highlight specific information on the surgery itself and on the surgeon, such as its level of expertise. In this study, we explored the automatic classification of a set of SPs based on the Dynamic Time Warping (DTW) algorithm. DTW allows to compute a distance between two SPs that focuses on the different types of activities performed during the surgery and their sequencing, by minimizing the time differences. Indeed, it turns out to be a complementary approach to classical methods focusing only on the time and the number of activities differences. Experiments were carried out on 24 lumbar disc herniation surgeries to discriminate the level of expertise of surgeons according to prior classification of SPs. Supervised and unsupervised classification experiments have shown that this approach was able to automatically identify groups of surgeons according to their level of expertise (senior and junior), and opens many perspectives for the creation of new metrics for surgeries comparison and evaluation. This work was performed in collaboration with Dr. Laurent Riffaud, and was published in the International Journal of Biomedical Informatics [14].

6.4.2. Surgical phases detection from microscope videos by machine learning

**Participants:** Pierre Jannin, Florent Lalys, Xavier Morandi.

Surgical process analysis and modeling is a recent and important topic aiming at introducing a new generation of computer-assisted surgical systems. Among all of the techniques already in use for extracting data from the Operating Room, the use of image videos allows automating the surgeons’ assistance without altering the surgical routine. In collaboration with Carl Zeiss Medical Systems (Oberkochen, Germany), we proposed an application-dependent framework able to automatically extract the phases of the surgery only by using microscope videos as input data and that can be adaptable to different surgical specialties. First, four distinct types of classifiers based on image processing were implemented to extract visual cues from video frames. Each of these classifiers was related to one kind of visual cue: visual cues recognizable through color were detected with a color histogram approach, for shape-oriented visual cues we trained a Haar classifier, for texture-oriented visual cues we used a bag-of-word approach with SIFT descriptors, and for all other visual cues we used a classical image classification approach including a feature extraction, selection, and a supervised classification. The extraction of this semantic vector for each video frame then permitted to classify time series using either Hidden Markov Model or Dynamic Time Warping algorithms. The framework was validated on cataract surgeries, obtaining accuracies of 95%. This work was performed in collaboration with Laurent Riffaud and was published at the ORASIS and MICCAI conferences.

6.4.3. Surgical tools recognition and pupil segmentation for cataract surgery modeling

**Participants:** Pierre Jannin, Florent Lalys.

In the above project work performed through the MS intership of David Bouget, we focus on developing an application-dependant framework able to extract surgical phases from microscope videos. The aim of this study was to enhance results of this framework by adding new visual cues extraction modules. We studied two modules: one to segment the pupil and one to extract and recognize surgical tools. Validation studies, performed with cataract surgery videos, show an increase of the framework accuracy to detect eight surgical phases. This work has been accepted at the MMVR 2012 international conference.

6.4.4. Automatic computation of electrode trajectories for Deep Brain Stimulation: a hybrid symbolic and numerical approach

**Participants:** Pierre Jannin, Florent Lalys, Camille Maumet, Claire Haegelen.
The optimal electrode trajectory is needed to assist surgeons in planning Deep Brain Stimulation (DBS). We developed and tested a method for image-based trajectory planning. Rules governing the DBS surgical procedure were defined with geometric constraints. A formal geometric solver using multimodal brain images and a template built from 15 brain MRI scans were used to identify a space of possible solutions and select the optimal one. For validation, a retrospective study of 30 DBS electrode implantations from 18 patients was performed. A trajectory was computed in each case and compared with the trajectories of the electrodes that were actually implanted. Computed trajectories had an average difference of 6.45 degrees compared with reference trajectories and achieved a better overall score based on satisfaction of geometric constraints. Trajectories were computed in 2min for each case. We demonstrated that a rule-based solver using pre-operative MR brain images can automatically compute relevant and accurate patient-specific DBS electrode trajectories. This work was published in the International Journal of Computer Assisted Radiology and Surgery.

6.4.5. Analysis of electrodes’ placement and deformation in deep brain stimulation from medical images

Participants: Pierre Jannin, Florent Lalys, Alexandre Abadie, Xavier Morandi, Claire Haegelen.

This work was performed during the internship of Maroua Mehri. Deep brain stimulation (DBS) is used to reduce the motor symptoms such as rigidity or bradykinesia, in patients with Parkinson’s disease (PD). The Subthalamic Nucleus (STN) has emerged as prime target of DBS in idiopathic PD. However, DBS surgery is a difficult procedure requiring the exact positioning of electrodes in the pre-operative selected targets. This positioning is usually planned using patients’ pre-operative images, along with digital atlases, assuming that electrode’s trajectory is linear. However, it has been demonstrated that anatomical brain deformations induce electrode’s deformations resulting in errors in the intra-operative targeting stage. In order to meet the need of a higher degree of placement accuracy and to help constructing a computer-aided-placement tool, we studied the electrodes’ deformation in regards to patients’ clinical data (i.e., sex, mean PD duration and brain atrophy index). Firstly, we presented an automatic algorithm for the segmentation of electrode’s axis from post-operative CT images, which aims to localize the electrodes’ stimulated contacts. To assess our method, we applied our algorithm on 25 patients who had undergone bilateral STNDBS. We found a placement error of 0.91±0.38 mm. Then, from the segmented axis, we quantitatively analyzed the electrodes’ curvature and correlated it with patients’ clinical data. We found a positive significant correlation between mean curvature index of the electrode and brain atrophy index for male patients and between mean curvature index of the electrode and mean PD duration for female patients. These results help understanding DBS electrode’ deformations and would help ensuring better anticipation of electrodes’ placement. This work has been accepted at the SPIE Medical Imaging 2012 conference.

6.5. Medical Image Computing in Brain Pathologies

6.5.1. Detection of cortical abnormalities in drug resistant epilepsy

Participants: Elise Bannier, Camille Maumet, Jean-Christophe Ferré, Jean-Yves Gauvrit, Christian Barillot.

Focal cortical dysplasia and heterotopias are a recognized cause of epilepsy. Indication for drug resistant epilepsy surgery relies on precise localization and delineation of the epileptogenic zone and lesion identification is an important issue. Visual detection and delineation of small or occult focal cortical dysplasia and heterotopias on MR images are sometimes difficult. The Double Inversion Recovery (DIR) imaging, by nulling white matter and cerebrospinal fluid signal, seems particularly appropriate to detect intracortical lesions in MS and Epilepsy. In this work we evaluated at 3T and using voxel-based morphometry (VBM) the ability of a 9-minute 3D DIR sequence to detect cortical and juxtacortical lesions in drug resistant epileptic patients. Results on 21 patients and 20 healthy volunteers show the potential of 3D DIR VBM to detect cortical abnormalities. Further work will investigate the use of alternate registration frameworks (e.g. DARTEL), improved intensity normalization of 3D DIR images and joint 3D T1-w/DIR analysis to improve detection sensitivity and specificity.
6.5.2. Multi-modal NMR cartography of USPIO positive and negative tissues in MS human models

**Participants:** Olivier Luong, Olivier Commowick, Christian Barillot.

The main objective of this work was to build an input object for an MRI simulator. Each voxel of the object is defined by its three physical entities which are $T_1$, $T_2$ and $\rho$ MR relaxation parameters. In our case, this object comes from Multiple Sclerosis brains. We initially defined a simplified model with respect to pathological regions, based on a combination of the Brainweb template and the lesion manually delineated from pathological images. From this, we allocated relaxation parameters for each voxels of these ROI based on fixed values of $T_1$, $T_2$ and $\rho$ (initialized from in vivo relaxometry acquisitions). This model model does not allow to obtain a fine description of the pathological regions, as potentially defined by differential contracts between USPIO and Gd enhanced images. In order to obtain this finer description, we used an MRI simulator based on the Bloch’s equations, in order to estimated the $T_1$, $T_2$ and $\rho$ parameters on each voxel from initial conditions coming from in-vivo images acquired in Rennes by using the USPIO-6 protocol.

This work is part of the VIP collaborative project, supported by ANR (Agence National de la Recherche), through grant ANR-AA-PPPP-000. The partners with whom we have the tightest relations are: Creatis (Lyon), I3S (Sophia), CEA-LETI (Grenoble).

6.6. Vascular Imaging and Arterial Spin Labelling

6.6.1. Arterial spin labeling for motor activation mapping at 3T

**Participants:** Jan Petr, Aymeric Stamm, Elise Bannier, Jean-Christophe Ferré, Jean-Yves Gauvrit, Christian Barillot.

Functional arterial spin labeling (fASL) is an innovative biomarker of neuronal activation that allows direct and absolute quantification of activation-related CBF and is less sensitive to venous contamination than BOLD fMRI. This study evaluated fASL for motor activation mapping in comparison with BOLD fMRI in terms of involved anatomical area localization, intra-individual reproducibility of location, quantification of neuronal activation, and spatial accuracy. Imaging was performed at 3T with a 32-channel coil and dedicated post-processing tools were used. Twelve healthy right-handed subjects underwent fASL and BOLD fMRI while performing a right hand motor activation task. Three sessions were performed 7 days apart in similar physiological conditions. Our results showed an activation in the left primary hand motor area for all 36 sessions in both fASL and BOLD fMRI. The individual functional maps for fASL demonstrated activation in ipsilateral secondary motor areas more often than the BOLD fMRI maps. This finding was corroborated by the group maps. In terms of activation location, fASL reproducibility was comparable to BOLD fMRI, with a distance between activated volumes of 2.1 mm and an overlap ratio for activated volumes of 0.76, over the 3 sessions. In terms of activation quantification, fASL reproducibility was higher, although not significantly, with a CVintra of 11.6% and an ICC value of 0.75. Functional ASL detected smaller activation volumes than BOLD fMRI but the areas had a high degree of co-localization. In terms of spatial accuracy in detecting activation in the hand motor area, fASL had a higher specificity (43.5%) and a higher positive predictive value (69.8%) than BOLD fMRI while maintaining high sensitivity (90.7%). The high intra-individual reproducibility and spatial accuracy of fASL revealed in the present study will subsequently be applied to pathological subjects [25].

6.6.2. Construction and evaluation of a quantitative ASL brain perfusion template at 3T

**Participants:** Jan Petr, Elise Bannier, Jean-Christophe Ferré, Jean-Yves Gauvrit, Christian Barillot.
Arterial spin labeling (ASL) allows non-invasive imaging and quantification of brain perfusion by magnetically labeling blood in the brain-feeding arteries. ASL has been used to study cerebrovascular diseases, brain tumors and neurodegenerative disorders as well as for functional imaging. The use of a perfusion template could be of great interest to study inter-subject regional variation of perfusion and to perform automatic detection of individual perfusion abnormalities. However, low spatial resolution and partial volume effects (PVE) issues inherent to ASL acquisitions remain to be solved. The purpose of this study is to enhance the template quality by using DARTEL non-rigid registration and by correcting for PVE. PICORE-Q2TIPS ASL datasets were acquired on 25 healthy volunteers at 3T. Four methods of creating the template were evaluated using leave-one-out cross correlation. Subsequently, these methods were applied to hyper-perfusion detection on functional ASL data of 8 healthy volunteers and compared with the standard generalized linear model (GLM) activation detection [40].

### 6.6.3. Evaluation of functional arterial spin labeling data using a perfusion template

Participants: Jan Petr, Elise Bannier, Jean-Christophe Ferré, Jean-Yves Gauvrit, Christian Barillot.

ASL allows non-invasive imaging and quantification of brain perfusion by magnetically labeling blood in the brain-feeding arteries. In this study, a template created from perfusion images of 25 resting healthy subjects was used to automatically detect hyper perfusion patterns of 8 other subjects. DARTEL registration was used to improve the precision of the template and partial volume correction to prevent interpolation artifacts. This study showed that a perfusion template can be used to assess task-related activation zones in functional ASL data while using only activated phase. Two assumptions can be made to explain why standard functional analysis yields slightly larger activation regions. First, the use of FWHM 6mm Gaussian kernel possibly enlarges the detected zones. Second, the data analyzed using SPM contains both resting and activated phases whereas only the activated phase was compared to the template. Future work will focus on detection of hyperperfusion in different neurodegenerative diseases taking into account registration issues of pathological T1 images. [24].

### 6.6.4. A contrario detection of focal brain perfusion abnormalities based on an ASL template

Participants: Camille Maumet, Elise Bannier, Jean-Christophe Ferré, Pierre Maurel, Christian Barillot.

Arterial Spin Labeling (ASL) is a recent MRI perfusion technique which enables quantification of cerebral blood flow (CBF). The presence of regions with atypical CBF can characterize a pathology. In brain tumors for instance, perfusion increase can be directly related to the grading of the malignant tissues. It is therefore of great interest to identify these regions in order to provide the patients with the most appropriate therapy. In this work, we proposed to detect abnormal brain perfusion by using an a contrario framework and an ASL template as a model of normal perfusion. Validation was undertaken by qualitative comparison with CBF extracted from dynamic susceptibility weighted contrast enhanced (DSC) sequence. We experimented this framework on four patients presenting brain tumors. Results show that high perfusion regions found in DSC CBF maps are correctly identified as hyperperfusions with a contrario detection. Automatic detection has clear advantages over manual delineation since it is less time-consuming, does not depend on medical expertise and allows quantification of perfusion abnormalities within the detected regions.

### 6.6.5. Peripheral angiography using non-contrast enhanced imaging

Participants: Elise Bannier, Isabelle Corouge, Nicolas Wiest-Daesslé.

Arteriography, CT and MR angiography are routinely performed in patients presenting peripheral arteriopathy. Yet, contrast agent injection is contraindicated in patients with renal insufficiency and the underlying risk of developing nephrogenic systemic fibrosis further encourages research on non-contrast enhanced MR angiography techniques (NCE MRA). In this context, we evaluated at 3T the ability of a 2 NCE MRA new sequences to reliably detect peripheral vascular abnormalities from the abdominal aorta to the calf in comparison with CE MRA.
A first study including 20 healthy volunteers and 4 patients evaluated the NCE ECG-gated T2 TSE NATIVE SPACE MRI sequence. It demonstrated its potential in noninvasively imaging peripheral vasculature, from the abdominal aorta to the calf, within a clinically acceptable acquisition duration. Although signal inhomogeneity and peristalsis artifacts were sometimes observed in the abdominal aortic station, very good image quality was obtained on all subjects on lower stations, with no venous contamination.

A second study evaluated the NCE ECG-gated Quiescent Interval Single Shot (QISS) MRA sequence. Preliminary results obtained on 11 patients show that several lesions were not detected with QISS MRA especially on the thigh station. Ongoing patient inclusions are required to confirm these results. Finally, a concomitant NCE and CE MRA reading will be performed to compare stenosis grading, stenosis-thrombosis mismatch and lesions not detected with NCE MRA.

6.7. Abnormal functional lateralization and activity of language brain areas in developmental dysphasia

**Participants:** Clément De Guibert, Camille Maumet, Jean-Christophe Ferré, Pierre Jannin, Christian Barillot.

Atypical functional lateralization and specialization for language have been proposed to account for developmental language disorders, yet results from functional neuroimaging studies are sparse and inconsistent. This functional magnetic resonance imaging study compared children with a specific subtype of specific language impairment affecting structural language, to a matched group of typically developing children using a panel of four language tasks neither requiring reading nor metalinguistic skills, including two auditory lexico-semantic tasks (category fluency and responsive naming) and two visual phonological tasks based on picture naming. Data processing involved normalizing the data with respect to a matched pairs paediatric template, groups and between-groups analysis, and laterality indices assessment within regions of interest using single and combined task analysis. Children with specific language impairment exhibited a significant lack of left lateralization in all core language regions (inferior frontal gyrus-opercularis, inferior frontal gyrus-triangularis, supramarginal gyrus and superior temporal gyrus), across single or combined task analysis, but no difference of lateralization for the rest of the brain. Between-group comparisons revealed a left hypoactivation of Wernicke’s area at the posterior superior temporal/supramarginal junction during the responsive naming task, and a right hyperactivation encompassing the anterior insula with adjacent inferior frontal gyrus and the head of the caudate nucleus during the first phonological task. This study thus provides evidence that this subtype of specific language impairment is associated with atypical lateralization and functioning of core language areas [12].
6. New Results

6.1. Physical modelling and simulation

6.1.1. Modal analysis for haptic manipulation of deformable models

Participants: Zhaoguang Wang, Georges Dumont [contact].

Real-time interaction between designer and deformable mock-up in VR (Virtual Reality) environment is a natural and promising manner to evaluate designing feasibility. Using finite element method (FEM) for solving this issue leads to high fidelity simulation but to simulation rates that do not meet the requirements (1000Hz) of real time haptic applications. We have proposed a two-stage method based on linear modal analysis. In this method, different modal subspaces, related to use scenarios, are pre-computed offline. These data are then combined online with respect to a simulation division scheme to obtain real time deformations of the parts with respect to the modal response. Two main features are developed in the method. First, we apply an adapted meshing method during the pre-computation process. This method allows to automatically switch between different modal subspaces depending on the interaction region. Second, we divide the real time deformation computation into two separate modules by extracting sub-matrixes from the pre-computed modal matrixes. This separates the haptic simulation loop from the whole deformation computation an thus preserves the haptic response. This work was presented in WINVR 2011 conference [31] is accepted for publication [8] and was the subject of the PhD Thesis of Zhaoguang Wang, that was defended in june 2011 [3].

6.1.2. Real-time mechanical simulation of brittle fracture

Participants: Loeiz Glondu, Georges Dumont [contact], Maud Marchal [contact].

Simulating brittle fracture of stiff bodies is now commonplace in computer graphics. However, simulating the deformations undergone by the bodies in a realistic way remains computationally expensive. Thus, physically-based simulation of brittle fracture in real-time is still challenging for interactive applications. We are currently working on a new physically-based approach for simulating realistic brittle fracture in real-time. Our method is composed of two main original parts: (1) a fracture initiation model based on modal analysis and a new contact force model and (2) a fracture propagation model based on a novel physically-based algorithm (Figure 2). First results of this method have been published in [32].

Adding physical properties to objects within a virtual world can not generally be handled in real-time during a simulation. For that reason, it is still difficult nowadays to physically simulate fragments of fractured objects or parts of teared/cut objects. We have proposed a method for handling the real-time physical simulations of arbitrary objects that are represented by their surface mesh. Our method is based on a pre-computed shape database in which physical data are stored for a wide variety of objects. When a query object needs to be physically simulated in the virtual world, a similarity search is performed inside the database and the associated physical data are extracted. Our approach proposes to compare three different similarity search methods that fit with our real-time needs. Our results show that our approach has a great potential for the physical simulation of arbitrary objects in interactive applications. These results have been published in the Eurographics International Workshop on Virtual Reality Interaction and Physical Simulation (Vriphys) [21].

6.1.3. Collision detection in large scale environments with High Performance Computing

Participants: Quentin Avril, Valérie Gouranton [contact], Bruno Arnaldi.
Virtual reality environments are becoming increasingly large and complex and real-time interaction level is becoming difficult to stably insure. Indeed, because of their complexity, detailed geometry and specific physical properties, these large scale environments create a critical computational bottleneck on physical algorithms. Our work focused on the first step of the physical process: the collision detection. These algorithms can sometimes have a quadratic complexity. Solving and simplifying the collision detection problem is integral to alleviating this bottleneck. Hardware architectures have undergone extensive changes in the last few years that have opened new ways to relieve this computational bottleneck. Multiple processor cores offer the ability to execute algorithms in parallel on one single processor. At the same time, graphics cards have gone from being a simple graphical display device to a supercomputer. These supercomputers now enjoy attention from a specialized community dealing solely with physical simulation. To perform large scale simulations and remain generic on the runtime architecture, we proposed unified and adaptive mapping models between collision detection algorithms and the runtime architecture using multi-core and multi-GPU architectures. We have developed innovative and effective solutions to significantly reduce the computation time in large scale environments while ensuring the stability and reproducibility of results (cf. Figure 3).

We proposed a new pipeline of collision detection with a granularity of parallelism on multicore processors or multi-GPU platforms[11]. It enables simultaneous execution of different stages of the pipeline and a parallel internal to each of these steps. This was the subject of the PhD thesis of Quentin Avril[1].

6.1.4. Assessment of inverse dynamics method for muscle activity analysis

Participants: Georges Dumont [contact], Charles Pontonnier.

The use of virtual reality tools for ergonomics applications is a very important challenge. In order to improve the design of workstations, an estimation of the muscle forces involved in the work tasks has to be done. Several methods can lead to these muscle forces. In this study, we try to assess the level of confidence for results obtained with an inverse dynamics method from real captured work tasks. The chosen tasks are meat cutting tasks, well known to be highly correlated to musculoskeletal troubles appearance in the slaughter industry.

The experimental protocol consists in recording three main data during meat cutting tasks, and analyse their variation when some of the workstation design parameters are changing [26].

1. External (cutting)force data: for this purpose, a 3D instrumented knife has been designed in order

Figure 3. Simulation of moving objects with varying size. Our approach enables to perform the Broad phase step in interactive time using optimized spatial brute force algorithm. (Left: 2,000 Objects - Right: 50,000 Objects.

- to record the force applied by the subject during the task;

- Motion Capture data: for this purpose, we use a motion capture system with active markers (Visualeyez II, Phoenix Technologies, Canada);

- EMG data: several muscle activities are recorded using electromyographic electrodes, in order to compare these activities to the ones obtained from the inverse dynamics method.

Then the motion is replayed in the AnyBody modeling system (AnyBody, Aalborg, Denmark) in order to obtain muscle forces generated during the motion. A trend comparison is then done [27], comparing recorded and computed muscle activations. Results show that most of the computed activations are qualitatively close from the recorded ones (similar shapes and peaks), but quantitative comparison leads to major differences between recorded and computed activations (the trend followed by the recorded activations in regard of a workstation design parameter, such as the table height, is not obtained with the computed activations). We currently explore those results to see if the fact that co-contraction of single joints muscles is badly estimated by classical inverse dynamics method can be a reason of this issue. We also work on the co-contraction simulation in order to improve the results [28].

This work has been done in collaboration with the Center for Sensory-motor Interaction (SMI, Aalborg University, Aalborg, Denmark), particularly Mark de Zee (Associate Professor) and Pascal Madeleine (Professor). Charles Pontonnier spent a 9 months post-doctoral fellowship at SMI from December 2010 to August 2011.

6.2. Multimodal immersive interaction

6.2.1. Brain-Computer Interaction based mental state

Participants: Anatole Lécuyer [contact], Bruno Arnaldi, Laurent George, Yann Renard.

In [20], presented at IEEE EMBS conference, we have explored the use of electrical biosignals measured on scalp and corresponding to mental relaxation and concentration tasks in order to control an object in a video game as illustrated in Figure 4. To evaluate the requirements of such a system in terms of sensors and signal processing we compared two designs. The first one used only one scalp electroencephalographic (EEG) electrode and the power in the alpha frequency band. The second one used sixteen scalp EEG electrodes and machine learning methods. The role of muscular activity was also evaluated using five electrodes positioned on the face and the neck.
Results show that the first design enabled 70% of the participants to successfully control the game, whereas 100% of the participants managed to do it with the second design based on machine learning. Subjective questionnaires confirm these results: users globally felt to have control in both designs, with an increased feeling of control in the second one. Offline analysis of face and neck muscle activity shows that this activity could also be used to distinguish between relaxation and concentration tasks. Results suggest that the combination of muscular and brain activity could improve performance of this kind of system. They also suggest that muscular activity has probably been recorded by EEG electrodes.

In [19], presented in the 5th International Brain-Computer Interface Conference, we introduce the concept of Brain-Computer Interface (BCI) inhibitor, which is meant to standby the BCI until the user is ready, in order to improve the overall performance and usability of the system. BCI inhibitor can be defined as a system that monitors user’s state and inhibits BCI interaction until specific requirements (e.g. brain activity pattern, user attention level) are met.

We conducted a pilot study to evaluate a hybrid BCI composed of a classic synchronous BCI system based on motor imagery and a BCI inhibitor (Figure 5). The BCI inhibitor initiates the control period of the BCI when requirements in terms of brain activity are reached (i.e. stability in the beta band).

Preliminary results with four participants suggest that BCI inhibitor system can improve BCI performance.

6.2.2. Navigating in virtual worlds using a Brain-Computer Interface

Participants: Anatole Lécuyer [contact], Jozef Legény.

When a person looks at a light flickering at a constant frequency, we can observe a corresponding electrical signal in their EEG. This phenomenon, located in the occipital area of the brain is called Steady-State Visual-Evoked Potential (SSVEP).
In [7] we introduce a novel paradigm for a controller using SSVEP. Compared to the state-of-the-art implementations which use static flickering targets, we have used animated and moving objects. In our example applications we have used animated butterflies flying in front of the user as shown in Figure 6. A study has revealed that, at the cost of decreased performance, this controller increases the personal feeling of presence.

These results show that integrating visual SSVEP stimulation into the environment is possible and that further study is necessary in order to improve the performance of the system.

### 6.2.3. Walking-in-place in virtual environments

**Participants:** Anatole Lécuyer [contact], Maud Marchal [contact], Léo Terziman, Bruno Arnaldi, Franck Multon.

The Walking-In-Place interaction technique was introduced to navigate infinitely in 3D virtual worlds by walking in place in the real world. The technique has been initially developed for users standing in immersive setups and was built upon sophisticated visual displays and tracking equipments. We have proposed to revisit the whole pipeline of the Walking-In-Place technique to match a larger set of configurations and apply it notably to the context of desktop Virtual Reality. With our novel “Shake-Your-Head” technique, the user has the possibility to sit down, and to use small screens and standard input devices for tracking. The locomotion simulation can compute various motions such as turning, jumping and crawling, using as sole input the head movements of the user (Figure 7).

In a second study [29] we analyzed and compared the trajectories made in a Virtual Environment with two different navigation techniques. The first is a standard joystick technique and the second is the Walking-In-Place (WIP) technique. We proposed a spatial and temporal analysis of the trajectories produced with both techniques during a virtual slalom task. We found that trajectories and users’ behaviors are very different across the two conditions. Our results notably showed that with the WIP technique the users turned more often and navigated more sequentially, i.e. waited to cross obstacles before changing their direction. However, the users were also able to modulate their speed more precisely with the WIP. These results could be used to optimize the design and future implementations of WIP techniques. Our analysis could also become the basis of a future framework to compare other navigation techniques.

### 6.2.4. Improved interactive stereoscopic rendering : SCVC

**Participants:** Jérôme Ardouin, Anatole Lécuyer [contact], Maud Marchal [contact], Eric Marchand.
Frame cancellation comes from the conflict between two depth cues: stereo disparity and occlusion with the screen border. When this conflict occurs, the user suffers from poor depth perception of the scene. It also leads to uncomfortable viewing and eyestrain due to problems in fusing left and right images.

In [10], presented at the IEEE 3DUI conference, we propose a novel method to avoid frame cancellation in real-time stereoscopic rendering. To solve the disparity/frame occlusion conflict, we propose rendering only the part of the viewing volume that is free of conflict by using clipping methods available in standard real-time 3D APIs. This volume is called the Stereo Compatible Volume (SCV) and the method is named Stereo Compatible Volume Clipping (SCVC).

Black Bands, a proven method initially designed for stereoscopic movies is also implemented to conduct an evaluation. Twenty two people were asked to answer open questions and to score criteria for SCVC, Black Bands and a Control method with no specific treatment. Results show that subjective preference and user’s depth perception near screen edge seem improved by SCVC, and that Black Bands did not achieve the performance we expected.

At a time when stereoscopic capable hardware is available from the mass consumer market, the disparity/frame occlusion conflict in stereoscopic rendering will become more noticeable. SCVC could be a solution to recommend. SCVC’s simplicity of implementation makes the method able to target a wide range of rendering software from VR application to game engine.

6.2.5. Six degrees-of-freedom haptic interaction

Participants: Anatole Lécuyer [contact], Maud Marchal [contact], Gabriel Cirio.

Haptic interaction with virtual objects is a major concern in the virtual reality field. There are many physically-based efficient models that enable the simulation of a specific type of media, e.g. fluid volumes, deformable and rigid bodies. However, combining these often heterogeneous algorithms in the same virtual world in order to simulate and interact with different types of media can be a complex task.

In [5], published at IEEE Transactions on visualization and Computer Graphics, we propose a novel approach that allows real-time 6 Degrees of Freedom (DoF) haptic interaction with fluids of variable viscosity. Our haptic rendering technique, based on a Smoothed-Particle Hydrodynamics (SPH) physical model, provides a realistic haptic feedback through physically-based forces. 6DoF haptic interaction with fluids is made possible thanks to a new coupling scheme and a unified particle model, allowing the use of arbitrary-shaped rigid bodies. Particularly, fluid containers can be created to hold fluid and hence transmit to the user force feedback coming from fluid stirring, pouring, shaking or scooping. We evaluate and illustrate the main features of our approach through different scenarios, highlighting the 6DoF haptic feedback and the use of containers.
The Virtual Crepe Factory [14] illustrates this approach for 6DoF haptic interaction with fluids. It showcases a 2-handed interactive haptic scenario: a recipe consisting in using different types of fluid in order to make a special pancake also known as "crepe". The scenario (Figure 8) guides the user through all the steps required to prepare a crepe: from the stirring and pouring of the dough to the spreading of different toppings, without forgetting the challenging flipping of the crepe. With the Virtual Crepe Factory, users can experience for the first time 6DoF haptic interactions with fluids of varying viscosity.

Figure 8. A complete use-case of our approach: a virtual crepe preparation simulator. The user manipulates a bowl (left hand, left haptic device) and a pan (right hand, right haptic device).

In [15], presented at the IEEE Virtual Reality Conference, we propose the first haptic rendering technique for the simulation and the interaction with multistate (Figure 9) media, namely fluids, deformable bodies and rigid bodies, in real-time and with 6DoF haptic feedback. The shared physical model (SPH) for all three types of media avoids the complexity of dealing with different algorithms and their coupling. We achieve high update rates while simulating a physically-based virtual world governed by fluid and elasticity theories, and show how to render interaction forces and torques through a 6DoF haptic device.

Figure 9. 6DoF haptic interaction in a medical scenario. Fluid blood pours from the deformable intestine when the user penetrates it with the rigid probe.

6.2.6. Joyman: a human-scale joystick for navigating in virtual worlds

Participants: Maud Marchal [contact], Anatole Lécuyer, Julien Pettré.
We have proposed a novel interface called Joyman (Figure 10), designed for immersive locomotion in virtual environments. Whereas many previous interfaces preserve or stimulate the users proprioception, the Joyman aims at preserving equilibrioception in order to improve the feeling of immersion during virtual locomotion tasks. The proposed interface is based on the metaphor of a human-scale joystick. The device has a simple mechanical design that allows a user to indicate his virtual navigation intentions by leaning accordingly. We have also proposed a control law inspired by the biomechanics of the human locomotion to transform the measured leaning angle into a walking direction and speed - i.e., a virtual velocity vector. A preliminary evaluation was conducted in order to evaluate the advantages and drawbacks of the proposed interface and to better draw the future expectations of such a device.

This principle of this new interface was published at international conference IEEE 3DUI [25] and a patent has been filed for the interface. A demonstration of this interface was proposed at ACM Siggraph Asia Emerging Technologies [33].

Figure 10. Prototype of the "Joyman"

6.2.7. Interactions within 3D virtual universes

Participants: Thierry Duval [contact], Valérie Gouranton [contact], Bruno Arnaldi, Laurent Aguerreche, Cédric Fleury, Thi Thuong Huyen Nguyen.

Our work focuses upon new formalisms for 3D interactions in virtual environments, to define what an interactive object is, what an interaction tool is, and how these two kinds of objects can communicate together. We also propose virtual reality patterns to combine navigation with interaction in immersive virtual environments.

We have worked upon generic interaction tools for collaboration, based on multi-point interaction. In that context we have studied the efficiency of one instance of our Reconfigurable Tangible Device, the RTD-3, for collaborative manipulation of 3D objects compared to state of the art metaphors [9]. We have setup an experiment for collaborative distant co-manipulation (figure 1) of a clipping plane inside for remotely analyzing 3D scientific data issued from an earthquake simulation.

6.3. Collaborative work in CVE’s

6.3.1. The immersive interactive virtual cabin (IIVC)

Participants: Thierry Duval [contact], Valérie Gouranton [contact], Alain Chauffaut, Bruno Arnaldi, Cédric Fleury.

We are still improving the architecture of our Immersive Interactive Virtual Cabin to improve the user’s immersion with all his real tools and so to make the design and the use of 3D interaction techniques easier, and to make possible to use them in various contexts, either for different kinds of applications, or with different kinds of physical input devices.
The IIVC is now fully implemented in our two VR platforms: OpenMASK 5.1 and Collaviz 7.1.3.

6.3.2. Generic architecture for 3D interoperability

**Participants:** Thierry Duval [contact], Valérie Gouranton, Cédric Fleury, Rozenn Bouville Berthelot, Bruno Arnaldi.

Our goal is to allow software developers to build 3D interactive and collaborative environments without bothering with the 3D graphics API they are using. This work is the achievement of the IIVC software architecture. We have proposed PAC-C3D (Figure 11), a new software architectural model for collaborative 3D applications, in order to provide a higher abstraction for designing 3D virtual objects, and in order to provide interoperability, making it possible to share a virtual universe between heterogeneous 3D viewers [17], [16].

![Figure 11. The PAC-C3D software architectural model makes interoperability possible between heterogeneous 3D viewers](image)

We also study how to offer interoperability between virtual objects that are loaded in the same virtual environment but that are described using different formats. This is why we have proposed a generic architecture for enabling interoperability between 3D formats (Figure 12), the Scene Graph Adapter [12]. Our SGA is now able to allow events coming from a 3D format to act upon data provided in another format, such as X3D events operating on Collada data [4].

6.4. Immersia Virtual Reality room

**Participants:** Georges Dumont [contact], Alain Chauffaut [contact], Ronan Gaugne [contact], Rémi Félix, Marwan Badawi, Bruno Arnaldi, Thierry Duval, Valérie Gouranton.

The team was the first in France to host a large-scale immersive virtual reality equipment known as Immersia. This platform, with full visual and sound immersion, is dedicated to real-time, multimodal (vision, sound, haptic, BCI) and immersive interaction. The Immersia platform is a key node of the European transnational VISIONAIR infrastructure and will be open in 2012 to the access of foreign research projects. It will accommodate experiments using interactive and collaborative virtual-reality applications that have multiple local or remote users. Our new wall has four faces: a front, two sides and a ground. Dimensions are 9.6 m wide, 2.9 m deep and 3.1 m height. The visual reproduction system combines eight Barco Galaxy NW12 projectors and three Barco Galaxy 7+ projectors. Visual images from Barco projectors are rendered on glass screens. They are adjusted for the user’s position, and this, together with their high resolution and homogeneous coloring, make them very realistic. The ART localization system, constituted of 16 ART-track2 cameras, enables real
Figure 12. Our architecture allows the loading of any 3D graphics format simultaneously in any available rendering engine. The scene graph adapter is an interface that adapts a scene graph (SG) of a given format into a renderer scene graph and which also allows the rendering part to request this scene graph.

objects to be located within the U-shape. Sound rendering is provided by a Yamaha processor, linked either to Genelec speakers with 10.2 format sound or Beyer Dynamic headsets with 5.1 virtual format sound, controlled by the user’s position.
6. New Results

6.1. Multimedia Models and Formats

6.1.1. SMIL timesheets

With the advent of HTML5 and its support in most popular browsers, HTML is becoming an important multimedia language. Video and audio can now be embedded in HTML pages without worrying about the availability of plugins. However, a major issue is to specify the dynamic behavior of documents (user interactions, timing and synchronization with continuous contents). This is done usually by writing (often complex) scripts, which require programming skills from the authors.

To address this issue, we have created the timesheets.js library, a scheduler that allows HTML documents to be animated and synchronized in a purely declarative way. This work is based on the SMIL Timing and Synchronization module and the SMIL Timesheets specification, with a few extensions.

The library is implemented in JavaScript, which makes it usable in any browser. Authors can specify the dynamic behavior of HTML5 (+CSS3) documents. They can thus develop multimedia applications without writing a single line of JavaScript. Timesheets can also be used with other XML document languages, such as SVG for instance. This approach was validated in a class with students learning web multimedia.

6.1.2. Multimedia content adaptation

Multimedia documents may have to be played on multiple devices such as mobile phones, tablets, desktop computers, set-top boxes, etc. Usage and platform diversity requires documents to be adapted according to execution contexts, sometimes unpredictable at design time. In a joint work with project-team Exmo, we have designed a semantic adaptation framework for multimedia documents. This framework captures the semantics of document composition and transforms the relations between media objects according to adaptation constraints.

6.2. XML Processing

Mature results about XML processing were obtained along three main directions: the formalization and implementation for checking the impact of schema evolution on validation and queries; logical extensions supporting a notion of counting and the shuffle operator in trees; and the decision of a subtyping relation for a very expressive type algebra supporting a notion of polymorphism.

In addition, preliminary results were obtained on the definition of a rigorous logical framework for the static analysis of semantic web languages, on the static analysis of cascading style sheets, and on the equipment of an IDE with new static analysis features for XQuery.

6.2.1. Impact of XML schema evolution

In the ever-changing context of the web, XML schemas continuously change in order to cope with the natural evolution of entities they describe. Schema changes have important consequences. First, existing documents valid with respect to the original schema are no longer guaranteed to fulfill the constraints described by the evolved schema. Second, the evolution also impacts programs manipulating documents whose structure is described by the original schema.

1 http://wam.inrialpes.fr/timesheets/
We have proposed a unifying framework for determining the effects of XML Schema evolution both on the validity of documents and on queries [2]. The system is very powerful in analyzing various scenarios in which forward/backward compatibility of schemas is broken, and in which the result of a query may not be anymore what was expected. Specifically, the system offers a predicate language which allows one to formulate properties related to schema evolution. The system then relies on exact reasoning techniques to perform a fine-grained analysis. This yields either a formal proof of the property or a counter-example that can be used for debugging purposes. The system has been fully implemented and tested with real-world use cases, in particular with the main standard document formats used on the web, as defined by W3C. The system identifies precisely compatibility relations between document formats. In case these relations do not hold, the system can identify queries that must be reformulated in order to produce the expected results across successive schema versions.

6.2.2. Counting in trees

A major challenge of query language design is the combination of expressivity with effective static analyses such as query containment. In the setting of XML, documents are seen as finite trees, whose structure may additionally be constrained by type constraints such as those described by an XML schema. We have considered the problem of query containment in the presence of type constraints for a class of regular path queries extended with counting and interleaving operators [1]. The counting operator restricts the number of occurrences of children nodes satisfying a given logical property. The interleaving operator provides a succinct notation for describing the absence of order between nodes satisfying a logical property. We have proposed a logic supporting these operators, which can be used to solve common query reasoning problems such as satisfiability and containment of queries in exponential time [4].

6.2.3. Typing higher-order programs

We have considered a type algebra equipped with recursive, product, function, intersection, union, and complement types together with type variables and universal quantification over them. We have defined the subtyping relation between such type expressions, and have proved its decidability[9].

This has solved an open problem that was attracting a considerable research effort. The novelty, originality and strength of our solution reside in introducing a logical modeling for the semantic subtyping framework. We have modeled semantic subtyping in a tree logic and use a satisfiability-testing algorithm in order to decide subtyping. We have shown how the subtyping relation can be decided in EXPTIME. We have reported on practical experiments made with a full implementation of the system. This has provided a powerful polymorphic type system aiming at maintaining full static type-safety of functional programs that manipulate trees, even with higher-order functions, which is particularly useful in the context of XML.

6.2.4. Detection of inconsistent paths and dead code in XML IDEs

One of the challenges in web software development is to help achieving a good level of quality in terms of code size and runtime performance, for increasingly popular domain specific languages such as XQuery. We have presented an IDE equipped with static analysis features for assisting the programmer [8]. These features are capable of identifying and eliminating dead code automatically. The tool is based on newly developed formal programming language verification techniques, which are now mature enough to be introduced in the process of software development.

6.2.5. Static analysis of semantic web languages

We work with the Exmo project-team on the static analysis of semantic web languages such as RDF, OWL and SPARQL by investigating modal logics over graphs. We seek to build a rigorous logical reasoning framework based on $\mu$-calculus adapted for the web semantic languages [7] [11]. In particular, we studied the containment problem for SPARQL queries: determining whether, for any graph, the answers to a query are contained in those of another query. Our approach consists in encoding RDF graphs as transition systems and queries as $\mu$-calculus formulas and then reducing the containment problem to testing satisfiability in the logic.
6.2.6. Static analysis of style sheets

Developing and maintaining cascading style sheets (CSS) is an important issue to web developers as they suffer from the lack of rigorous methods. Most existing means rely on validators that check syntactic rules, and on runtime debuggers that check the behavior of a CSS style sheet on a particular document instance. However, the aim of most style sheets is to be applied to an entire set of documents, usually defined by some schema. To this end, a CSS style sheet is usually written w.r.t. a given schema. While usual debugging tools help reducing the number of bugs, they do not ultimately allow to prove properties over the whole set of documents to which the style sheet is intended to be applied.

We have proposed a novel approach to fill this lack [14] by analyzing CSS style sheets using the same logic and compile-time verification technique we use for other XML problems. We have developed an original tool based on our XML Reasoning Solver (see section 5.2). The tool is capable of statically detecting a wide range of errors (such as empty CSS selectors and semantically equivalent selectors), as well as proving properties related to sets of documents (such as coverage of styling information), in the presence or absence of schema information. This new tool can be used in addition to existing runtime debuggers to ensure a higher level of quality of CSS style sheets.

6.3. Multimedia Authoring

6.3.1. C2M project

The C2M project (see section 7.2.2) aims at developing industrial solutions that allow multimedia developers to achieve mass production with high quality results. It uses the SCENARI platform for document production and we have proposed a solution for dealing with multimedia content in such a framework [16]. Indeed, automatic tools are not always sufficient for generating high quality documents; manual editing of documents in their publishing format is often necessary to tune a number of details.

Our approach consists in providing a post-editing service to allow authors to adjust their multimedia presentations directly on the final form of documents. The first step is to provide a web rendering engine based on the latest advances in web standards, as described in section 6.1.1. The second step consists in designing web-aware authoring tools based on this library, thus providing authors with direct editing services for producing high quality multimedia documents while preserving the advantages of using an XML production workflow. We have developed a prototype of this authoring tool in which all editing templates are described with XUL (XML User interface Language) and XBL (XML Binding Language) elements that we have defined for handling time-based content and widgets (timeContainer, timeNode, timeLine, etc.).

With such a solution, we can combine two worlds: a semantic-oriented authoring approach, as provided by an XML document workflow, and a direct web-based editing system. The first guarantees homogeneous rendering while the latter enables direct adjustments on the final form of the document. Bridging these two worlds is made possible by using declarative web languages (namely HTML5, SMIL and CSS) and implementing their timing part in the browser (with the Timesheets.js library, see section 6.1.1). The authoring components are directly mapped to the document structures.

6.3.2. On-line editing of multimedia web content

In cooperation with EPFL (Lausanne) we have continued to explore the concept of template-driven editing for XML multimedia contents (see section 3.3.2). This year, we have carried out more experiments with very different types of contents, including structured documents, factual data, and multimedia objects [17].

These experiments have been done with the AXEL library developed by EPFL, based on our joint work on template languages. AXEL is an innovative client-side authoring tool that runs in the browser for editing XML documents, driven by an XTiger template. It allows average web users to easily edit XML content on web servers with no specific knowledge of XML. Our experiments have shown that the template-based approach significantly enhances the ability for web users to directly feed various applications with structured content.
6.4. Augmented Environments

A large part of the research on augmented environments specializes in the use of visual media. In WAM, we focus on the use of audio media and we put a strong emphasis on mobility.

We have developed the first indoor augmented reality audio navigation application running on personal AR devices such as mobile phones. The main idea behind the development of this application was a joint use of three concepts:

- Continuous localization by using embedded sensors together with physiological models of walking and assumptions about walking in structured indoor environments.
- OpenStreetMap Indoor Mapping used for map-aided positioning, assistive routing for visually impaired people, and environmental queries through audio panoramics.
- Guidance and navigation through AR audio, both 3D and environmental, with mixing of synthetic and natural sounds and support for timely audio information presentation.

We have demonstrated that these concepts are inter-dependent [12], and that bringing them together is a way to find new solutions to problems which are difficult to tackle when looking at them separately. These three concepts are implemented with web technologies we use XML languages and XML tools for interactive audio, building modeling, and personal navigation module configuration. This enables easy authoring of sound objects or audio icons used for building sonification [15], indoor navigation maps and panoramics, and walking models. Adaptability of navigation to preferences of people is based on the concept of audio stylesheets for OpenStreetMap data rendering, XML configuration of the Pedestrian Dead Reckoning module, and assistive routing specification.

We have developed two mobile browsers and a framework for generic navigation:

1. The Mixed Reality Browser [10] that we have developed can display PoI content either remotely through panoramics with spatialized audio, or on-site by walking to the corresponding place. MRB is the only browser of geolocalized data to use a declarative XML format for PoIs, panoramics, 3D audio and to be based on HTML5 both for the iconic and full information content of PoIs. MRB can be used for any kind of augmented reality visits. A cultural heritage visit of Grenoble (see section 7.1.2) has been realized with the tourist office of Grenoble and the CCSTI (Centre de Culture Scientifique Technique et Industrielle de Grenoble).

2. The Pedestrian Way Browser that we have developed can be used for indoor-outdoor navigation with assistive audio technology for visually impaired people on pedestrian ways with precise geospatial description. Its main characteristic is to be based entirely on the OpenStreetMap XML format for the representation of the route. We anticipate that in the context of the european project Venturi (see section 7.3.1), we will have a convergence of the MRB and PWB, allowing visually impaired people to undertake cultural heritage visit. An demonstration showing the use of the PWB in a structured outdoor environment is available online: http://www.youtube.com/watch?v=h2b8yfCauZ8

3. We have created an extensible client-server framework named TARA which allows navigation on an OpenStreetMap XML graph (indoor and outdoor) by computing routes in real-time. User preferences, like stairs versus lift, are supported through a ponderation of paths in the routing algorithm. The client is an HTML5 running in the browser on mobiles and desktop computers. It can therefore be used for simulation, to test or learn a route before the navigation in the real world. The user interface is based on three modalities, touch, audio and visual and can be operated by visually impaired people through VoiceOver using only touch and audio. Localization through embedded or external sensors is not mandatory as step by step instructions can be accessed through touch modality. The server is a full REST server (Sling-Apache) giving priority to the representation of geospatial resources and allowing environmental queries through the use of XQuery.
WILLOW Project-Team

6. New Results

6.1. 3D object and scene modeling, analysis, and retrieval

6.1.1. Quantitative image analysis for archeology

Participants: Bryan Russell, Jean Ponce, Josef Sivic, Helene Dessales [ENS Archeology laboratory].

Figure 1. (a) Example photographs captured of the Pompeii site (563 photographs are used in total), (b) Rendered viewpoints of the recovered 3D model. Notice the fine-level details that are captured by the model.

Accurate indexing and alignment of images is an important problem in computer vision. A successful system would allow a user to retrieve images with similar content to a query image, along with any information associated with the image. Prior work has mostly focused on techniques to index and match photographs depicting particular instances of objects or scenes (e.g. famous landmarks, commercial product labels, etc.). This has allowed progress on tasks, such as the recovery of a 3D reconstruction of the depicted scene.

However, there are many types of images that cannot be accurately aligned. For instance, for many locations there are drawings and paintings made by artists that depict the scene. Matching and aligning photographs, paintings, and drawings is extremely difficult due to various distortions that can arise. Examples include perspective and caricature distortions, along with errors that arise due to the difficulty of drawing a scene by hand.

In this project, we seek to index and align a database of images, paintings, and drawings. The focus of our work is the Championnet house in the Roman ruins at Pompeii, Italy. Given an alignment of the images, paintings, and drawings, we wish to explore tasks that are of interest to archaeologists and curators who wish to study and preserve the site. Example applications include: (i) digitally restoring paintings on walls where the paintings have disappeared over time due to erosion, (ii) geometrically reasoning about the site over time through the drawings, (iii) indexing and searching patterns that exist throughout the site.
Figure 2. Final alignment between the paintings and 3D model. For each example, left: painting; middle: 3D model contours projected onto painting; right: synthesized viewpoint from 3D model using recovered camera parameters. For the examples in (a-c), note how the final alignment is close to the painting. Our system handles paintings that depict the 3D structure of the scene over time and span different artistic styles and mediums (e.g. water colors, cross-hatching, copies of originals on engravings). Notice how the site changes over time, with significant structural changes (e.g. the wall murals decay over time, the columns change). Example failure cases are shown in (d,e).
Recently, we have addressed the problem of automatically aligning historical architectural paintings with 3D models obtained using multi-view stereo technology from modern photographs. This is a challenging task because of the variations in appearance, geometry, color and texture due to environmental changes over time, the nonphotorealistic nature of architectural paintings, and differences in the viewpoints used by the painters and photographers. Our alignment procedure consists of two novel aspects: (i) we combine the gist descriptor with the view-synthesis/retrieval of Irschara et al. to obtain a coarse alignment of the painting to the 3D model, and (ii) we have developed an ICP-like viewpoint refinement procedure, where 3D surface orientation discontinuities (folds and creases) and view-dependent occlusion boundaries are rendered from the automatically obtained and noisy 3D model in a view-dependent manner and matched to gPB contours extracted from the paintings. We demonstrate the alignment of XIXth Century architectural watercolors of the Casa di Championnet in Pompeii with a 3D model constructed from modern photographs using the PMVS public-domain multi-view stereo software. Figure 1 shows some of the captured photographs and snapshots of the 3D reconstruction of the site. Notice that the 3D reconstruction captures much detail of the walls and structures. Example painting to 3D model alignments are shown in figure 2.

This work resulted in a workshop publication [16].

6.1.2. Visual localization by linear combination of image descriptors

Participants: Josef Sivic, Akihiko Torii [Tokyo Institute of Technology], Tomas Pajdla [CTU in Prague].

In this work, we seek to predict the GPS location of a query image given a database of images localized on a map with known GPS locations. The contributions of this work are three-fold: (1) we formulate the image-based localization problem as a regression on an image graph with images as nodes and edges connecting close-by images; (2) we design a novel image matching procedure, which computes similarity between the query and pairs of database images using edges of the graph and considering linear combinations of their feature vectors. This improves generalization to unseen viewpoints and illumination conditions, while reducing the database size; (3) we demonstrate that the query location can be predicted by interpolating locations of matched images in the graph without the costly estimation of multi-view geometry. We demonstrate benefits of the proposed image matching scheme on the standard Oxford building benchmark, and show localization results on a database of 8,999 panoramic Google Street View images of Pittsburgh.

This work resulted in a publication [18].

6.2. Category-level object and scene recognition

6.2.1. Task-Driven Dictionary Learning

Participants: Julien Mairal, Jean Ponce, Francis Bach [INRIA SIERRA].

Modeling data with linear combinations of a few elements from a learned dictionary has been the focus of much recent research in machine learning, neuroscience and signal processing. For signals such as natural images that admit such sparse representations, it is now well established that these models are well suited to restoration tasks. In this context, learning the dictionary amounts to solving a large-scale matrix factorization problem, which can be done efficiently with classical optimization tools. The same approach has also been used for learning features from data for other purposes, e.g., image classification, but tuning the dictionary in a supervised way for these tasks has proven to be more difficult. In this paper, we present a general formulation for supervised dictionary learning adapted to a wide variety of tasks, and present an efficient algorithm for solving the corresponding optimization problem. Experiments on handwritten digit classification, digital art identification, nonlinear inverse image problems, and compressed sensing demonstrate that our approach is effective in large-scale settings, and is well suited to supervised and semi-supervised classification, as well as regression tasks for data that admit sparse representations.

This work has resulted in a publication [4].

6.2.2. Ask the locals: multi-way local pooling for image recognition

Participants: Y-Lan Boureau, Jean Ponce, Nicolas Le Roux [INRIA SIERRA], Francis Bach [INRIA SIERRA], Yann LeCun [New York University].
Invariant representations in object recognition systems are generally obtained by pooling feature vectors over spatially local neighborhoods. But pooling is not local in the feature vector space, so that widely dissimilar features may be pooled together if they are in nearby locations. Recent approaches rely on sophisticated encoding methods and more specialized codebooks (or dictionaries), e.g., learned on subsets of descriptors which are close in feature space, to circumvent this problem. In this work, we argue that a common trait found in much recent work in image recognition or retrieval is that it leverages locality in feature space on top of purely spatial locality. We propose to apply this idea in its simplest form to an object recognition system based on the spatial pyramid framework, to increase the performance of small dictionaries with very little added engineering. State-of-the-art results on several object recognition benchmarks show the promise of this approach.

This work has resulted in a publication [7].

### 6.2.3. A Graph-matching Kernel for Object Categorization

**Participants:** Olivier Duchenne, Armand Joulin, Jean Ponce.

This paper addresses the problem of category-level image classification. The underlying image model is a graph whose nodes correspond to a dense set of regions, and edges reflect the underlying grid structure of the image and act as springs to guarantee the geometric consistency of nearby regions during matching. A fast approximate algorithm for matching the graphs associated with two images is presented. This algorithm is used to construct a kernel appropriate for SVM-based image classification, and experiments with the Caltech 101, Caltech 256, and Scenes datasets demonstrate performance that matches or exceeds the state of the art for methods using a single type of features.

This work has resulted in an ICCV 2011 publication [9] (oral presentation).

### 6.2.4. A Tensor-Based Algorithm for High-Order Graph Matching

**Participants:** Olivier Duchenne, Jean Ponce, Francis Bach [INRIA SIERRA], Inso Kweon [KAIST, Korea].

This paper addresses the problem of establishing correspondences between two sets of visual features using higher-order constraints instead of the unary or pairwise ones used in classical methods. Concretely, the corresponding hypergraph matching problem is formulated as the maximization of a multilinear objective function over all permutations of the features. This function is defined by a tensor representing the affinity between feature tuples. It is maximized using a generalization of spectral techniques where a relaxed problem is first solved by a multi-dimensional power method, and the solution is then projected onto the closest assignment matrix. The proposed approach has been implemented, and it is compared to state-of-the-art algorithms on both synthetic and real data.

This work has resulted in a PAMI publication [2].

### 6.2.5. Clusterpath: an algorithm for clustering using convex fusion penalties

**Participants:** Armand Joulin, Toby Hocking [INRIA SIERRA], Francis Bach [INRIA SIERRA], Jean-Philippe Vert [Mines ParisTech].

We present a new clustering algorithm by proposing a convex relaxation of hierarchical clustering, which results in a family of objective functions with a natural geometric interpretation. We give efficient algorithms for calculating the continuous regularization path of solutions, and discuss relative advantages of the parameters. Our method experimentally gives state-of-the-art results similar to spectral clustering for non-convex clusters, and has the added benefit of learning a tree structure from the data.

This work has resulted in a publication [10].

### 6.2.6. An MRF model for binarization of natural scene text

**Participants:** Karteek Alahari, Anand Mishra [IIT India], C.V. Jawahar [IIT India].
Scene text recognition has gained significant attention from the computer vision community in recent years. Recognizing text in the wild is a challenging problem, even more so than the recognition of scanned documents. In this work, we focus on the problem of cropped word recognition. We present a framework that exploits both bottom-up and top-down cues. The bottom-up cues are derived from individual character detections from the image. We build a Conditional Random Field model on these detections to jointly model the strength of the detections and the interactions between them. We impose top-down cues obtained from a lexicon-based prior, i.e. language statistics, on the model. The optimal word represented by the text image is obtained by minimizing the energy function corresponding to the random field model.

We show very significant improvements in accuracies on two challenging public datasets, namely Street View Text (over 15%) and ICDAR 2003 (over 10%).

This work has resulted in a publication [12].

6.2.7. Strongly-supervised deformable part model for object detection

Participants: Hossein Azizpour [KTH Stockholm], Ivan Laptev, Stefan Carlsson [KTH Stockholm].

Deformable part models achieve state-of-the-art performance for object detection while relying on the greedy initialization during training. The goal of this paper is to investigate limitations of such initialization and to improve the model for the case when part locations are known at the training time. To this end, we deploy part-level supervision and demonstrate improved detection results when learning models with manually-initialized part locations. We further explore the benefits of the strong supervision and learn model structure by minimizing the variance among adjacent model parts. Our method can simultaneously handle samples with and without part-level annotation making benefit even from a fraction of fully-annotated training samples. Experimental results are reported for the detection of six animal classes in PASCAL VOC 2007 and 2010 datasets. We demonstrate significantly improved performance of our model compared to the state-of-the-art LSVM object detector and poselet detector. Example learnt models are shown in figure 3.

This work has resulted in a submission to CVPR 2012.

6.2.8. Exploiting Photographic Style for Category-Level Image Classification by Generalizing the Spatial Pyramid

Participant: Jan van Gemert [University of Amsterdam].

This paper investigates the use of photographic style for category-level image classification. Specifically, we exploit the assumption that images within a category share a similar style defined by attributes such as colorfulness, lighting, depth of field, viewpoint and saliency. For these style attributes we create correspondences across images by a generalized spatial pyramid matching scheme. Where the spatial pyramid groups features spatially, we allow more general feature grouping and in this paper we focus on grouping images on photographic style. We evaluate our approach in an object classification task and investigate style differences between professional and amateur photographs. We show that a generalized pyramid with style-based attributes improves performance on the professional Corel and amateur Pascal VOC 2009 image datasets.

This work has resulted in a publication [20].

6.2.9. Generalized Fast Approximate Energy Minimization via Graph Cuts: Alpha-Expansion Beta-Shrink Moves

Participants: Karteek Alahari, Mark Schmidt [INRIA SIERRA].

We present alpha-expansion beta-shrink moves, a simple generalization of the widely-used alpha beta-swap and alpha-expansion algorithms for approximate energy minimization. We show that in a certain sense, these moves dominate both alpha beta-swap and alpha-expansion moves, but unlike previous generalizations the new moves require no additional assumptions and are still solvable in polynomial-time. We show promising experimental results with the new moves, which we believe could be used in any context where alpha-expansions are currently employed.
This work has resulted in a publication [17].

6.3. Image restoration, manipulation and enhancement

6.3.1. Non-uniform Deblurring for Shaken Images

**Participants:** Oliver Whyte, Josef Sivic, Andrew Zisserman, Jean Ponce.

We argue that blur resulting from camera shake is mostly due to the 3D rotation of the camera, causing a blur that can be significantly non-uniform across the image. However, most current deblurring methods model the observed image as a convolution of a sharp image with a uniform blur kernel. We propose a new parametrized geometric model of the blurring process in terms of the rotational velocity of the camera during exposure. We apply this model in the context of two different algorithms for camera shake removal: the first uses a single blurry image (blind deblurring), while the second uses both a blurry image and a sharp but noisy image of the same scene. We show that our approach makes it possible to model and remove a wider class of blurs than previous approaches, and demonstrate its effectiveness with experiments on real images.

The project resulted in a publication [5].

6.3.2. Deblurring shaken and partially saturated images

**Participants:** Oliver Whyte, Josef Sivic, Andrew Zisserman.

We address the problem of deblurring images degraded by camera shake blur and saturated or over-exposed pixels. Saturated pixels are a problem for existing non-blind deblurring algorithms because they violate the assumption that the image formation process is linear, and often cause significant artifacts in deblurred outputs. We propose a forward model that includes sensor saturation, and use it to derive a deblurring algorithm properly treating saturated pixels. By using this forward model and reasoning about the causes of artifacts
in the deblurred results, we obtain significantly better results than existing deblurring algorithms. Further we propose an efficient approximation of the forward model leading to a significant speed-up. Example result is shown in figure 4.

The project resulted in a publication [19].

![Figure 4. Deblurring saturated images. Note that the ringing around saturated regions, visible in columns (b) and (c) is removed by our method (d), without causing any loss in visual quality elsewhere.](image)

6.3.3. Dictionary Learning for Deblurring and Digital Zoom

**Participants:** Florent Couzinie, Julien Mairal, Jean Ponce, Francis Bach [INRIA SIERRA].

This work proposes a novel approach to image deblurring and digital zooming using sparse local models of image appearance. These models, where small image patches are represented as linear combinations of a few elements drawn from some large set (dictionary) of candidates, have proven well adapted to several image restoration tasks. A key to their success has been to learn dictionaries adapted to the reconstruction of small image patches. In contrast, recent works have proposed instead to learn dictionaries which are not only adapted to data reconstruction, but also tuned for a specific task. We introduce here such an approach to deblurring and digital zoom, using pairs of blurry/sharp (or low-/high-resolution) images for training, as well as an effective stochastic gradient algorithm for solving the corresponding optimization task. Although this learning problem is not convex, once the dictionaries have been learned, the sharp/high-resolution image can be recovered via convex optimization at test time. Experiments with synthetic and real data demonstrate the effectiveness of the proposed approach, leading to state-of-the-art performance for non-blind image deblurring and digital zoom.

This work has resulted in a publication [1].

6.3.4. Sparse Image Representation with Epitomes

**Participants:** Louise Benoit, Julien Mairal, Jean Ponce, Francis Bach [INRIA SIERRA].

Sparse coding, which is the decomposition of a vector using only a few basis elements, is widely used in machine learning and image processing. The basis set, also called dictionary, is learned to adapt to specific data. This approach has proven to be very effective in many image processing tasks. Traditionally, the dictionary is an unstructured "flat" set of atoms. In this work, we study structured dictionaries which are
obtained from an epitome, or a set of epitomes. The epitome is itself a small image, and the atoms are all the patches of a chosen size inside this image. This considerably reduces the number of parameters to learn and provides sparse image decompositions with shift invariance properties. We propose a new formulation and an algorithm for learning the structured dictionaries associated with epitomes, and illustrate their use in image denoising tasks.

This work has resulted in a CVPR’11 publication [6].

6.3.5. Proximal Methods for Hierarchical Sparse Coding

Participants: Julien Mairal, Rodolphe Jenatton [INRIA SIERRA], Guillaume Obozinski [INRIA SIERRA], Francis Bach [INRIA SIERRA].

Sparse coding consists in representing signals as sparse linear combinations of atoms selected from a dictionary. We consider an extension of this framework where the atoms are further assumed to be embedded in a tree. This is achieved using a recently introduced tree-structured sparse regularization norm, which has proven useful in several applications. This norm leads to regularized problems that are difficult to optimize, and in this paper, we propose efficient algorithms for solving them. More precisely, we show that the proximal operator associated with this norm is computable exactly via a dual approach that can be viewed as the composition of elementary proximal operators. Our procedure has a complexity linear, or close to linear, in the number of atoms, and allows the use of accelerated gradient techniques to solve the tree-structured sparse approximation problem at the same computational cost as traditional ones using the l1-norm. Our method is efficient and scales gracefully to millions of variables, which we illustrate in two types of applications: first, we consider fixed hierarchical dictionaries of wavelets to denoise natural images. Then, we apply our optimization tools in the context of dictionary learning, where learned dictionary elements naturally self-organize in a prespecified arborescent structure, leading to better performance in reconstruction of natural image patches. When applied to text documents, our method learns hierarchies of topics, thus providing a competitive alternative to probabilistic topic models.

This work has resulted in a publication [3].

6.4. Human activity capture and classification

6.4.1. Track to the future: Spatio-temporal video segmentation with long-range motion cues

Participants: Jose Lezama, Karteek Alahari, Ivan Laptev, Josef Sivic.

Video provides rich visual cues such as motion and appearance but also much less explored long-range temporal interactions among objects. We aim to capture such interactions and to construct powerful intermediate-level video representation for subsequent recognition. Motivated by this goal, we seek to obtain spatio-temporal oversegmentation of the video into regions that respect object boundaries and, at the same time, associate object pixels over many video frames. The contributions of this paper are twofold. First, we develop an efficient spatio-temporal video segmentation algorithm, that naturally incorporates long-range motion cues from the past and future frames in the form of clusters of point tracks with coherent motion. Second, we devise a new track clustering cost-function that includes occlusion reasoning, in the form of depth ordering constraints, as well as motion similarity along the tracks. We evaluate the proposed approach on a challenging set of video sequences of office scenes from feature length movies.

This work resulted in a publication [11].

6.4.2. Density-aware person detection and tracking in crowds

Participants: Mikel Rodriguez, Ivan Laptev, Josef Sivic, Jean-Yves Audibert [INRIA SIERRA].
We address the problem of person detection and tracking in crowded video scenes. While the detection of individual objects has been improved significantly over the recent years, crowd scenes remain particularly challenging for the detection and tracking tasks due to heavy occlusions, high person densities and significant variation in people’s appearance. To address these challenges, we propose to leverage information on the global structure of the scene and to resolve all detections jointly. In particular, we explore constraints imposed by the crowd density and formulate person detection as the optimization of a joint energy function combining crowd density estimation and the localization of individual people. We demonstrate how the optimization of such an energy function significantly improves person detection and tracking in crowds. We validate our approach on a challenging video dataset of crowded scenes. The proposed approach is illustrated in figure 5.

This work has resulted in a publication [14].

Figure 5. Individual head detections provided by state-of-the-art object detector (Felzenswalb et al. 2009) (bottom-left; green: true positives; red: false positives) are improved significantly by our method (bottom-right; yellow: new true positives) using the crowd density estimate (topright) obtained from the original frame (top-left).

6.4.3. Data-driven Crowd Analysis in Videos

Participants: Mikel Rodriguez, Josef Sivic, Ivan Laptev, Jean-Yves Audibert [INRIA SIERRA].

In this work we present a new crowd analysis algorithm powered by behavior priors that are learned on a large database of crowd videos gathered from the Internet. The algorithm works by first learning a set of crowd behavior priors off-line. During testing, crowd patches are matched to the database and behavior priors are transferred. We adhere to the insight that despite the fact that the entire space of possible crowd behaviors is infinite, the space of distinguishable crowd motion patterns may not be all that large. For many individuals in a crowd, we are able to find analogous crowd patches in our database which contain similar patterns of behavior that can effectively act as priors to constrain the difficult task of tracking an individual in a crowd. Our algorithm is data-driven and, unlike some crowd characterization methods, does not require us to have seen the test video beforehand. It performs like state-of-the-art methods for tracking people having common crowd behaviors and outperforms the methods when the tracked individual behaves in an unusual way.

This work has resulted in a publication [15].

6.4.4. Learning person-object interactions for action recognition in still images

 Participants: Vincent Delaitre, Josef Sivic, Ivan Laptev.
In this work, we investigate a discriminatively trained model of person-object interactions for recognizing common human actions in still images. We build on the locally order-less spatial pyramid bag-of-features model, which was shown to perform extremely well on a range of object, scene and human action recognition tasks. We introduce three principal contributions. First, we replace the standard quantized local HOG/SIFT features with stronger discriminatively trained body part and object detectors. Second, we introduce new person-object interaction features based on spatial co-occurrences of individual body parts and objects. Third, we address the combinatorial problem of a large number of possible interaction pairs and propose a discriminative selection procedure using a linear support vector machine (SVM) with a sparsity inducing regularizer. Learning of action-specific body part and object interactions bypasses the difficult problem of estimating the complete human body pose configuration. Benefits of the proposed model are shown on human action recognition in consumer photographs, outperforming the strong bag-of-features baseline. The proposed model is illustrated in figure 6.

This work has resulted in a publication [8].

Figure 6. Representing person-object interactions by pairs of body part (cyan) and object (blue) detectors. To get a strong interaction response, the pair of detectors (here visualized at positions $p_i$ and $p_j$) must fire in a particular relative 3D scale-space displacement (given by the vector $v$) with a scale-space displacement uncertainty (deformation cost) given by diagonal 3x3 covariance matrix $C$ (the spatial part of $C$ is visualized as a yellow dotted ellipse). Our image representation is defined by the max-pooling of interaction responses over the whole image, solved efficiently by the distance transform.

6.4.5. People Watching: Human Actions as a Cue for Single View Geometry

Participants: David Fouhey [CMU], Vincent Delaitre, Abhinav Gupta [CMU], Ivan Laptev, Alexei Efros [CMU], Josef Sivic.

We present an approach which exploits the coupling between human actions and scene geometry. We investigate the use of human pose as a cue for single-view 3D scene understanding. Our method builds upon recent advances in still-image action recognition and pose estimation, to extract functional and geometric constraints about the scene from people detections. These constraints are then used to improve state-of-the-art single-view 3D scene understanding approaches. The proposed method is validated on a collection of single-viewpoint time-lapse image sequences as well as a dataset of still images of indoor scenes. We demonstrate that observing people performing different actions can significantly improve estimates of scene geometry and 3D layout. The main idea of this work is illustrated in figure 7.
This work is in submission to CVPR 2012.

Figure 7. What can human actions tell us about the 3D structure of the scene? Quite a lot, actually. Consider the two person detections and their estimated pose in (a). They were detected in a time-lapse sequence of one of the three scenes (b-d). Can you guess which one? Most people can easily see that it is (b). Even though this is only a static image, the actions and the pose of the disembodied figures reveal a lot about the geometric structure of the scene. The pose of the left figure reveals a horizontal surface right under its pelvis, which ends abruptly at the knees. The right figure’s pose reveals a ground plane under its feet as well as a likely horizontal surface near the hand location. In both cases we observe a strong physical and functional coupling that exists between people and the 3D geometry of the scene. Our aim in this work is to exploit this coupling.

6.4.6. Joint pose estimation and action recognition in image graphs
Participants: K. Raja [INRIA Rennes], Ivan Laptev, Patrick Perez [Technicolor], L. Osei [INRIA Rennes].

Human analysis in images and video is a hard problem due to the large variation in human pose, clothing, camera view-points, lighting and other factors. While the explicit modeling of this variability is difficult, the huge amount of available person images motivates for the implicit, data-driven approach to human analysis. In this work we aim to explore this approach using the large amount of images spanning a subspace of human appearance. We model this subspace by connecting images into a graph and propagating information through such a graph using a discriminatively trained graphical model. We particularly address the problems of human pose estimation and action recognition and demonstrate how image graphs help solving these problems jointly. We report results on still images with human actions from the KTH dataset.

This work has resulted in a publication [ 13 ].

6.5. Creation of the SIERRA project-team
6.5.1. From WILLOW alone to WILLOW and SIERRA

The WILLOW team officially started in the Spring of 2007. From the start, it was clear that machine learning was a key ingredient to new breakthroughs, and our activities have steadily grown in this area. In three short years, WILLOW has grown into a mature group of about 30 people, and it divides its activities between computer vision, machine learning, and the cross-pollination of the two fields, with video as one of the core research areas. We have been very successful, with many publications in all the major international conferences and leading journals in both areas, but we are a large group with very diverse interests, ranging from camera
geometry to statistics, and from image retrieval to bioinformatics applications of structured sparse coding. With the creation of the SIERRA project-team, the core machine learning activities of WILLOW have been transferred to the new group.

The two teams continue collaborating with each other (they remain co-located at the INRIA site in central Paris), but have a sharper focus on their respective computer vision and machine learning activities.

6.5.2. SIERRA

The SIERRA project-team was created by the INRIA on January 1st 2011 and is headed by Francis Bach, who received in 2009 a Jr. ERC grant.
ZENITH Team

6. New Results

6.1. Data and Metadata Management

6.1.1. Uncertain Data Management

Participants: Reza Akbarinia, Patrick Valduriez, Guillaume Verger.

Data uncertainty in scientific applications can be due to many different reasons: incomplete knowledge of the underlying system, inexact model parameters, inaccurate representation of initial boundary conditions, inaccuracy in equipments, etc. For instance, in the monitoring of plant contamination, sensors generate periodically data which may be uncertain. Instead of ignoring (or correcting) uncertainty, which may generate major errors, we need to manage it rigorously and provide support for querying.

In [46], we address the problem of aggregate queries that return possible sum values and their probabilities. This kind of query which, we call ALL-SUM, is also known as sum probability distribution. The results of ALL-SUM can be used for answering many other type of queries over probabilistic data. In general, the problem of ALL-SUM query execution is NP-complete. We propose pseudo-polynomial algorithms that are efficient in many practical applications, e.g. when the aggr attribute values are small integers or real numbers with small precision, i.e. small number of digits after decimal point. These cases cover many practical attributes, e.g. temperature, blood pressure, needed human recourses per patient in medical applications.

We have started to develop a probabilistic database prototype, called ProbDB (Probabilistic Database), on top of an RDBMS. ProbDB divides a query into two parts: probabilistic and deterministic (i.e. non probabilistic). The deterministic part is executed by the underlying RDBMS, and the rest of work is done by our probabilistic query processing algorithms that are executed over the data returned by the RDBMS. In [51], we demonstrated the efficient execution of aggregate queries with the first version of ProbDB.

6.1.2. Metadata Integration

Participants: Zohra Bellahsène, Rémi Coletta, Duy Hoa Ngo.

Due to the various types of heterogeneity of ontologies, ontology matching must exploit many features of ontology elements in order to improve matching quality. For this purpose, numerous similarity metrics have been proposed to deal with ontology semantics at different levels: elements level, structural level and instance level.

Elements level metrics can be categorized in three groups: (1) terminological, (2) structural and (3) semantic. Metrics of the first group exploit text features such as names, labels and comments to compute the similarity score between entities. Whereas metrics of the last two groups exploit the hierarchy and semantic relationship features. Our approach consists in first using terminological metrics. Then, during the matching process, mappings discovered by terminological metrics are used as input mappings to other metrics of the second and third groups. Obviously, the more precise results terminological metrics are, the more accurate results structural and semantic metrics have.

However, finding a good combination of different metrics is very difficult and time consuming. We proposed YAM++ (not Yet Another Matcher), an approach that uses machine learning to combine similarity metrics. Our main contributions are: the definition of new metrics dealing with terminological and context profile features of entities in ontologies [37], and the use of a decision tree model to combine similarity metrics [38].

To improve matching quality of YAM++, we exploit instances accompanying ontologies. We then apply similarity flooding propagation algorithm to discover more semantic mappings. At the 2011 competition of the Ontology Alignment Evaluation Initiative (http://oaei.ontologymatching.org), YAM++ achieved excellent results: first position on the Conference track and second position on the Benchmark track [39].
6.2. Data and Process Sharing

6.2.1. Social-based P2P Data Sharing

Participants: Hinde Bouziane, Michèle Cart, Esther Pacitti, Didier Parigot, Guillaume Verger.

This work focuses on P2P content recommendation for on-line communities. In [20], we propose P2Prec, a recommendation service for P2P content sharing systems that exploits users’ social data. Given a query, P2Prec finds peers that can recommend high quality documents that are relevant for the query. A document is relevant to a query if it covers the same topics. It is of high quality if relevant peers have rated it highly. P2Prec finds relevant peers through a variety of mechanisms including advanced content-based and collaborative filtering. The topics each peer is interested in are automatically calculated by analyzing the documents the peer holds. Peers become relevant for a topic if they hold a certain number of highly rated documents on this topic. To efficiently disseminate information about peers’ topics and relevant peers, we proposed new semantic-based gossip protocols. In our experimental evaluation, using the TREC09 dataset, we showed that using semantic gossip increases recall by a factor of 1.6 compared to well-known random gossiping. Furthermore, P2Prec has the ability to get reasonable recall with acceptable query processing load and network traffic. P2Prec was demonstrated in [31] and [47].

In [30], we exploit social relationships between users as a parameter to increase the trust of recommendation. We propose a novel P2P recommendation approach (called F2FRec) that leverages content and social-based recommendation by maintaining a P2P and friend-to-friend network. This network is used as a basis to provide useful and high quality recommendations. Based on F2FRec, we propose new metrics, such as usefulness and similarity (among users and their respective friend network). We define our proposed metrics based on users’ topic of interest and relevant topics that are automatically extracted from the contents stored by each user. Our experimental evaluation, using the TREC09 dataset and Wiki vote social network, shows the benefits of our approach compared to anonymous recommendation. In addition, we show that F2FRec increases recall by a factor of 8.8 compared with centralized collaborative filtering.

6.2.2. Satisfaction-based Query Replication

Participant: Patrick Valduriez.

In a large-scale Internet-based distributed, participants (consumers and providers) who are willing to share data are typically autonomous, i.e. they may have special interests towards queries and other participants’ data. In this context, a way to avoid a participant to voluntarily leave the system is satisfying its interests when allocating queries. However, participants’ satisfaction may also be negatively affected by the failures of other participants. Query replication can deal with providers failures, but, it is challenging because of autonomy: it cannot only quickly overload the system, but also dissatisfy participants with uninteresting queries. Thus, a natural question arises: should queries be replicated? If so, which ones? and how many times?

In [25], we answer these questions by revisiting query replication from a satisfaction and probabilistic point of view. We propose a new algorithm, called S b QR, that decides on-the-fly whether a query should be replicated and at which rate. As replicating a large number of queries might overload the system, we propose a variant of our algorithm, called S b QR+. The idea is to voluntarily fail to allocate as many replicas as required by consumers for low critical queries so as to keep resources for high critical queries during query-intensive periods. Our experimental results demonstrate that our algorithms significantly outperform the baseline algorithms from both the performance and satisfaction points of view. We also show that our algorithms automatically adapt to the criticality of queries and different rates of participant failures.

6.2.3. View Selection in Scientific Data Warehousing

Participants: Zohra Bellahsène, Rémi Coletta, Imen Mami.
Scientific data generate large amounts of data which have to be collected and stored for analytical purpose. One way to help managing and analyzing large amounts of data is data warehousing, whereby views over data are materialized. However, view selection is an NP-hard problem because of many parameters: query cost, view maintenance cost and storage space. In [36], we propose a new solution based on constraint programming, which has proven efficient at solving combinatorial problems. This allows using a constraint programming solver to set up the search space by identifying a set of views that minimizes the total query cost. We address view selection under two cases: (1) only the total view maintenance cost needs be minimized, assuming unlimited storage space (meaning that it is not a critical resource anymore); (2) both storage space and maintenance cost must be minimized. We implemented our approach and compared it with a randomized method (i.e., genetic algorithm). We experimentally show that our approach provides better performance resulting from evaluating the quality of the solutions in terms of cost savings. Furthermore, our approach scales well with the query workload.

6.2.4. Scientific Workflow Management

Participants: Ayoub Ait Lahcen, Eduardo Ogasawara, Didier Parigot, Patrick Valduriez.

Scientific workflows have emerged as a basic abstraction for structuring and executing scientific experiments in computational environments. In many situations, these workflows are computationally and data-intensive, thus requiring execution in large-scale parallel computers. However, parallelization of scientific workflows remains low-level, ad-hoc and laborintensive, which makes it hard to exploit optimization opportunities.

To address this problem, we propose in [23] an algebraic approach (inspired by relational algebra) and a parallel execution model that enable automatic optimization of scientific workflows. With our scientific workflow algebra, data is uniformly represented by relations and workflow activities are mapped to operators that have data aware semantics. Our workflow execution model is based on the concept of activity activation, which enables transparent distribution and parallelization of activities;

We conducted a thorough validation of our approach using both a real oil exploitation application and synthetic data scenarios. The experiments were run in Chiron, a data-centric scientific workflow engine implemented at UFRJ to support our algebraic approach. Our experiments demonstrate performance improvements of up to 226% compared to an ad-hoc workflow implementation. This work was done in the context of the Equipe Associée Sarava and the CNPq-INRIA project DatLuge.

In the context of SON, we also proposed a declarative workflow language based on service/activity rules [41]. This language makes it possible to infer a dependency graph for SON applications that provides for automatic parallelization.

6.3. Scalable Data Analysis

6.3.1. Massive Graph Management

Participant: Patrick Valduriez.

Traversing massive graphs as efficiently as possible is essential for many scientific applications. Many common operations on graphs, such as calculating the distance between two nodes, are based on the Breadth First Search (BFS) traversal. However, because of the exhaustive exploration of all the nodes and edges of the graph, this operation might be very time consuming. A possible solution is partitioning the graph among the nodes of a shared-nothing parallel system. However, partitioning a graph and keeping the information regarding the location of vertices might be unrealistic for massive graphs because of much inter-node communication. In [28], we propose ParallelGDB, a new graph database system based on specializing the local caches of any node in this system, providing a better cache hit ratio. ParallelGDB uses a random graph partitioning, avoiding complex partition methods based on the graph topology, that usually require managing extra data structures. This proposed system provides an efficient environment for distributed graph databases.

6.3.2. Top-k Query Processing in Unstructured P2P Systems

Participants: Reza Akbarinia, William Kokou Dedzoe, Patrick Valduriez.
Top-k query processing techniques are useful in unstructured P2P systems to avoid overwhelming users with too many results and provide them with the best ones. However, existing approaches suffer from long waiting times, because top-k results are returned only when all queried peers have finished processing the query. As a result, response time is dominated by the slowest queried peer. We proposed to revisit the problem of top-k query processing.

In [29] we address the problem of reducing user waiting time of top-k query processing, in the case of unstructured P2P systems with overloaded peers. We propose a new algorithm, called QUAT, in which each peer maintains a semantic description of its local data and the semantic descriptions of its neighborhood (i.e. the semantic descriptions of data owned locally by its direct neighbors and data owned locally by these neighbors direct neighbors). These semantic descriptions allow peers to prioritize the queries that can provide high quality results, and to forward them in priority to the neighbors that can provide high quality answers. We validated our solution through a thorough experimental evaluation using a real-world dataset. The results show that QUAT significantly outperforms baseline algorithms by returning faster the final top-k results to users.

6.3.3. Top-k Query Processing Over Sorted Lists

Participants: Reza Akbarinia, Esther Pacitti, Patrick Valduriez.

The problem of answering top-k queries can be modeled as follows. Suppose we have $m$ lists of $n$ data items such that each data item has a local score in each list and the lists are sorted according to the local scores of their data items. Each data item has an overall score computed based on its local scores in all lists using a given scoring function. Then, the problem is to find the $k$ data items whose overall scores are the highest. This problem model is a general model for top-k queries in many centralized, distributed and P2P applications. For example, in IR systems one of the main problems is to find the top-k documents whose aggregate rank is the highest wrt. some given keywords. To answer this query, the solution is to have for each keyword a ranked list of documents, and return the $k$ documents whose aggregate rank in all lists are the highest.

In [16], we propose an extension of our best position algorithms (BPA) which had been proposed for top-k query processing over sorted lists model. The BPA algorithms have been shown to be more efficient than the well known TA Algorithm. We propose several techniques using different data structures for managing best positions that are crucial for efficient execution of top-k algorithms. We also provide a complete discussion on the instance optimality of TA algorithm (TA was considered so far as optimal over any database of sorted lists). We illustrate that, the existence of deterministic algorithms such as BPA shows that if we are aware of positions of seen data, then one of the main arguments used for proving the instance optimality of TA is invalidated. Therefore, in this case the proof of TA's instance optimality is incorrect, and must be revisited.

6.3.4. Satellite Image Mining

Participant: Florent Masseglia.

Satellite Image Time Series (SITS) provide us with precious information on land cover evolution. By studying SITS, we can both understand the changes of specific areas and discover global phenomena that spread over larger areas. Changes that can occur throughout the sensing time can spread over very long periods and may have different start time and end time depending on the location, which complicates the mining and the analysis of series of images. In [45], we propose a frequent sequential pattern mining method for SITS analysis. Designing such a method called for important improvements on the data mining principles. First, the search space in SITS is multi-dimensional (the radiometric levels of different wavelengths correspond to infra-red, red, etc.). Furthermore, the non evolving regions, which are the vast majority and overwhelm the evolving ones, challenge the discovery of these patterns. Our framework enables discovery of these patterns despite these constraints and characteristics. We introduce new filters in the mining process to yield important reductions in the search space by avoiding consecutive occurrences of similar values in the sequences. Then, we propose visualization techniques for results analysis (where modified regions are highlighted). Experiments carried out on a particular dataset showed that our method allows extracting repeated, shifted and distorted temporal behaviors. The flexibility of this method makes it possible to capture complex behaviors from multi-source, noisy and irregularly sensed data.
6.3.5. **Distributed Approximate Similarity Join**  
**Participant:** Alexis Joly.

Efficiently constructing the KNN-graph of large and high dimensional feature datasets is crucial for many data intensive applications involving feature-rich objects, such as image features, text features or sensor’s features. In this work we investigate the use of high dimensional hashing methods for efficiently approximating the full kNN graph of large collections, in particular, in distributed environments. We first analyzed and experimented what seems to be the most intuitive hashing-based approach: constructing several Locality Sensitive Hashing (LSH) tables in parallel and computing the frequency of all emitted collisions. We show that balancing issues of classical LSH functions strongly affect the performance of this approach. On the other side, we show that using an alternative data-dependent hashing function (RMMH), that we introduced recently [34], can definitely change that conclusion. The main originality of RMMH hash function family is that it is based on randomly trained classifiers, allowing to learn random and balanced splits of the data instead of using random splits of the feature space as in LSH. We show that the hash tables constructed through RMMH are much more balanced and that the number of emitted collisions can be strongly reduced without degrading quality. In the end, our hashing-based filtering algorithm of the all-pairs graph is two orders of magnitude faster than the one based on LSH. An efficient distributed implementation of the method was implemented within the MapReduce framework (and is the basis of the SimJoin prototype). This work is done in the context of the supervision of a PhD student working at INRIA Imedia (Riadh Mohamed Trad).

6.3.6. **Visual objects mining**  
**Participant:** Alexis Joly.

State-of-the-art content-based object retrieval systems have demonstrated impressive performance in very large image datasets. These methods, based on fine local descriptions and efficient matching techniques, can detect accurately very small rigid objects with unambiguous semantics such as logos, buildings, manufactured objects, posters, etc. Mining such small objects in large collections is however difficult. Constructing a full local matching graph with a naïve approach would indeed require to probe all candidate query leading to an intractable algorithm complexity. In this work, we first introduce an adaptive weighted sampling scheme, starting with some prior distribution and iteratively converging to unvisited regions [35]. We show that the proposed method allows to discover highly interpretable visual words while providing excellent recall and image representativity. We then focused on mining visual objects on top of the discovered visual words. We therefore developed an original shared nearest-neighbors clustering method, working directly on the generated bi-partite graph. This work is in the context of the supervision of two PhD students, one working jointly with INA and INRIA and who will join the Zenith team next year (Pierre Letessier), one working at INRIA Imedia (Amel Hamzaoui).

6.3.7. **Visual-based plant species identification from crowdsourced data**  
**Participant:** Alexis Joly.

Inspired by citizen sciences, the main goal of this work is to speed up the collection and integration of raw botanical observation data, while providing to potential users an easy and efficient access to this botanical knowledge. We therefore designed and developed an original crowdsourcing web application dedicated to the access of botanical knowledge through automated identification of plant species by visual content. Technically, the first side of the application deals with content-based identification of plant leaves. Whereas state-of-the-art methods addressing this objective are mostly based on leaf segmentation and boundary shape features, we developed a new approach based on local features and large-scale matching. This approach obtained the best results within ImageCLEF 2011 plant identification benchmark [48]. The second side of the application deals with interactive tagging and allows any user to validate or correct the automatic determinations returned by the system. Overall, this collaborative system allows to enrich automatically and continuously the visual botanical knowledge and thus to increase progressively the accuracy of the automated identification. A demo of the developed application was presented at the ACM Multimedia conference [33]. This work is done in collaboration with INRIA Imedia and with the botanists of the AMAP UMR team (CIRAD). It is also closely related to a citizen science project around plant’s identification that we develop with the support of the TelaBotanica social network.
