5. New Results

5.1. Modeling Interfaces and Contacts

5.1.1. On the Morphology of Protein Binding Patches

Participants: Frédéric Cazals, Noël Malod-Dognin.

*In collaboration with A. Bansal, former summer intern from IIT Bombay.*

Understanding the specificity of protein interactions is a central question in structural biology, whence the importance of models for protein binding patches—a patch refers to the collection of atoms of a given partner accounting for the interaction. To improve our understanding of the relationship between the structure of binding patches and the biological function of protein complexes, we present a binding patch model decoupling the topological and geometric properties [21]. While the geometry is classically encoded by the 3D positions of the atoms, the topology is recorded in a graph encoding the relative position of concentric shells partitioning the interface atoms. The topological - geometric duality provides the basis of a generic dynamic programming based algorithm to compare patches, which is instantiated to respectively favor topological or geometric comparisons.

On the biological side, using a dataset of 92 co-crystallized structures organized in biological sub-families, we exploit our encoding and the two comparison algorithms in two directions. First, we show that Nature enjoyed the topological and geometric degrees of freedom independently while retaining a finite set of qualitatively distinct topological signatures, and show that topological similarity is a less stringent notion that the ubiquitously used geometric similarity. Second, we analyze the topological and geometric coherence of binding patches within sub-families and across the whole database, and show that complexes related to the same biological function can encompass geometrically distinct shapes. Previous work on binding patches focused on the investigation of correlations between structural parameters and biochemical properties on the one hand, and on structural comparison algorithms on the other hand. We believe that the abstraction coded by the topological - geometric duality paves the way to new classifications, in particular in the context of flexible docking.

The corresponding software is presented in section 4.1.1.

5.2. Modeling Macro-molecular Assemblies

5.2.1. Assessing the Reconstruction of Macro-molecular Assemblies with Toleranced Models

Participants: Frédéric Cazals, Tom Dreyfus.

*In collaboration with Valérie Doye, Institut Jacques Monod, Paris.*

In [20], we introduce TOleranced Models (TOM), a generic and versatile framework meant to handle models of macro-molecular assemblies featuring uncertainties on the shapes and the positions of proteins. A TOM being a continuum of nested shapes, the inner (resp. outer) ones representing high (low) confidence regions, we present statistics to assess features of this continuum at multiple scales. While selected statistics target topological aspects (pairwise contacts, complexes involving proteins of prescribed types), others are of geometric nature (geometric accuracy of complexes). We validate the TOM framework on recent average models of the Nuclear Pore Complex (NPC) obtained from reconstruction by data integration, and confront our statistics against experimental findings related to sub-complexes of the NPC. In a broader perspective, the TOM framework should prove instrumental to handle uncertainties of various kind, in particular in electron-microscopy and crystallography.
5.2.2. Probing a Continuum of Macro-molecular Assembly Models with Graph Templates of Sub-complexes

**Participants:** Frédéric Cazals, Tom Dreyfus.

Reconstruction by data integration is an emerging trend to reconstruct large protein assemblies, but uncertainties on the input data yield average models whose quantitative interpretation is challenging. This paper presents methods to probe fuzzy models of large assemblies against atomic resolution models of sub-systems. Consider a Toleranced Model (TOM) of a macro-molecular assembly, namely a continuum of nested shapes representing the assembly at multiple scales. Also consider a template namely an atomic resolution 3D model of a sub-system of this assembly—also called a complex. We present algorithms performing a multi-scale assessment of the complexes of the TOM, by comparing the pairwise contacts which appear in the TOM against those of the template. These operations reduce to the comparison of graphs, which we perform by computing Maximal Common Induced Sub-graphs (MCIS) and Maximal Common Edge Sub-graphs (MCES).

We apply this machinery to recent average models of the NPC. First, we show how our contact analysis allows assessing the quality of probability density maps. Regarding particular sub-systems of the NPC, we focus on the Y-complex and on the T-complex. In particular for the latter, our analysis suggests a new 3D template of pairwise contacts.

We believe that these tools should become standard to assess the reconstruction of fuzzy assemblies.

The software associated to these developments is presented in section 4.1.2.

5.3. Protein Shape Matching and Family Identification

5.3.1. Using Dominances for Solving the Protein Family Identification Problem

**Participant:** Noël Malod-Dognin.

In collaboration with R. Andonov (IRISA), M. Le Boudic-Jamin (IRISA) and P. Kamath (former summer intern within the SYMBIOSE project at IRISA).

The 3D structure of macro-molecules underpins all biological functions. Similarities between protein structures may come from evolutionary relationships, and similar protein structures relate to similar functions.

The exponential growth of the number of known protein structures in the Protein Data Bank over the past decade led to the problem of protein classification. We mean here how to automatically insert new protein structures into an already existing classified database \( Q = \{ q_1, q_2, \cdots, q_m \} \) such as CATH or SCOP. The problem of determining in which classes new structures \( P = \{ p_1, p_2, \cdots, p_n \} \) belong, according to a similarity function \( S : Q \times P \rightarrow \mathbb{R}^+ \), is referred here as the Protein Family Identification Problem (FIP).

There are computational pitfalls in the FIP. The number of similarity scores \( S(q_i, p_j) \) that need to be computed is \( |Q| \times |P| \), where \( |P| \) can be very large (there are currently 152920 classified protein structures in the expert classification CATH). Moreover, computing a single similarity score is often equivalent to solving a NP-hard problem (ex: DALI, DAST, CMO, VAST, etc...).

In [17] and [18], we propose a notion of dominance between the protein structure comparison instances that allows the computation of optimal FIP without optimally solving all the comparison instances, and thus reduces the effect of the NP-Hardness of the similarity score.

5.4. Algorithmic Foundations

5.4.1. Shape Matching by Localized Calculations of Quasi-isometric Subsets

**Participants:** Frédéric Cazals, Noël Malod-Dognin.
Consider a protein complex involving two partners, the receptor and the ligand. In [16], we address the problem of comparing their binding patches, i.e. the sets of atoms accounting for their interaction. This problem has been classically addressed by searching quasi-isometric subsets of atoms within the patches, a task equivalent to a maximum clique problem, a NP-hard problem, so that practical binding patches involving up to 300 atoms cannot be handled. We extend previous work in two directions. First, we present a generic encoding of shapes represented as cell complexes. We partition a shape into concentric shells, based on the shelling order of the cells of the complex. The shelling order yields a shelling tree encoding the geometry and the topology of the shape. Second, for the particular case of cell complexes representing protein binding patches, we present three novel shape comparison algorithms. These algorithms combine a Tree Edit Distance calculation (TED) on shelling trees, together with Edit operations respectively favoring a topological or a geometric comparison of the patches. We show in particular that the geometric TED calculation strikes a balance, in terms of accuracy and running time between a purely geometric and topological comparisons, and we briefly comment on the biological findings reported in a companion paper [21].
6. New Results

6.1. Abstractions of Functions
Participants: Patrick Cousot, Radhia Cousot.

The idea of domain segmentation for arrays [18] has been extended to the abstraction of functions [41] by combination of a partitioning of their domain of definition and a functional or relational abstraction of blocks into their co-domain [17].

6.2. Analysis of Biological Pathways

We have improved our framework to design and analyze biological networks. This framework focused on protein-protein interaction networks described as graph rewriting systems. Such networks can be used to model some signaling pathways that control the cell cycle. The task is made difficult due to the combinatorial blow up in the number of reachable species (i.e., non-isomorphic connected components of proteins).

6.2.1. Automatic Reduction of Differential Semantics
Participants: Ferdinanda Camporesi, Vincent Danos [University of Edinburgh], Jérôme Feret, Walter Fontana [Harvard Medical School], Russ Harmer [Harvard Medical School], Jean Krivine [Paris VII].

We have developed an abstract interpretation-based framework that enables the reduction of the differential semantics for protein-protein interaction networks. Results are sound since trajectories in the abstract system are projections of the trajectories in the concrete system.

The flow of information is a key element in our model reduction framework because it enables the identification of the correlations which are useless when computing observables of interest. Thus there is a need of providing good trade-off in the description of the flow of information throughout the biochemical structure of chemical species.

The notion of symmetries between sites is also important, since knowing that two sites have exactly the same capabilities of interaction enable exact quotienting (or lumping) of the set of reachable species.

In [13], [14], we have proposed a heterogeneous over-approximation of the flow of information where the flow that is attached to an agent can depend on its relative position in a chemical species. Moreover, we have showed how to use symmetries between sites so as to define another model reduction and we have proposed an algebraic product to combine model reductions, the product of two reduced models being the least abstract model which is at least as abstract as both model.

6.2.2. Automatic Reduction of Stochastic Semantics
Participants: Ferdinanda Camporesi, Jérôme Feret, Thomas Henzinger [Institute of Science and Technology, Austria], Heinz Koeppel [ETH Zürich], Tatjana Petrov [ETH Zürich].

We have proposed an abstract interpretation-based framework for reducing the state-space of stochastic semantics for protein-protein interaction networks. Our framework ensures that the trace distribution of the reduced system is the exact projection of the trace distribution of the concrete system. Moreover, when the abstraction is complete, if any pair of concrete states that have the same abstraction are equipropable at initial state, any pair of concrete states that share the same abstraction are equiprobable at any time $t$.

In [12], we have formalized the model reduction framework for the stochastic semantics and we have established the relationships with the notions of lumpability, and bisimulation is established.
6.3. Automatic Array Content Analysis by Segmentation

Participants: Patrick Cousot, Radhia Cousot, Francesco Logozzo [Microsoft Research (Redmond, USA)].

In [18], we introduce FunArray, a parametric segmentation abstract domain functor for the fully automatic and scalable analysis of array content properties. The functor enables a natural, painless and efficient lifting of existing abstract domains for scalar variables to the analysis of uniform compound data-structures such as arrays and collections (as well as matrices when instantiating the functor on itself). The analysis automatically and semantically divides arrays into consecutive non-overlapping possibly empty segments. Segments are delimited by sets of bound symbolic expressions and abstracted uniformly. All bound expressions appearing in a set are equal in the concrete. The FunArray can be naturally combined via reduced product with any existing analysis for scalar variables. The bound expressions, the segment abstractions and the reduction operator are the three parameters of the analysis. Once the functor has been instantiated with fixed parameters, the analysis is fully automatic.

We first prototyped FunArray in Arrayal to adjust and experiment with the abstractions and the algorithms to obtain the appropriate precision/ratio cost. Then it was implemented into CCCHECK (formerly CLOUSOT), an abstract interpretation-based static contract checker for .NET by Francesco Logozzo. The precision and the performance of the analysis has been empirically validated by running it on the main libraries of .NET and on its own code. It was able to infer thousands of invariants and to verify the implementation with a modest overhead (circa 1%). To the best of our knowledge this is the first analysis of this kind applied to such a large code base, and proven to scale.

6.4. Extrapolation operators for combinations of abstract domains

Participants: Agostino Cortesi [Università Ca’ Foscari di Venezia], Matteo Zanioli.

Extrapolation operators are crucial to ensure the scalability of the analysis to large software systems. In [10], we set the ground for a systematic design of widening and narrowing operators, by comparing the different definitions introduced in the literature and by discussing how to tune them in case of domain abstraction and domains’ combination through Cartesian and reduced products.

6.5. Grammar Semantics, Analysis and Parsing

Participants: Patrick Cousot, Radhia Cousot.

In [11], we study the abstract interpretations of a fixpoint protoderivation semantics defining the maximal derivations of a transitional semantics of context-free grammars akin to pushdown automata. The result is a hierarchy of bottom-up or top-down semantics refining the classical equational and derivational language semantics and including Knuth grammar problems, classical grammar flow analysis algorithms, and parsing algorithms.

6.6. Information Flow

The analysis of the flow of information in a program consists in detecting the propagation of sensitive information through the program points of this program thanks to a dependency analysis.

6.6.1. Dependency Analysis and Numerical Invariants

Participants: Agostino Cortesi [Università Ca’ Foscari di Venezia], Matteo Zanioli.

A new framework has been proposed in [16], that combines variable dependency analysis, based on propositional formulas, and variables’ value analysis, based on generic numerical domains.

6.6.2. Leakage Analysis

Participants: Matteo Zanioli [Correspondent], Pietro Ferrara [ETH, Zurich], Agostino Cortesi [Università Ca’ Foscari].
In [24], we present SAILS, a new tool that combines SAMPLE, a generic static analyzer, and a sophisticated domain for leakage analysis. This tool does not require to modify the original language, since it works with mainstream languages like JAVA™, and it does not require any manual annotation. SAILS can combine the information leakage analysis with different heap abstractions, inferring information leakage over programs with complex data structures. SAILS has been applied to the analysis of the SecuriBench-micro suite. The experimental results underline the effectiveness of the analysis, since SAILS is in position to analyze several benchmarks in about 1 second without producing false alarms in more than 90% of the programs.

6.7. Linear Absolute Value Relation Analysis

Participants: Liqian Chen [National Laboratory for Parallel and Distributed Processing, Changsha, P. R. China], Antoine Miné, Ji Wang [National Laboratory for Parallel and Distributed Processing, Changsha, P. R. China], Patrick Cousot.

We present in [15] an abstract domain dealing with linear inequalities involving variables together with their absolute values. It is an extension of the classical linear relation analysis, which permits to deal with some non convex numerical sets. A first nice result states the equivalence between these “linear absolute value inequalities” (AVI) and “interval linear inequalities”, and “extended linear complementary inequalities” (XLCP, pairs of positive solutions whose pairwise components are not both not zero). The key contribution is the extension of the double-description of polyhedra to XLCP solutions, which is then used to define the standard operations on AVI. The method has been implemented, and experiments show interesting results, with reasonable performances with respect to linear relation analysis.

6.8. Probabilistic Analysis

Participants: Patrick Cousot, Michaël Monerau.

The abstract interpretation theory has been widely used in the past decades for verifying properties of computer systems. We have introduced a new extension of this well-known framework to the case of probabilistic systems [21].

The probabilistic abstraction framework we propose allows to systematically lift any classical analysis or verification method to the probabilistic setting by separating in the program semantics the probabilistic behavior from the (non-)deterministic behavior. This separation provides new insights for designing novel probabilistic static analyses and verification methods.

We have defined concrete probabilistic semantics and proposed different ways to abstract them. The approach is expressive and effective. The previous techniques for probabilistic analysis are actually abstractions expressible in our framework.

6.9. Safety

Participants: Patrick Cousot, Radhia Cousot.

The abstract interpretation design principle has been applied to the design of new forward and backward proof, verification and analysis methods for safety [17]. The safety collecting semantics defining the strongest safety property of programs is first expressed in a constructive fixpoint form. Safety proof and checking/verification methods then immediately follow by fixpoint induction. Static analysis of abstract safety properties such as invariance are constructively designed by fixpoint abstraction (or approximation) to (automatically) infer safety properties.

6.10. Security

Participants: Patrick Cousot, Radhia Cousot.
We have developed, episodically since 2007, an abstract interpretation framework for security and program securization that is the transformation of a program into a secured program satisfying security criteria defined by a human or artificial supervisor (this is verification when no transformation is needed). The securization is based on the notion of responsibility analysis determining which choices in the program (inputs, random draws, schedules, etc.) can definitely cause or avoid desired or menacing events, or have no control at all on the occurrence of these events. Various securization policies (eager, early or late lazy, etc.) have been identified to prevent or enforce the occurrence of events.

6.11. Shape Analysis

We have extended the XISA (eXTensible Inductive Shape Analysis) framework, in order to better deal with low level coding styles and programming languages, and in order to analyze recursive programs in a context dependent way. We also introduced a classification for semantic memory models.

6.11.1. Abstracting Calling-Context with Shapes

Participants: Bor-Yuh Evan Chang [University of Colorado at Boulder (USA)], Xavier Rival.

Interprocedural program analysis is often performed by computing procedure summaries. While possible, computing adequate summaries is difficult, particularly in the presence of recursive procedures. In [23], we propose a complementary framework for interprocedural analysis based on a direct abstraction of the calling context. Specifically, our approach exploits the inductive structure of a calling context by treating it directly as a stack of activation records. We built an abstraction based on separation logic with inductive definitions. A key element of this abstract domain is the use of parameters to refine the meaning of such call stack summaries and thus express relations across activation records and with the heap. In essence, we define an abstract interpretation-based analysis framework for recursive programs that permits a fluid per call site abstraction of the call stack—much like how shape analyzers enable a fluid per program point abstraction of the heap.

6.11.2. Abstract domains for the analysis of programs manipulating complex data-structures

Participant: Xavier Rival.

We proposed a framework for building abstract domains for the static analysis of programs which manipulate complex data-structures [8]. Our abstract domain is parametric in the choice of a numerical abstract domain to represent properties of numeric memory cells and in the choice of a set of inductive definitions to be used in order to summarize unbounded heap regions. It features standard primitives for the computation of transfer functions, for the inclusion checking and for the computation of widening iterates. We also proposed an extension to handle programs that make use of low-level memory addressing, and proposed an extension of the widening to infer inductive definitions.

6.11.3. Composite abstract domain for the analysis of dynamic structures

Participants: Xavier Rival, Antoine Toubhans.

Reduced product is a general operation to combine abstract domains into more powerful abstract domains, which has been especially used to construct numerical abstract domains. However, until now, it has not been applied to memory structures. We proposed an instance of a reduced product operation, which can be applied on shape abstract domains based on separation logic and on inductive definitions. The advantage of this construction is that it allows to describe more complex heap dynamic data structures without making the design of all abstract operation more complex. In the other hand, it incurs a reduction cost, whenever we need to transport some information from one domain to the other. We showed that optimal reduction cannot be achieved, and identified the main source of complexity of this operation. A prototype implementation was also carried out. This work was done as part of Antoine Toubhans Master internship.

6.12. Static Analysis of Parallel Software

Participant: Antoine Miné.
We present in [22] a static analysis by abstract interpretation to check for run-time errors in parallel C programs. Following our work on ASTRÉE, we focus on embedded critical programs without recursion nor dynamic memory allocation, but extend the analysis to a static set of threads. Our method iterates a slightly modified non-parallel analysis over each thread in turn, until thread interferences stabilize. We prove the soundness of the method with respect to a sequential consistent semantics and a reasonable weakly consistent memory semantics. We then show how to take into account mutual exclusion and thread priorities through partitioning over the scheduler state. We present preliminary experimental results analyzing a real program with our prototype ASTRÉEA (see 5.3) and demonstrate the scalability of our approach.

6.13. Termination

Participants: Patrick Cousot, Radhia Cousot.

In [17], we have introduced an abstract interpretation for termination. Proof, verification and analysis methods for termination all rely on two induction principles: (1) a variant function or induction on data ensuring progress towards the end and (2) some form of induction on the program structure.

So far, no clear design principle did exist for termination as is the case for safety so that the existing approaches are scattered and largely not comparable with each other.

For (1), we show that this design principle applies equally well to potential and definite termination. The trace-based termination collecting semantics is given a fixpoint definition. Its abstraction yields a fixpoint definition of the best variant function. By further abstraction of this best variant function, we derive the Floyd/Turing termination proof method as well as new static analysis methods to effectively compute approximations of this best variant function.

For (2), we introduce a generalization of the syntactic notion of structural induction (as found in Hoare logic) into a semantic structural induction based on the new semantic concept of inductive trace cover covering execution traces by segments, a new basis for formulating program properties. Its abstractions allow for generalized recursive proof, verification and static analysis methods by induction on both program structure, control, and data. Examples of particular instances include Floyd’s handling of loop cut-points as well as nested loops, Burstall’s intermittent assertion total correctness proof method, and Podelski-Rybalchenko transition invariants.

6.14. Theories, Solvers and Static Analysis

Participants: Patrick Cousot, Radhia Cousot, Laurent Mauborgne [IMDEA Software (Madrid, Spain)].

In [20], we have introduced a reduced product combining algebraic and logical abstractions to design program correctness verifiers and static analyzers by abstract interpretation. The key new idea is to show that the Nelson-Oppen procedure for combining theories in SMT-solvers computes a reduced product in an observational semantics, so that algebraic and logical abstract interpretations can naturally be combined in a classical way using a reduced product on this observational semantics. The main practical benefit is that reductions can be performed within the logical abstract domains, within the algebraic abstract domains, and also between the logical and the algebraic abstract domains, including the case of abstractions evolving during the analysis.

6.15. Underapproximation for Precondition Inference

Participants: Patrick Cousot, Radhia Cousot, Francesco Logozzo [Microsoft Research (Redmond, USA)], Manuel Fähndrichh [Microsoft Research (Redmond, USA)].
In the context of program design by contracts, programmers often insert assertions in their code to be optionally checked at runtime, at least during the debugging phase. These assertions would better be given as a precondition of the method/procedure in which they appear. Potential errors would be discovered earlier and, more importantly, the precondition could be used in the context of separate static program analysis as part of the abstract semantics of the code. However in the case of collections (data structures such as arrays, lists, etc) checking both the precondition and the assertions at runtime appears superfluous and costly. So the precondition is often omitted since it is checked anyway at runtime by the assertions. It follows that the static analysis can be much less precise, a fact that can be difficult to understand since “the precondition and assertions are equivalent” (i.e. at runtime, up to the time at which warnings are produced, but not statically) e.g. for separate static analysis. Moreover preconditions are often understood as overapproximations and thus may exclude good runs which is counter-intuitive for programmers. On the contrary, with considering underapproximations [37], [28] which exclude no good run, ensures that if the precondition is violated then a runtime error must definitely be raised later, and if the precondition is not strong enough to catch all errors they will definitely be captures by a later runtime check.

In [19], we define precisely and formally the contract inference problem from intermittent assertions on scalar variables and elements of collections inserted in the code by the programmer. Our definition excludes no good run even when a non-deterministic choice (e.g. an interactive input) could lead to a bad one. We then introduce new abstract interpretation-based methods to automatically infer both the static contract precondition of a method/procedure and the code to check it at runtime on scalar and collection variables. It has been implemented in CCCHECK (formerly CLOUSOT) by Francesco Logozzo and Manuel Fähndrich.

6.16. Verification of spreadsheet programs by abstract interpretation

Participants: Tie Cheng, Xavier Rival.

Spreadsheet tools (Excel, Openoffice) come with powerful languages which can manipulate sheets in various ways. However, no type discipline is enforced, so that the programs may corrupt spreadsheet contents in many ways. We proposed an abstraction to describe sets of valid spreadsheet states, and designed a verifier for invariants expressed in this abstract domain. Our verifier assumes invariants are defined at the head of loops in the programs (as widening operators for the inference of loop invariants). This work was done as part of Tie Cheng Master internship.
4. New Results

4.1. Spatial Computing approach and RFIDs

Participants: Michel Banâtre, Paul Couderc [contact], Yann Glouche, Arnab Sinha.

In the line of our previous research in pervasive computing, we are working on spatial computing approaches in the context of RFID. Spatial computing consists in data structures and computing processes directly supported by physical objects. RFID is an attractive technology for supporting spatial computing, enabling any object to interact in a smart environment. Traditional RFID solutions use a logical model, where the RFID tags are simple identifiers referring to data in a remote information system. In our approach, we use the memory of the tags to build self-contained data structures and self-describing objects. While featuring interesting properties, such as autonomous operation and high scalability, this approach also raises difficult challenges: the memory capacity of the tags is very limited, requiring compact and efficient data structures. Some results have been achieved for security applications, where we contributed to efficient integrity checking solution for coupled objects. Integrity checking based on objects group can also be used to provide reliable inventory protocol for RFID, which current readers are lacking. A paper has just been submitted on this aspect.

An applicative project (see 5.2.1) in the context of domestic waste management is broadly investigating the use of RFID at item level to provide early waste sorting, to avoid incompatible mix of waste and to prevent hazards. An ontology based system has been proposed to determine the possible interactions of tagged products based on their properties and the external conditions.

4.2. Integrity checking with coupled objects

Participants: Michel Banâtre [contact], Paul Couderc, Jean-Francois Verdonck.

Integrity checking is an important concern in many activities, such as logistic, telecommunication or even day to day tasks such as checking for someone missing in a group. While the computing and telecommunication worlds commonly use digital integrity checking, many activities from the real world do not benefit from automatic integrity control mechanisms. RFID technology offers promising perspectives for facing this problem, but also raises strong privacy concerns as most of the RFID-based systems rely on global identification and tracking. Previously we have already designed Ubi-Check to provide an approach aiming at coupling physical objects and enabling integrity control built on local interactions, without the support of a global information system. Ubi-Check led to the development of various novel applications running quite on the same technology. Most of the partners showed a high interest in defining coupled object-based security solutions, but they were lacking the possibility of defining hierarchical couplings. This is that we have studied and implemented this year. We have designed the Ubi-Tree software which strives to deal with those new requirements.

4.2.1. Hierarchical physical object coupling

Ubi-Tree is a new solution/software designed at INRIA aiming at setting-up and reading hierarchical couplings. It relies on a structure in which physical objects (also called fragments) are seen as external nodes of a tree that we call coupling tree. External nodes of a tree are called leaves. In the system, internal nodes are called coupling nodes. Each fragment embeds an RFID tag supporting coupling data. Coupling data stores the coupling tree. Each internal node can be checked, which means a lacking, illegally forged or corrupted node can be detected at any depth of a coupling. Ubi-Tree proposes a new API to create and check hierarchical couplings and an interactive editing GUI is under development.
4.2.2. Coupling tree structure

New algorithms and structure to store and read hierarchical couplings trees in its leaves (RFID tags) have been developed, making it possible to use multiple coupling levels. Let’s take an example: given three physical objects $o_1, o_2, o_3$. A user can couple $o_1$ and $o_2$ together. Let $N_1$ be the parent coupling of $o_1$ and $o_2$: $N_1 = o_1, o_2$. Then he couples this coupling with $o_3$ to create the $N_2 = o_1, o_2, o_3$ coupling node. Figure 2 gives an illustration of the described coupling.

The key idea of the coupling structure is that coupling data are spread in a way that only descendant leaves of a coupling node are required to read it and process its integrity control. This way, $N_1$ only needs $o_1$ and $o_2$ to be read and / or checked as $o_1$ and $o_2$ are descendants from $N_1$ whereas $o_3$ is not. This choice enables to process integrity controls at multiple coupling levels. It is very convenient, as an example, if $o_3$ is physically separated from $o_1$ and $o_2$. So if $o_1$, $o_2$ and $o_3$ are brought into the field of the RFID reader, $N_1$ and $N_2$ can be written, read and checked. If $o_3$ is not present in its field, $N_2$ will not be recovered from the read data but $N_1$ can still be read and checked. If checked, $N_1$ will notify it was not the root of the coupling tree when the coupling tree was written. This way, the user knows it did not read the whole structure $o_1$ and $o_2$ are part of. Indeed, coupling nodes can have the following status:

- Valid: the set of detected tags enabled to decode a structure in which the node has the children and the parent it is supposed to have.
- Partial: same as the valid status except the node should have a parent that could not be read from detected tags.
- Incomplete: the node is missing some of its children.

4.2.3. Ongoing work

Today the management algorithms of graphs are located on the memory available RFID reading and writing. However, in the various applications envisaged, only a subset of RFID memory are read / write, others are only accessible in read-only. Currently we are working on the development of our algorithms that take into account this kind of configuration. The other problem we are working on today is the interface provided to users to be sure that the association between RFID tag and physical object is the one that is perceived by our coupling software. The idea is to be able to identify in the right way the RFID tag associated to a physical object when we place one physical object $O$ onto the support of the antenna linked to the RFID reader. The position of $O$, and the tag associated to $O$, in the physical space is determined using a camera coupled with an image recognition algorithm. The result is displayed onto a touch screen. In that way, when we want to couple a set of physical objects $o_1, o_2, ...$ We place sequentially all these objects onto the support of the antenna, and
from the image of these objects displayed onto the touch screen we touch those we want to couple and activate the coupling operation. This solution is under development.

4.3. Pervasive support for Smart Homes

Participants: Minh Tuan Ho, Michele Dominici, Bastien Pietropaoli, Frédéric Weis [contact].

Pervasive computing involves tight links between real world activities and computing process. While the perception of the real world events can be handled entirely by the application, we think that ad hoc approaches have limitations, in particular the complexity and the difficulty to re-use the code between applications. Instead, we promote the use of system level abstraction that leverage on tangible structures and processes. Important properties of this approach is that applications are, by design, operating in an implicit way ("in the background" of physical processes). They also often exhibits simpler architectures, and "natural" scalability in the sense that being build upon existing real-world process, they are strongly distributed design that relies essentially on local interactions between physical entities. We are applying this approach to "Smart Homes". A Smart Home is a residence equipped with computing and information technology devices conceived to collaborate in order to anticipate and respond to the needs of the occupants, working to promote their comfort, convenience, security and entertainment while preserving their natural interaction with the environment.

4.3.1. Definition of a system architecture

In a classical "logical" approach, all the intelligence of the Smart Home is condensed in a single entity that takes care of every device in the house. The sensors distributed in the environment have to send back all the gathered data to the central entity, that takes all the burden of parsing the sensitive information and infer the policies to be implemented. Our architecture is instead focused on a physical approach, where every device carries a part of the global intelligence: every single entity can analyze the part of information sensitive for its goal, derive useful data, and communicate meaningful information to the other devices.

Figure 3. Four-layer model

Our work is based on a four-layer model [8], as showed in Figure 3. The first layer of our system should be simply composed of sensors, but some constraints have to be fitted. In order to reduce the global system cost and to protect the inhabitants’ privacy, the number of sensors dispatched in the environment has to be reduced as much as possible. However, a huge number of different sensors are required to sense context pieces and redundancy can significantly increase the reliability of the sources. With this idea in mind, the sensors are grouped in nodes. These nodes are able to preprocess the data with simple computation such as minimum, maximum and average. They also enable the sensors to communicate, using, for instance, 6LowPAN (IPv6 over LoW Power wireless Area Networks).
In the second layer, the raw data are processed to obtain more abstract data about context and occurring situations. It could be, for instance, a presence in a room, the number of people in this room or the posture of someone. The aggregation of raw data is realized thanks to a data fusion algorithm. The one we adopted is called the belief functions theory or theory of evidence [6].

The bridge between the second and the third layer is realized integrating the results of sensor data fusion into a context model called Context Spaces. This model uses geometrical metaphors to describe context and situations, relying on the following concepts: the context attributes, the application space, the situation spaces and the context state. The context attributes are information types that are relevant and obtainable by the system; in our case, the context attribute values are provided by the perception layer, together with a degree of confidence on them, needed to cope with the intrinsic uncertainty of sensing systems in real world scenarios. In the situation and context identification layer, the context state provided by the perception layer is analyzed to infer the ongoing situation spaces (representing real-life situations) and also produce a measure of confidence in their occurrence. As the same context state can correspond to several different situation spaces (and vice versa), reasoning techniques are needed to discern the actual ongoing real-life situations in spite of uncertainty [5].

4.3.2. Experimentation

The computations required by the second and the third layers to obtain abstract data and to analyze context and situations are too heavy for our nodes to be processed on. To remedy to this problem, more powerful nodes acting like sinks are used. These nodes are small “plug and play” computers called plug computers. Their role is to gather data from sensor nodes and to perform data fusion, required to produce the context attributes, and context space reasoning, used to identify ongoing situations.

The figure gives an overview of our system architecture. The latter has been demonstrated by ACES team at EDF R&D in November.
6. New Results

6.1. Adaptive Middleware

In 2011, we pursued our goal to demonstrate that general and high level concepts and solutions can be proposed to design multi-scale middleware systems. The multi-scale aspect has particularly been put forward and we obtained several interesting results: we showed that the concepts of service, component, and software architecture can be successfully used, in the small for wireless sensor middleware platforms [19], [43] with applications to the Internet of Things (IoT) [27] and for embedded systems [14], in mid-size distributed environments such as digital home networks [17], and in the large in cloud computing platforms [30]. We focus below on two achievements which are illustrative in the sense that they address both ends of the targeted spectrum of sizes.

At the scale of small systems, we proposed the REMORA platform [19], [43], [27] which defines a lightweight event-based programming model for wireless sensor networks. A C-like language for component implementation and an extension of the state-of-the-art Service Component Architecture (SCA) standard for service-oriented systems are proposed. The platform has been successfully deployed on the Contiki operating system. We showed that despite the characteristics of such resource-constrained environments, we are still able to obtain reconfigurability and adaptability properties for the deployed systems.

At the scale of very large systems, we showed in [30] first results that illustrate the fact that the FraSCAti platform [18] can be used to achieve interoperability between applications deployed on heterogeneous cloud platforms. The experiment is currently deployed on 13 public IaaS and PaaS cloud infrastructures. The very same concepts of service and software architecture that are used at smaller scales are put into practice here. Furthermore, we benefit from the same adaptability properties to address the heterogeneity of concepts needed to fit these very large scale infrastructures.

6.2. Context-awareness and Ambient Intelligence Software

Participants: Laurence Duchien, Sébastien Mosser, Clément Quinton.

Context-aware applications are applications that can react to changes on their environment. To achieve such reacting behavior, several challenges have to be faced in terms of: context management, support for dynamic reconfiguration, automation of development, and a consistent development process. One possible way to face those challenges is to use the principles of Software Product Line (SPL) and specifically dynamic SPL (DSPL). DSPLs focus on variability management and aim at deriving different products from a same product family. Additionally, DSPLs allow for products to be derived both at design and at runtime. This enables applications to be adapted during execution and dynamically fit new requirements or resource changes. In [16] we have proposed an approach to unify adaptation at design and at runtime based on Aspect Oriented Modeling. Our approach proposes a unified aspect metamodel and a platform that realizes two different weaving processes to achieve design and runtime adaptations. This approach is used in a Dynamic Software Product Line which derives products that can be configured at design time and adapted at runtime in order to dynamically fit new requirements or resource changes. Such products are implemented using the Service Component Architecture and Java. Finally, we have illustrated the use of our approach based on an adaptive e-shopping scenario. This work corresponds to Carlos Parra’s PhD thesis [11] and is partially funded by the CAPPUCINO project. Finally, in [40], we have proposed to develop an application for mobile devices using Software Product Lines (SPL). Considering variation factors, SPL allows the conception and the development of a software products family minimizing realization cost and time. The result is the APPLIDE framework, which provides SPL for smartphones, and we show how it works with a short demonstration.
6.3. SCeSAME: Formal Definition of Software Architecture Adaptation

Participants: Rubby Casallas, Laurence Duchien, Nohra Villegas, Gabriel Tamura.

In order to define properties on adaptation process, we need to formally model the architecture reconfiguration of a component-based (CB) system as an action performed by itself. These actions are performed in response to the disruption of Quality of Service (QoS) contracts, in the spirit of the Effeil’s rescue clause in object-oriented programming. By doing this, we aim to develop on the vision of the CBSE as a sound base to produce software systems enabled to automatically and safely reconfigure themselves by reconfiguring their abstract (reflection) architectures at runtime. For such structural reconfigurations, a system architect may reuse design patterns from other disciplines with the purpose of restoring QoS contracts, thus preserving them.

Our approach, named SCeSAME for “A Safe Contract-based Self-Adaptive Framework to Preserve QoS Properties on Mobile Devices” is built on the theory of extended graph (e-graph) rewriting proposed in e-graph [60], as a formalism to represent QoS contracts on component. We have given a formal definition of component-based structure systems, QoS contracts, and architecture reconfiguration rules. Based on these definitions, we built a framework that enables a component-based system to preserve its QoS contracts through architecture self-reconfiguration as a responding action to QoS contract violations. Our approach extends a theory of graph rewriting and defines a process calculus as formalisms to model the structure and reconfiguration process of architecture reconfiguration. The reconfiguration process, once parameterized with reconfiguration rules, can be verified as safe, i.e., component structural-compliant, terminating and confluent. This result is a part of Gabriel Tamura’s PhD and the results have been published in [36], [44].
5. New Results

5.1. Snell enveloppe with small probability criteria

We present in [33] a new algorithm to compute the Snell envelope in the specific case where the criteria to optimize is associated with a small probability or a rare event. This new approach combines the Stochastic Mesh approach of Broadie and Glasserman with a particle approximation scheme based on a specific change of measure designed to concentrate the computational effort in regions pointed out by the criteria. The theoretical analysis of this new algorithm provides non asymptotic convergence estimates. Finally, the numerical tests confirm the practical interest of this approach.

5.2. On the concentration properties of Interacting particle processes

In [34], we present some new concentration inequalities for Feynman-Kac particle processes. We analyze different types of stochastic particle models, including particle profile occupation measures, genealogical tree based evolution models, particle free energies, as well as backward Markov chain particle models. We illustrate these results with a series of topics related to computational physics and biology, stochastic optimization, signal processing and bayesian statistics, and many other probabilistic machine learning algorithms. Special emphasis is given to the stochastic modeling and the quantitative performance analysis of a series of advanced Monte Carlo methods, including particle filters, genetic type island models, Markov bridge models, interacting particle Markov chain Monte Carlo methodologies.

5.3. A Robbins-Monro procedure for estimation in semiparametric regression models

The paper [39] is devoted to the parametric estimation of a shift together with the nonparametric estimation of a regression function in a semiparametric regression model. We implement a Robbins-Monro procedure very efficient and easy to handle. On the one hand, we propose a stochastic algorithm similar to that of Robbins-Monro in order to estimate the shift parameter. A preliminary evaluation of the regression function is not necessary for estimating the shift parameter. On the other hand, we make use of a recursive Nadaraya-Watson estimator for the estimation of the regression function. This kernel estimator takes in account the previous estimation of the shift parameter. We establish the almost sure convergence for both Robbins-Monro and Nadaraya-Watson estimators. The asymptotic normality of our estimates is also provided.

5.4. Discrete Time Markovian Agents Interacting Through a Potential

A discrete time stochastic model for a multiagent system given in terms of a large collection of interacting Markov chains is studied. The evolution of the interacting particles is described through a time inhomogeneous transition probability kernel that depends on the ’gradient’ of the potential field. The particles, in turn, dynamically modify the potential field through their cumulative input. Interacting Markov processes of the above form have been suggested as models for active biological transport in response to external stimulus such as a chemical gradient. One of the basic mathematical challenges is to develop a general theory of stability for such interacting Markovian systems and for the corresponding nonlinear Markov processes that arise in the large agent limit. Such a theory would be key to a mathematical understanding of the interactive structure formation that results from the complex feedback between the agents and the potential field. It will also be a crucial ingredient in developing simulation schemes that are faithful to the underlying model over long periods of time. The goal of the work developed in [42] is to study qualitative properties of the above stochastic system as the number of particles (N) and the time parameter (n) approach infinity. In this regard asymptotic properties of a deterministic nonlinear dynamical system, that arises in the propagation of chaos
limit of the stochastic model, play a key role. We show that under suitable conditions this dynamical system has a unique fixed point. This result allows us to study stability properties of the underlying stochastic model. We show that as \( N \to \infty \), the stochastic system is well approximated by the dynamical system, uniformly over time. As a consequence, for an arbitrarily initialized system, as \( N \to \infty \) and \( n \to \infty \), the potential field and the empirical measure of the interacting particles are shown to converge to the unique fixed point of the dynamical system. In general, simulation of such interacting Markovian systems is a computationally daunting task. We propose a particle based approximation for the dynamic potential field which allows for a numerically tractable simulation scheme. It is shown that this simulation scheme well approximates the true physical system, uniformly over an infinite time horizon.

5.5. An Adaptive Interacting Wang-Landau Algorithm for Automatic Density Exploration

While statisticians are well-accustomed to performing exploratory analysis in the modeling stage of an analysis, the notion of conducting preliminary general-purpose exploratory analysis in the Monte Carlo stage (or more generally, the model-fitting stage) of an analysis is an area which we feel deserves much further attention. Towards this aim, the paper \([41]\) proposes a general-purpose algorithm for automatic density exploration. The proposed exploration algorithm combines and expands upon components from various adaptive Markov chain Monte Carlo methods, with the Wang-Landau algorithm at its heart. Additionally, the algorithm is run on interacting parallel chains – a feature which both decreases computational cost as well as stabilizes the algorithm, improving its ability to explore the density. Performance is studied in several applications. Through a Bayesian variable selection example, the authors demonstrate the convergence gains obtained with interacting chains. The ability of the algorithm’s adaptive proposal to induce mode-jumping is illustrated through a trimodal density and a Bayesian mixture modeling application. Lastly, through a 2D Ising model, the authors demonstrate the ability of the algorithm to overcome the high correlations encountered in spatial models.

5.6. A sharp analysis on the asymptotic behavior of the Durbin-Watson statistic for the first-order autoregressive process

The purpose of the paper \([40]\) is to provide a sharp analysis on the asymptotic behavior of the Durbin-Watson statistic. We focus our attention on the first-order autoregressive process where the driven noise is also given by a first-order autoregressive process. We establish the almost sure convergence and the asymptotic normality for both the least squares estimator of the unknown parameter of the autoregressive process as well as for the serial correlation estimator associated to the driven noise. In addition, the almost sure rates of convergence of our estimates are also provided. It allows us to establish the almost sure convergence and the asymptotic normality for the Durbin-Watson statistic. Finally, we propose a new bilateral statistical test for residual autocorrelation.

5.7. Large deviations for Gaussian stationary processes and semi-classical analysis

In \([37]\), we obtain a large deviation principle for quadratic forms of Gaussian stationary processes. It is established by the conjunction of a result of Roch and Silbermann on the spectrum of products of Toeplitz matrices together with the analysis of large deviations carried out by Gamboa, Rouault and the rst author. An alternative proof of the needed result on Toeplitz matrices, based on semi-classical analysis, is also provided.

5.8. Sharp large deviations for the non-stationary Ornstein-Uhlenbeck process

For the Ornstein-Uhlenbeck process, the asymptotic behavior of the maximum likelihood estimator of the drift parameter is totally different in the stable, unstable, and explosive cases. Notwithstanding of this trichotomy, we investigate sharp large deviation principles for this estimator in the three situations. In the explosive case, we exhibit in \([38]\) a very unusual rate function with a shaped flat valley and an abrupt discontinuity point at its minimum.
5.9. Markovian quadratic and superquadratic BSDEs with an unbounded terminal condition

The work in [43] deals with the existence and the uniqueness of solutions to quadratic and superquadratic Markovian backward stochastic differential equations (BSDEs for short) with an unbounded terminal condition. Our results are deeply linked with a strong a priori estimate on $Z$ that takes advantage of the Markovian framework. This estimate allows us to prove the existence of a viscosity solution to a semilinear parabolic partial differential equation with nonlinearity having quadratic or superquadratic growth in the gradient of the solution. This estimate also allows us to give explicit convergence rates for time approximation of quadratic or superquadratic Markovian BSDEs.

5.10. New approach on recursive and non-recursive SIR

In [3], we consider a semiparametric single index regression model involving a p-dimensional quantitative covariable $x$ and a real dependent variable $y$. A dimension reduction is included in this model via an index $x^T \beta$. Sliced inverse regression (SIR) is a well-known method to estimate the direction of the Euclidean parameter $\beta$ which is based on a "slicing step" of $y$ in the population and sample versions. The goal of this paper is twofold. On the one hand, we focus on a recursive version of SIR which is also suitable for multiple indices model. On the other hand, we propose a new method called SIRoneslice when the regression model is a single index model. The SIRoneslice estimator of the direction of $\beta$ is based on the use of only one "optimal" slice chosen among the H slices. Then, we provide its recursive version. We give an asymptotic result for the SIRoneslice approach. Simulation study shows good numerical performances of the SIRoneslice method and clearly exhibits the main advantage of using recursive versions of the SIR and SIRoneslice methods from a computational time point of view. A real dataset is also used to illustrate the approach. The proposed methods and criterion have been implemented in R and the corresponding codes are made available.

5.11. Classification of EEG data by evolutionary algorithm for the study of vigilance states

The objective of this work [18] is to predict the state of vigilance of an individual from the study of its brain activity (EEG signals). The variable to predict is binary (alertness "normal" or "relaxed"). EEG of 44 participants in both states (88 records) were collected with a helmet with 58 electrodes. After a pretreatment step and data validation, a test called "test slope" was chosen. The usual methods of supervised classification (k nearest neighbors, binary classification trees, random forests, and discriminant sparse PLS) were used to provide predictions of the state of participants. The test was then refined using a genetic algorithm, which has built a reliable model (average true classification rate by using CART equal to 86.68 +/- 1.87%) and to select an electrode from the initial 58.

5.12. Genetic Programming

Recently, it has been stated that the complexity of a solution is a good indicator of the amount of overfitting it incurs. However, measuring the complexity of a program, in Genetic Programming, is not a trivial task. In [22], we study the functional complexity and how it relates with overfitting on symbolic regression problems. We consider two measures of complexity, Slope-based Functional Complexity, inspired by the concept of curvature, and Regularity-based Functional Complexity based on the concept of Holderian regularity. In general, both complexity measures appear to be poor indicators of program overfitting. However, results suggest that Regularity-based Functional Complexity could provide a good indication of overfitting in extreme cases. During the development of applied systems, an important problem that must be addressed is that of choosing the correct tools for a given domain or scenario. This general task has been addressed by the genetic programming (GP) community by attempting to determine the intrinsic difficulty that a problem poses for a GP search. In [21], we present an approach to predict the performance of GP applied to data classification, one of the most common problems in computer science. The novelty of the proposal is to extract statistical descriptors
and complexity descriptors of the problem data, and from these estimate the expected performance of a GP classifier. We derive two types of predictive models: linear regression models and symbolic regression models evolved with GP. The experimental results show that both approaches provide good estimates of classifier performance, using synthetic and real-world problems for validation. In conclusion, this paper shows that it is possible to accurately predict the expected performance of a GP classifier using a set of descriptors that characterize the problem data.

The analysis of image regularity using Holder exponents can be used to characterize singular structures contained within an image, and provide a compact description of local shape and appearance. However, estimating the Holder exponent is not a trivial task and current methods tend to be slow and complex. Therefore, the goal in [35] is to automatically synthesize image operators that can be used to estimate the Holder regularity of an image. We pose this task as an optimization problem and use Genetic Programming (GP) to search for operators that can approximate a traditional estimator, the oscillations method. In our experiments, GP was able to evolve estimators that achieve a low error and a high correlation with the ground truth estimation. Furthermore, most of the GP estimators are faster than the traditional approaches, in some cases their runtime is orders of magnitude smaller. This result allowed us to implement a real-time estimation of the Holder exponent on a live video signal, the first such implementation in current literature. Moreover, the evolved estimators are used to generate local descriptors of salient image regions, a task for which we obtain a stable and robust matching that is comparable with state-of-the-art methods. In conclusion, the evolved estimators produced by GP could help expand the application domain of Holderian regularity within the fields of image analysis and signal processing.

5.13. Relevance of the Holderian regularity-based interpolation for range-Doppler ISAR image post-processing

In ISAR processing, post-processing of the range Doppler image is useful to help the practitioner for ship recognition. Among the image post-processing tools, interpolation methods can be of interest especially when zooming. In [19], we study the relevance of the Holderian regularity-based interpolation. In that case, interpolating consists in adding a new scale in the wavelet transform and the new wavelet coefficients can be estimated from others. In the original method, initially proposed by two of the authors, the image is first interpolated along the rows and then along the columns. Concerning the diagonal pixels, they are estimated as the mean of the adjacent original and interpolated pixels. Here, we propose a variant where the diagonal pixels are estimated by taking into account the local orientation of the image. It has the advantage of conserving local regularity on all interpolated pixels of the image. A comparative study on synthetic data and real range-Doppler images is then carried out with alternative interpolation techniques such as the linear interpolation, the bicubic one, the nearest neighbour interpolation, etc. The simulation results confirm the effectiveness of the approach.

5.14. On-line changepoint detection and parameter estimation with application to genomic data

We propose in [10] an efficient on-line changepoint detection algorithm for an important class of Bayesian product partition models. The algorithm allows to estimate jointly on-line the static parameters of the model using a recursive maximum likelihood estimation strategy. This particle filter type algorithm has a computational complexity which scales linearly both in the number of data and the number of particles. We demonstrate our methodology on a synthetic and two real world datasets from RNA transcript analysis. On simulated data, it is shown that our approach outperforms standard techniques used in this context and hence has the potential to detect novel RNA transcripts.

5.15. Bayesian Sparsity-Path-Analysis of Genetic Association Signal using Generalized t Priors
In [17], we explore the use of generalized t priors on regression coefficients to help understand the nature of association signal within "hit regions" of genome-wide association studies. The particular generalized t distribution we adopt is a Student distribution on the absolute value of its argument. For low degrees of freedom we show that the generalized t exhibits 'sparsity-prior' properties with some attractive features over other common forms of sparse priors and includes the well known double-exponential distribution as the degrees of freedom tends to infinity. We pay particular attention to graphical representations of posterior statistics obtained from sparsity-path-analysis (SPA) where we sweep over the setting of the scale (shrinkage / precision) parameter in the prior to explore the space of posterior models obtained over a range of complexities, from very sparse models with all coefficient distributions heavily concentrated around zero, to models with diffuse priors and coefficients distributed around their maximum likelihood estimates. The SPA plots are akin to LASSO plots of maximum a posteriori (MAP) estimates but they characterize the complete marginal posterior distributions of the coefficients plotted as a function of the precision of the prior. Generating posterior distributions over a range of prior precisions is computationally challenging but naturally amenable to sequential Monte Carlo (SMC) algorithms indexed on the scale parameter. We show how SMC simulation on graphic-processing-units (GPUs) provides very efficient inference for SPA. We also present a scale-mixture representation of the generalized t prior that leads to an EM algorithm to obtain MAP estimates should only these be required.
6. New Results

6.1. Processor Architecture

Participants: Damien Hardy, Pierre Michaud, Nathanaël Prémillieu, Ricardo Andrés Velasquéz, Luis-Germán García Morales, Bharath Narasimha Swamy, André Seznec.

Our research in computer architecture covers memory hierarchy, branch prediction, superscalar implementation, as well as SMT and multicore issues.

This year, we have also initiated new research directions within the context of the ERC DAL project.

6.1.1. Null block management on the memory hierarchy

Participant: André Seznec.

It has been observed that some applications manipulate large amounts of null data. Moreover, these zero data often exhibit high spatial locality. On some applications more than 20% of the data accesses concern null data blocks. To reduce the pressure on main memory, we have proposed a hardware compressed memory that only targets null data blocks, the decoupled zero-compressed memory [27]. Borrowing some ideas from the decoupled sectored cache [20], the decoupled zero-compressed memory, or DZC memory, manages the main memory as a decoupled sectored set-associative cache where null blocks are only represented by a validity bit. Our experiments show that for many applications, the DZC memory allows to artificially enlarge the main memory, i.e., it reduces the effective physical memory size needed to accommodate the working set of an application without excessive page swapping. Moreover, the DZC memory can be associated with a ZCA cache [5] to manage null blocks across the whole memory hierarchy. For some applications, such a management significantly decreases the memory traffic and therefore can significantly improve performance.

This work corresponds to the PhD of Julien Dusser defended in December 2010.

6.1.2. Emerging memory technologies

Participant: André Seznec.

Phase change memory (PCM) technology appears more scalable than DRAM technology. As PCM exhibits access time slightly longer but in the same range as DRAMs, several recent studies have proposed to use PCMs for designing main memory systems. Unfortunately, PCM technology suffers from a limited write endurance; typically, each memory cell can only be written a large but still limited number of times (10 millions to 1 billion writes are reported for current technology). Research proposals have essentially focused their attention on designing memory systems that will survive the average behavior of conventional applications. However, PCM memory systems should be designed to survive worst-case applications, i.e., malicious attacks targeting the physical destruction of the memory through overwriting a limited number of memory cells.

In 2010, we have proposed the first design of a secure PCM-based main memory that would by construction survive overwrite attacks [19]. This secure PCM-based main memory requires a significant read and write extra memory traffic (an extra memory write per 8 demand memory writes) on all applications. Concurrent proposals require even higher extra read and write memory traffic. In collaboration with a research group from IBM, we have proposed a hardware method to detect malicious overwrite attacks on the main memory, thus limiting the memory traffic overhead on non-malicious applications [32].

6.1.3. Microarchitecture exploration of control flow reconvergence

Participants: Nathanaël Prémillieu, André Seznec.
After continuous progress over the past 15 years [18], [17], the accuracy of branch predictors seems to be reaching a plateau. Other techniques to limit control dependency impact are needed. Control flow reconvergence is an interesting property of programs. After a multi-option control-flow instruction (i.e. either a conditional branch or an indirect jump including returns), all the possible paths merge at a given program point: the reconvergence point.

Superscalar processors rely on aggressive branch prediction, out-of-order execution and instruction level parallelism for achieving high performance. Therefore, on a superscalar core, the overall speculative execution after the mispredicted branch is cancelled, leading to a substantial waste of potential performance. However, deep pipelines and out-of-order execution induce that, when a branch misprediction is resolved, instructions following the reconvergence point have already been fetched, decoded and sometimes executed. While some of this executed work has to be cancelled since data dependencies exist, cancelling the control independent work is a waste of resources and performance. We have proposed a new hardware mechanism called SYRANT, SYmmetric Resource Allocation on Not-taken and Taken paths, addressing control flow reconvergence at a reasonable cost. Moreover, as a side contribution of this research we have shown that, for a modest hardware cost, the outcomes of the branches executed on the wrong paths can be used to guide branch prediction on the correct path.

6.1.4. Confidence estimation for the TAGE predictor

Participant: André Seznec.

For the past 15 years, it has been shown that confidence estimation of branch prediction (i.e., estimating the probability of correct or incorrect prediction) can be used for various usages such as fetch gating or throttling for power saving or for controlling resource allocation policies in an SMT processor. In many proposals, using extra hardware and particularly storage tables for branch confidence estimators has been considered as a worthwhile silicon investment.

The TAGE predictor, presented in 2006 [18], is so far considered as the state-of-the-art conditional branch predictor. We have shown that very accurate confidence estimations can be done for the branch predictions realized by the TAGE predictor by simply observing the outputs of the predictor tables. Many confidence estimators proposed in the literature only discriminate between high confidence predictions and low confidence estimations. It has been recently pointed out that a more selective confidence discrimination could be useful. The observation of the outputs of the predictor tables is sufficient to grade the confidence in the branch predictions with a very good granularity. Moreover a slight modification of the predictor automaton allows to discriminate the prediction in three classes, low-confidence (with a misprediction rate in the 30% range), medium confidence (with a misprediction rate in 8-12% range) and high confidence (with a misprediction rate lower than 1%) [37].

6.1.5. Improving branch prediction accuracy

Participant: André Seznec.

The TAGE predictor [18] is often considered as state-of-the-art in conditional branch predictors proposed by academia. For the 3rd championship branch prediction, we have further improved its accuracy by augmenting it with small side predictors (Loop predictor, Statiscal Corrector Predictor, Immediate Update Mimicker) [34]. This predictor won the conditional branch track of the 3rd championship branch prediction. In order to further argue for real hardware implementation of the TAGE predictor, we have presented several propositions to reduce the complexity of its hardware design, to reduce its energy consumption [36] and further improve branch accuracy. On a hardware implementation of a conditional branch predictor, the predictor tables are updated at retire time. A retired branch normally induces three accesses to the branch predictor tables: read at prediction time, read at retire time and write for the update. We show that in practice, the TAGE predictor accuracy would not be significantly impaired by avoiding a systematic second read of the prediction tables at retire time for correct prediction. Combined with the elimination of silent updates, this significantly reduces the number of accesses to the predictor. Furthermore, we present a technique allowing to implement the TAGE predictor tables as bank-interleaved structures using single-port memory components. This significantly
reduces the silicon footprint of the predictor as well as its energy consumption without significantly impairing its accuracy.

Correctly predicting the indirect branches has become critical with the introduction of object oriented programming, java programming as well as with the renewed importance of interpreters. The ITTAGE indirect branch predictor was introduced in [15]. Threes versions of the ITTAGE predictor were presented at the indirect branch track at the championship branch prediction by three different teams, and secured the three first places. Our proposition [35] won the championship.

6.1.6. Hardware acceleration of sequential loops

**Participant:** Pierre Michaud.

In a decade it will be possible to put on a single chip several hundreds of superscalar cores. A simple application of Amdahl's law shows that it will make sense to dedicate to sequential performance the silicon area and power budget corresponding to that of several tens, or perhaps several hundreds of conventional superscalar cores. This will lead to a **sequential accelerator** which will be used to accelerate sequential programs and sequential code sections in parallel programs. The question is, what will this sequential accelerator look like? In a previous work, we have proposed a possible solution for implementing a sequential accelerator, which is to implement a superscalar core with a very "aggressive" microarchitecture and design, and to replicate this core and migrate the execution periodically on the replicas to keep the temperature resulting from the high power density under control [11]. However, future sequential accelerators will probably rely on a combination of several techniques, some already known, some yet to be invented.

We have started exploring a new solution for sequential acceleration, the hardware acceleration of dynamic loops, which are periodic sequences of dynamic instructions. A **loop accelerator** sits beside a conventional superscalar core and is specialized in executing dynamic loops [40]. Dynamic loops are detected and accelerated automatically, without help from the programmer or the compiler. The execution is migrated from the superscalar core to the loop accelerator when a dynamic loop is detected, and back to the superscalar core when a loop exit condition is encountered. Our simulations show that about one third of all the instructions executed by the SPEC CPU2006 benchmark suite belong to dynamic loops with a length of several thousands dynamic instructions, or more. The loop body size is quite diverse, ranging from a few instructions to several hundreds.

We have described a possible loop accelerator microarchitecture that exploits loop properties and avoids the main bottlenecks of conventional superscalar microarchitectures. Our preliminary study demonstrates significant global speedup on some benchmarks, with a local acceleration for loops typically around 2. Our future research on loop acceleration will explore the solution space for obtaining greater performance speedups.

6.1.7. Exploiting confidence in SMT processors

**Participants:** Pierre Michaud, André Seznec.

Simultaneous multithreading (SMT) [57] processors dynamically share processor resources between multiple threads. The hardware allocates resources to different threads. The resources are either managed explicitly through setting resource limits to each thread or implicitly through placing the desired instruction mix in the resources. In this case, the main resource management tool is the instruction fetch policy which must predict the behavior of each thread (branch mispredictions, long-latency loads, etc.) as it fetches instructions.

We propose the use of Speculative Instruction Window Weighting (SIWW) [25] to bridge the gap between implicit and explicit SMT fetch policies. SIWW estimates for each thread the amount of outstanding work in the processor pipeline. Fetch proceeds for the thread with the least amount of work left. SIWW policies are implicit as fetch proceeds for the thread with the least amount of work left. They are also explicit as maximum resource allocation can also be set. SIWW can use and combine virtually any of the indicators that were previously proposed for guiding the instruction fetch policy (number of in-flight instructions, number of low confidence branches, number of predicted cache misses, etc.). Therefore, SIWW is an approach to design SMT fetch policies, rather than a particular fetch policy.
Targeting fairness and throughput is often contradictory and a SMT scheduling policy often optimizes only one performance metric with the sacrifice of the other metric. Our simulations show that the SIWW fetch policy can achieve at the same time state-of-the-art throughput, state-of-the-art fairness and state-of-the-art harmonic performance mean.

As a side contribution of this study, we have published a study on fairness metrics for SMT processors and multicore processors [24].

This study was done in collaboration with Hans Vandierendonck from University of Ghent.

6.1.8. Analytical model to estimate the interaction between hardware faults on caches and predictors

Participant: Damien Hardy.

This research was undertaken during Damien Hardy’s stay in the Computer Architecture group of the University of Cyprus (June-August 2011).

Technology trends suggest that in tomorrow’s computing systems, failures will become a commonplace due to many factors, and the expected probability of failure will increase with scaling. Faults can result in execution errors (e.g. on caches) or simply in performance loss (e.g. predictors). Although faults can occur anywhere in the processor, the performance implications of a faulty cell vary depending on how the array is used in a processor.

A direction to determine the impact on performance due to permanent faulty cells is to predict the performance vulnerability by using analytical models. Such models, studied at the University of Cyprus, are representative for the average performance and its probability distribution. So far, analytical models have been defined to determine the impact on performance of faulty mechanisms such as caches and predictors in isolation without any interactions between them.

On the other side, in the real-time systems community, caches and predictors have been intensively studied to estimate the worst-case execution time of application by using static analysis. The ongoing research aims at defining an analytical model of performance that captures the effects of faults on both caches and predictors. This analytical model will be useful to predict future processors performance vulnerability to faults and to determine the benefits in terms of performance of reliability mechanisms.

6.1.9. Hardware support for transactional memory

Participants: Mridha-Mohammad Waliullah, André Seznec.

Parallel programming has become immensely important to harness the power of today’s many core CPU. Over several years, a lot of efforts has been laid out to make parallel programming easier. Transactional memory (TM) has come out as an infrastructure that promises to simplify parallel programming. Implementation of TM in hardware is carried out to get higher performance, which is referred to as hardware transactional memory (HTM). We have focused mainly into two issues related to HTM: (1) exploring TM benchmarks to better understand the performance bottlenecks and (2) exploring innovative techniques that can streamline common case transitional execution to achieve higher performance [38].

This work was done in the framework of the Ercim postdoc stay (01/04/11 to 30/11/11) of Mridha-Mohammad Waliullah.

6.1.10. Microarchitecture research initiated in the DAL project

Participants: Pierre Michaud, Luis-Germán García Morales, Bharath Narasimha Swamy, André Seznec.
Multicore processors have now become mainstream for both general-purpose and embedded computing. Instead of working on improving the architecture of the next generation multicore, with the DAL project, we deliberately anticipate the next few generations of multicores. While multicores featuring 1000s of cores might become feasible around 2020, there are strong indications that sequential programming style will continue to be dominant. Even future mainstream parallel applications will exhibit large sequential sections. Amdahl’s law indicates that high performance on these sequential sections is needed to enable overall high performance on the whole application. On many (most) applications, the effective performance of future computer systems using a 1000-core processor chip will significantly depend on their performance on both sequential code sections and single threads.

We envision that, around 2020, the processor chips will feature a few complex cores and many (may be 1000’s) simpler, more silicon and power effective cores.

In the DAL research project, we will explore the microarchitecture techniques that will be needed to enable high performance on such heterogeneous processor chips. Very high performance will be required on both sequential sections, -legacy sequential codes, sequential sections of parallel applications-, and critical threads on parallel applications, -e.g. the main thread controlling the application. Our research will focus on enhancing single processes performance.

On the microarchitecture side, we will explore both a radically new approach, the sequential accelerator [11], and more conventional processor architectures. We will also study how to exploit heterogeneous multicore architectures to enhance sequential thread performance. Two PhD thesis have been initiated on these topics at fall 2011.

### 6.2. Compiler, vectorization, interpretation

**Participants:** Erven Rohou, David Yuste, André Seznec.

The usage of the bytecote-based languages such as Java has been generalized in the past few years. Applications are now very large and are deployed on many different platforms, since they are highly portable. With the new diversity of multicore platforms, functional, but also performance portability will become the major issue in the next 10 years. Therefore our research effort focuses on efficiently compiling towards bytecodes and on efficiently executing the bytecodes through JIT compilation or through direct interpretations.

#### 6.2.1. Iterative and JIT compilation

**Participants:** Erven Rohou, David Yuste.

Over the last decade, iterative compilation has been an attempt to overcome the difficulty to generate extremely optimized code by letting the compilers explore many alternatives to select the best one. In this research, we extend previous work in the direction of portability. Future processors will be increasingly diverse and heterogenous, and portability is likely to be attained thanks to a bytecode format and JIT compilers. We explore how iterative compilation performed offline can generate useful information to allow the online JIT compiler to generate efficient code at very limited cost.

Part of this research is done in collaboration with STMicroelectronics, in the context of the Nano2012 Mediacom project.

#### 6.2.2. Split vectorization

**Participants:** Erven Rohou, David Yuste, André Seznec.

We attempt to reconcile two apparently contradictory trends of computing systems. On the one hand, hardware heterogeneity favors the adoption of bytecode format and late, just-in-time code generation. On the other hand, exploitation of hardware features, in particular SIMD extensions through vectorization, is key to obtaining the required performance.
We showed in [33] that speculatively vectorized bytecode is: (1) robust — the approach is general enough to allow execution, both when using SIMD capabilities and also in the absence of SIMD extensions, or when using an unmodified, non-vectorizing JIT compiler; (2) risk-free — the penalty of running vectorized bytecode without SIMD support is kept at a minimum; (3) efficient — the improvement of running vectorized bytecode with SIMD support is maximized.

In [31], we focused on providing an infrastructure capable of supporting diverse SIMD targets (SSE, AltiVec, NEON), across a wide range of vectorizable kernels, with performance comparable to monolithic compiler vectorization.

This research is done within the framework of the HIPEAC2 network in collaboration with Albert Cohen (INRIA Alchemy), Ayal Zaks and Dorit Nuzman (IBM Research Labs, Haifa, Israel).

6.2.3. Vectorization Technology To Improve Interpreter Performance

Participants: Erven Rohou, David Yuste.

Recent trends in consumer electronics have created a new category of portable, lightweight software applications. Typically, these applications have fast development cycles and short life spans. They run on a wide range of systems and are deployed in a target independent bytecode format over Internet and cellular networks. Their authors are untrusted third-party vendors, and they are executed in secure managed runtimes or virtual machines. Furthermore, due to security policies, these virtual machines are often lacking just-in-time compilers and are reliant on interpreter execution.

The main performance penalty in interpreters arises from instruction dispatch. Each bytecode requires a minimum number of machine instructions to be executed. In this work we introduce a powerful and portable representation that reduces instruction dispatch thanks to vectorization technology. It takes advantage of the vast research in vectorization and its presence in modern compilers. Thanks to a split compilation strategy, our approach exhibits almost no overhead. Complex compiler analyses are performed ahead of time. Their results are encoded on top of the bytecode language, becoming new SIMD IR (i.e., intermediate representation) instructions. The bytecode language remains unmodified, thus this representation is compatible with legacy interpreters.

This approach drastically reduces the number of instructions to interpret and improves execution time. SIMD IR instructions are mapped to hardware SIMD instructions when available, with a substantial improvement.

6.2.4. Tiptop

Participant: Erven Rohou.

Hardware performance monitoring counters have recently received a lot of attention. They have been used by diverse communities to understand and improve the quality of computing systems: for example, architects use them to extract application characteristics and propose new hardware mechanisms; compiler writers study how generated code behaves on particular hardware; software developers identify critical regions of their applications and evaluate design choices to select the best performing implementation.

We propose [41] that counters be used by all categories of users, in particular non-experts, and we advocate that a few simple metrics derived from these counters are relevant and useful. For example, a low IPC (number of executed instructions per cycle) indicates that the hardware is not performing at its best; a high cache miss ratio can suggest several causes, such as conflicts between processes in a multicore environment.

We propose tiptop: a new tool, similar to the UNIX top utility, that requires no special privilege and no modification of applications. Tiptop provides more informative estimates of the actual performance than existing UNIX utilities, and better ease of use than current tools based on performance monitoring counters. With several use cases, we have illustrated possible usages of such a tool.

6.3. Understanding performance issues

Participants: Junjie Lai, Ricardo Andrés Velasquéz, Pierre Michaud, André Seznec.
6.3.1. Behavioral application-dependent superscalar core modeling

Participants: Ricardo Andrés Velasquéz, Pierre Michaud, André Seznec.

In recent years, research in microarchitecture has shifted from single-core to multi-core processors. Cycle-accurate models for many-core processors featuring hundreds or even thousands of cores are out of reach for realistic workloads. Approximate simulation methodologies which trade accuracy for simulation speed are necessary for conducting certain research, in particular for studying the impact of resource sharing between cores, where the shared resource can be caches, on-chip network, memory bus, power, temperature, etc.

Behavioral superscalar core modeling is a possible way to trade accuracy for simulation speed in situations where the focus of the study is not the core itself but what is outside the core, i.e., the uncore. In this modeling approach, a superscalar core is viewed as a black box emitting requests to the uncore at certain times. A behavioral core model can be connected to a cycle-accurate uncore model. Behavioral core models are built from detailed simulations. Once the time to build the model is amortized, significant simulation speedups are achieved.

We have proposed a new method for defining behavioral models for modern superscalar cores. Our method, behavioral application-dependent superscalar core (BADCO) modeling, requires two traces generated with cycle-accurate simulations. For the first trace, all the requests from the core (which includes the level-1 caches) to the uncore are forced with a null latency, i.e., we simulate a perfect uncore. For the second trace, all the requests are forced with a fixed and very long latency. Then we build a BADCO model from the timing information recorded in these two traces. A BADCO model is basically a directed graph where each node represents a group of micro-ops that may carry some requests to the uncore. Edges in this graph represent dependencies between requests. After the model is built, it can be used for simulations. During simulation, the BADCO model emulates the processor’s reorder buffer, the level-1 miss status holding registers, and honors dependencies between nodes. We have compared BADCO with Lee et al.’s PDCM behavioral core model. BADCO is more accurate than PDCM on average and is more reliable [42]. BADCO predicts the execution time of a thread running on a modern superscalar core with an error typically under 5%. From our experiments, we found that BADCO is qualitatively accurate, being able to predict how performance changes when we change the uncore. The simulation speedups obtained with BADCO are typically greater than 10.

6.3.2. Architecture for Lattice QCD

Participants: Junjie Lai, André Seznec.

Simulation of Lattice QCD is a challenging computational problem that requires very high performance exceeding sustained Petaflops/s. In the framework of the ANR Cosinus PetaQCD project, we are modeling the demands of this application on the memory system and synchronization mechanisms.

In particular, GPUs have become popular to execute computing intensive scientific applications. In [39], we have introduced a GPU timing model to provide more insights into the applications’ performance on GPU. A GPU CUDA program timing estimation tool (TEG) is developed based on the GPU timing model. Especially, TEG illustrates how performance scales from one warp (CUDA thread group) to multiple concurrent warps on SM (Streaming Multiprocessor). Because TEG takes the native GPU assembly code as input, it allows to estimate the execution time with only a small error. TEG can help programmers to better understand the performance results. It also allows to identify and quantify performance bottlenecks.

6.4. WCET estimation

Participants: Damien Hardy, Benjamin Lesage, Isabelle Puaut, Erven Rohou, André Seznec.

Predicting the amount of resources required by embedded software is of prime importance for verifying that the system will fulfill its real-time and resource constraints. A particularly important point in hard real-time embedded systems is to predict the Worst-Case Execution Times (WCETs) of tasks, so that it can be proven that tasks temporal constraints (typically, deadlines) will be met. Our research concerns methods for obtaining automatically upper bounds of the execution times of applications on a given hardware. Our focus this year is on (i) multicore architectures, (ii) applications compiled using just-in-time (JIT) compilation, and (iii) definition of both predictable and efficient hardware.
6.4.1. **Timing analysis for multicore platforms with shared caches**  
**Participants:** Benjamin Lesage, Damien Hardy, Isabelle Puaut.

WCET estimation for multicore platforms is challenging task because of the possible interferences between cores due to shared hardware resources such as shared caches, memory bus, etc. Moreover, multi-core platforms use a hierarchy of caches, whose worst-case behavior has to be predicted safely and as tightly as possible.

6.4.1.1. **Scalable fixed-point free instruction cache analysis**

Estimating worst-case execution times (WCETs) for architectures with caches requires the worst-case number of cache misses to be upper bounded. Most existing static cache analysis methods, a large majority of those applying to unicore and a single cache level, use fixed-point computation and do not scale well with large code sizes.

Estimating WCETs for multicores requires the base cache analysis used to analyze every cache level in the memory hierarchy to be fast. To address this issue, we have proposed in [28] a new fast and scalable instruction cache analysis technique. In contrast to existing work, neither fixed-point computation nor heavyweight interprocedural analysis are required. Thus, code sizes that are too long to analyze with existing techniques becomes then analyzable with lower analysis time and memory consumption, and with only a slight degradation of the analysis precision. Experimental results show a reduction of the analysis execution time of a factor 5 in average (with a peak near 30 for the largest and most complex code) with a limited waste of tightness of the analysis.

6.4.1.2. **Static analysis of cache hierarchies**  
**Participants:** Benjamin Lesage, Damien Hardy, Isabelle Puaut.

Determining the worst-case number of cache misses in multicore architectures requires the definition of analysis techniques applicable to cache hierarchies. In our previous work [6] we have defined the first technique that safely analyzes such hierarchies, first considering non-inclusive caches and LRU cache replacement.

We have recently generalized our previous work to support different cache hierarchy management policies between cache levels: non-inclusive, inclusive and exclusive cache hierarchies. Moreover, our analysis now supports cache hierarchies with different replacement policies: Least Recently Used (LRU), Pseudo-LRU, First-In First-Out (FIFO), Most Recently Used (MRU) and Random. Experimental results, detailed in [21] show that the method is precise in many cases (non-inclusive and exclusive cache hierarchies with the LRU replacement policy) and has a reasonable computation time. Nevertheless, considering inclusion enforcement mechanisms and non-LRU replacement policies leads to an increase of the analysis pessimism. Moreover, these two sources of pessimism are cumulative, thus resulting, in some cases, in a significant overestimation. Although inclusive cache hierarchies with non-LRU replacement policies can be analyzed statically, the cache hierarchies to be favored to obtain the tighter WCET estimates are hierarchies of non-inclusive or exclusive caches with the LRU replacement policy.

6.4.1.3. **Reconciling Predictability and Just-In-Time Compilation**  
**Participants:** Isabelle Puaut, Erven Rohou.

Virtualization and just-in-time (JIT) compilation have become important tools to address application portability issues without deteriorating average-case performance. Unfortunately, JIT compilation raises predictability issues, which currently hinders its dissemination in real-time applications. Our work aims at reconciling the two domains, i.e. taking advantage of the portability and performance provided by JIT compilation, while providing predictability guarantees.
As a first step towards this ambitious goal, we have proposed two structures of code caches and have demonstrated their predictability [26]. On the one hand, the binary code caches we propose avoid too frequent function recompiations, providing good average-case performance. On the other hand, and more importantly for the system determinism, we show that the behavior of the code cache is predictable: a safe upper bound of the number of function recompiations can be computed, enabling the verification of timing constraints. Experimental results show that fixing function addresses in the binary cache ahead of time results in tighter Worst Case Execution Times (WCETs) than organizing the binary code cache in fixed-size blocks replaced using a Least Recently Used (LRU) policy.

6.4.1.4. Predictable shared caches for mixed-criticality real-time systems

**Participants:** Benjamin Lesage, Isabelle Puaut, André Seznec.

The general adoption of multi-core architectures has raised new opportunities as well as new issues in all application domains. In the context of real-time applications, it has created one major opportunity and one major difficulty. On the one hand, the availability of multiple high performance cores has created the opportunity to mix on the same hardware platform the execution of a complex critical real-time workload and the execution of non-critical applications. On the other hand, for real-time tasks timing deadlines must be met and enforced. Hardware resource sharing inherent to multicores hinders the timing analysis of concurrent tasks. Two different objectives are then pursued: enforcing timing deadlines for real-time tasks and achieving highest possible performance for the non-critical workload.

In this work, we suggest a hybrid hardware-based cache partitioning scheme that aims at achieving these two objectives at the same time. Plainly considering inter-task conflicts on shared cache for real-time tasks yields very pessimistic timing estimates. We remove this pessimism by reserving private cache space for real-time tasks. Upon the creation of a real-time task, our scheme reserves a fixed number of cache lines per set for the task. Therefore uniprocessor worst case execution time (WCET) estimation techniques can be used, resulting in tight WCET estimates. Upon the termination of the real-time task, this private cache space is released and made available for all the executed threads including non-critical ones. That is, apart the private spaces reserved for the real-time tasks currently running, the cache space is shared by all tasks running on the processor, i.e. non-critical tasks but also the real-time tasks for their least recently used blocks. Experiments show that the proposed cache scheme allows to both guarantee the schedulability of a set of real-time tasks with tight timing constraints and enable high performance on the non-critical tasks.

6.4.2. Preemption delay analysis for floating non-preemptive region scheduling

**Participant:** Isabelle Puaut.

This is joint work with Stefan M. Petters, Vincent Nélis and José Marinho, ISEP Porto, Portugal.

In real-time systems, there are two distinct trends for scheduling task sets on unicore systems: non-preemptive and preemptive scheduling. Non-preemptive scheduling is obviously not subject to any preemption delays but its schedulability may be quite poor, whereas fully preemptive scheduling is subject to preemption delays, but benefits from a higher flexibility in the scheduling decisions.

The time-delay involved by task preemptions is a major source of pessimism in the analysis of the task Worst-Case Execution Time (WCET) in real-time systems. Cache related preemption delays (CRPD) are the most important ones, and are caused by the preemptions that modify the cache; the preempted task then suffers an indirect delay after the preemption to reload the cache with useful information.

Preemptive scheduling policies including non-preemptive regions are a hybrid solution between non-preemptive and fully preemptive scheduling paradigms, which enables to conjugate both worlds benefits. In this work [29], we exploit the connection between the progression of a task in its operations, and the knowledge of the preemption delays as a function of its progression. Thus the pessimism in the preemption delay estimation is reduced, in comparison to state of the art methods, due to the increase in information available in the analysis.
6. New Results

6.1. Structuring of Applications for Scalability

Participants: Sylvain Contassot-Vivier, Thomas Jost, Jens Gustedt, Soumeya Leila Hernane, Constantinos Makassikis, Stéphane Vialle.

6.1.1. Large Scale and Interactive Fine Grained Simulations

Our library *parXXL* allows the validation of a wide range of fine grained applications and problems. We were able to test the interactive simulation of PDEs in physics, see [5], on a large scale. Also, biologically inspired neural networks have been investigated using *parXXL* and the InterCell software suite. The InterCell suite and these applicative results have been presented in [29].

6.1.2. Large Scale Models and Algorithms for Random Structures

A realistic generation of graphs is crucial as an input for testing large scale algorithms, theoretical graph algorithms as well as network algorithms, e.g. platform generators.

Commonly used techniques for the random generation of graphs have two disadvantages, namely their lack of bias with respect to history of the evolution of the graph, and their incapability to produce families of graphs with non-vanishing prescribed clustering coefficient. In this work we propose a model for the genesis of graphs that tackles these two issues. When translated into random generation procedures it generalizes well-known procedures such as those of Erdős & Rényi and Barabási & Albert. When just seen as composition schemes for graphs they generalize the perfect elimination schemes of chordal graphs. The model iteratively adds so-called *contexts* that introduce an explicit dependency to the previous evolution of the graph. Thereby they reflect a historical bias during this evolution that goes beyond the simple degree constraint of preference edge attachment. Fixing certain simple statical quantities during the genesis leads to families of random graphs with a clustering coefficient that can be bounded away from zero.

A journal article describing intensive simulations of these models that confirm the theoretical results and that show the ability of that approach to model the properties of graphs from application domains has been published as [13].

6.1.3. Development environment for co-processing units

In the framework of the PhD thesis of Wilfried Kirschenmann, co-supervised by Stéphane Vialle (SUPELEC & AlGorille team) and Laurent Plagne (EDF SINETICS team), we have designed and implemented a unified framework based on generic programming to achieve a development environment adapted both to multi-core CPUs, multi-core CPUs with SSE units, and GPUs, for linear algebra applied to neutronic computations.

Our framework is composed of two layers: (1) MTPS is a low-level layer hiding the real parallel architecture used, and (2) Legolas++ is a high-level layer allowing the application developer to rapidly implement linear algebra operations. The Legolas++ layer aims at decreasing the development time, while the MTPS layer aims at automatically generating very optimized code for the target architecture, thus leading to decreased execution times. Experimental performances of the MTPS layer appeared very good, the same source code achieved performances close to 100% of the theoretical ones, on any of the supported target architectures. Our strategy is to generate optimized data storage and data access code for each target architecture, not just different computing codes.

A new version of Legolas++ is under development, and a minimal version has been implemented in 2011. It is optimized to use the MTPS layer: source code is generic while an optimized code is automatically generated to efficiently use all SSE/AVX vector units of a multicore CPU. An article on that work is accepted in the post-proceedings of PARA 2010 and will be published at the end of 2011; the thesis of Wilfried Kirschenmann will be defended in early 2012.
6.1.4. Structuring algorithms for co-processing units

Since 2009, we have designed and experimented several algorithms and applications, in the fields of option pricing for financial computations, generic relaxation methods, and PDE solving applied to a 3D transport model simulating chemical species in shallow waters. We aim at designing a large range of algorithms for GPU cluster architectures, to develop a real knowledge about mixed coarse and fine grained parallel algorithms, and to accumulate practical experience about heterogeneous cluster programming.

Our PDE solver on GPU cluster has been designed in the context of a larger project on the study of asynchronism (see 3.1 and 6.1.5). The iterations of the asynchronous parallel algorithm runs faster, but it requires more iterations and a more complex detection of convergence, see Section 6.1.5 below. We measured both computing and energy performances of our PDE solver in order to track the best solution, in function of the problem size, the cluster size and the features of the cluster nodes. We are tracking the most efficient solution for each configuration. It can be based on a CPU or a GPU computing kernel, and on a synchronous or asynchronous parallel algorithm. Moreover, the fastest solution is not always the less energy consuming. Our recent results are introduced in [26], and in an article accepted in the post-proceedings of PARA 2010. In 2011 we improved our asynchronous implementation. However, the most asynchronous version has led to significantly more complex code (with an increased probability of remaining bugs) but to similar performances. At the opposite, we designed and implemented different convergence detection mechanisms in our asynchronous version, and some versions seem to achieve really better performances. Execution time and energy consumption performances have now to be measured again for many configurations. We aim to get new complete performance evaluation at the beginning of 2012. Then we will design an automatic selection of the right kernel and the right algorithm, and we will implement an auto-setting application function of a global instruction of the user (to achieve a fast run, or a low consumption run, or a compromise...).

At last, we have continued to design option pricers on clusters of GPUs, with Lokman Abbas-Turki (PhD student at University of Marne-la-Valée) and some colleagues from financial computing. In the past we developed some European option pricers, distributing independent Monte-Carlo computations on the nodes of a GPU cluster. In 2010 we succeeded to develop an American Option pricer on our GPU clusters, distributing strongly coupled Monte-Carlo computations. The Monte-Carlo trajectories depend on each others, and lead to many data transfers between CPUs and GPUs, and to many communications between cluster nodes. First results were encouraging, we achieve speedup and size up. In 2011 we optimized a major step of our algorithm, consisting in a 4D to 2D reduction on GPU. Performances have increased, and are significantly easier to achieve. The configuration tuning of the application, function of the problem size and the number of computing nodes, has been simplified. Again, we investigate both computing and energy performances of our developments, in order to compare interests of CPU clusters and GPU clusters considering execution speed and the exploitation cost of our solution.

6.1.5. Asynchronism

In the previous paragraph is mentioned a project including the study of sparse linear solvers on GPU. That project deals with the study of asynchronism in hierarchical and hybrid clusters mentioned in 3.1.

In that context, we study the adaptation of asynchronous iterative algorithms on a cluster of GPUs for solving PDE problems. In our solver, the space is discretized by finite differences and all the derivatives are approximated by Euler equations. The inner computations of our PDE solver consist in solving linear equations (generally sparse). Thus, a linear solver is included in our solver. As this part is the most time consuming, to decrease the overall computation time it is essential to get a version that is as fast as possible. This is why we have decided to implement it on GPU, as discussed in the previous paragraph. Our parallel scheme uses the Multisplitting-Newton which is a more flexible kind of block decomposition. In particular, it allows for asynchronous iterations.

Our first experiments, conducted on an advection-diffusion problem, have shown very interesting results in terms of performances [8]. However, we investigate the possibility to insert periodic synchronous iterations inside the asynchronous scheme in order to improve the convergence detection delay. This is especially interesting on small/middle clusters with efficient networks.
Moreover, another aspect which is worth being studied is the full use of all the computational power present on each node, in particular the multiple cores, in conjunction with the GPU. This is still a work in progress.

6.1.6. New Control and Data Structures for Efficiently Overlapping Computations, Communications and I/O

With the thesis of Pierre-Nicolas Clauss we introduced the framework of ordered read-write locks, ORWL, see [3]. These are characterized by two main features: a strict FIFO policy for access and the attribution of access to lock-handles instead of processes or threads. These two properties allow applications to have a controlled pro-active access to resources and thereby to achieve a high degree of asynchronism between different tasks of the same application. For the case of iterative computations with many parallel tasks which access their resources in a cyclic pattern we provide a generic technique to implement them by means of ORWL. It was shown that the possible execution patterns for such a system correspond to a combinatorial lattice structure and that this lattice is finite iff the configuration contains a potential deadlock. In addition, we provide efficient algorithms: one that allows for a deadlock-free initialization of such a system and another one for the detection of deadlocks in an already initialized system.

We have developed a standalone distributed implementation of the API that is uniquely based on C and POSIX socket communications. Our goal is to simplify the usage of ORWL and to allow portability to a large variety of platforms. This implementation runs on different flavors of Linux and BSD, on different processor types Intel and ARM, and different compilers, gcc, clang, opencc and icc. An experimental evaluation of the performance is on its way. An engineering support from the local INRIA center has allowed to advance this implementation and to perform intensive benchmarks. The results have been presented in [28].

Data Handover, DHO, is a general purpose API that combines locking and mapping of data in a single interface. The access strategies are similar to ORWL, but locks and maps can also be hold only partially for a consecutive range of the data object. It is designed to ease the access to data for client code, by ensuring data consistency and efficiency at the same time.

In the thesis of Soumeya Hernane, we use the Grid Reality And Simulation (GRAS) environment of SimGrid, see 5.4, as a support for an implementation of DHO. GRAS has the advantage of allowing the execution in either the simulator or on a real platform. A first series of tests and benchmarks of that implementation demonstrates the ability of DHO to provide a robust and scalable framework, [18]. A step forward towards a distributed algorithm that allows distributed read-write locks with dynamic participation of process has been achieved in [30].

6.1.7. Energy performance measurement and optimization

Several experiments have been done on the GPU clusters of SUPÉLEC with different kinds of problems ranging from an embarrassingly parallel one to a strongly coupled one, via some intermediate levels. Our first results tend to confirm our first intuition that the GPUs are a good alternative to CPUs for problems which can be formulated in a SIMD or massively multi-threading way. However, when considering not embarrassingly parallel applications the supremacy of a GPU cluster tends to decrease when the number of nodes increases. This observation was the starting point of our participation to the COST-IC0804 about energy efficiency in large scale distributed systems, and an article accepted in the post-proceedings of PARA 2010 introduces our results achieved with our PDE solver distributed on our GPU clusters.

In 2011 we conducted new experiments and optimizations of our PDE solver and our American option pricer on the GPU clusters of SUPELEC. These experiments are still ongoing, and the optimization of this software should be achieved at the beginning of 2012. Simultaneously, we designed the foundations of a complete software architecture of self-configuring applications, choosing the right compute kernel and the right parallel algorithm to use, automatically. The global objectives to respect would either the overall speed, low energy consumption, or a speed-energy compromise. This global objective can be set by the user, or by an intelligent scheduler that aims to optimize a set of runs on a large cluster. This software architecture foundation has been introduced to a COST-IC0804 meeting in Budapest in June 2011.
In order to achieve this goal we need to establish some models of energy consumption of our applications on our CPU+GPU clusters, to be able to implement some heuristic of auto-setting. In 2011 we published a book chapter [26] introducing our first modeling strategies. Next step will be to implement a first auto-setting application, and to experiment its performances.

6.1.8. Load balancing

A load-balancing algorithm based on asynchronous diffusion with bounded delays has been designed to work on dynamical networks [34]. It is by nature iterative and we have provided a proof of its convergence in the context of load conservation. Also, we have given some constraints on the load migration ratios on the nodes in order to ensure the convergence. This work has been extended, especially with a detailed study of the imbalance of the system during the execution of a parallel algorithm simulated in the SimGrid platform.

The perspectives of that work are double. The first one concerns the internal functioning of our algorithm. There is an intrinsic parameter which tunes the load migration ratios and we would like to determine the optimal value of that ratio. The other aspect is on the application side in a real parallel environment. Indeed, we are currently applying this algorithm to a parallel version of the AdaBoost learning algorithm. This will allow us to study the best parameter to choose and to compare our load-balancing scheme to other existing ones.

Concerning the Neurad project, our parallel learning proceeds by decomposing the data-set to be learned. However, using a simple regular decomposition is not sufficient as the obtained sub-domains may have very different learning times. Thus, we have designed a first domain decomposition of the data set yielding subsets of similar learning times [40]. One of the main issue in this work has been the determination of the best estimator of the learning time of a sub-domain. As the learning time of a data set is directly linked to the complexity of the signal, several estimators taking into account that complexity have been tested, among which the entropy. However, the entropy is not the best estimator in that context, and we had to design a specific estimator. Also, we have optimized the decomposition process and added a selection phase that produces learning subsets of the same size [20]. Finally, we have also developed a parallel multi-threaded version of that decomposition/selection process.

6.1.9. Fault Tolerance

6.1.9.1. Application-level fault tolerance

Concerning fault tolerance, we have worked with Marc Sauget, from the University of Franche-Comté, on a parallel and robust algorithm for neural network learning in the context of the Neurad project [35]. A short description of that project is given in Section 4.1.5.

Our fault-tolerance strategy has shown to be rather efficient and robust in our different experiments performed with real data on a local cluster where faults were generated. Although those results are rather satisfying, we would like to investigate yet more reactive mechanisms as well as the insertion of robustness at the server level.

6.1.9.2. Programming model and frameworks for fault-tolerant applications

During the PhD thesis of Constantinos Makassikis [11], supervised by Stéphane Vialle, we have designed a new fault tolerance programming model (MoLoToF) to ease the development of fault-tolerant distributed applications. Main features of MoLoToF include so-called “fault-tolerant skeletons” to embed checkpoint-based fault tolerance within applications, and enable various collaborations, such as application-semantic knowledge supplied by users to the underlying system (e.g.: middleware), in order to fine tune fault tolerance.

Two development frameworks have been designed according to two different parallel programming paradigms: ToMaWork for Master-Workers applications [17] and FT-GReLoSSS (FTG) for some kind of SPMD applications including inter-node communications [10]. The programmer’s task is limited. He only needs to supply some computing routines (functions of the application), has to add some extra code to specify a fault-tolerant parallel programming skeletons and then to tune the checkpointing frequency.
Our experiments have exhibited limited runtime overheads when no failure occurs and acceptable runtime
overheads in the worst case failures. Observed runtime overheads are less than the ones obtained with all other
system-level fault tolerance solutions we have experimented, while maintaining very limited development time
overhead. Moreover, detailed experiments up to 256 nodes of our cluster have shown that it is possible to finely
tune the checkpointing policies of the frameworks in order to implement different fault tolerance strategies,
for example, according to cluster reliability.

In 2011, we have used the FTG framework to make fault-tolerant an existing parallel financial application [31]
from EDF R&D, where it is used for gas storage valuation. The resulting application kept its initial runtime
performance despite some source code modifications which are required in order to use FTG. As it was the
case in earlier experiments with other applications, these modifications accounted for a limited development
time overhead and fault tolerance remained more efficient than system-level fault tolerance solutions.

6.2. Experimentation Methodology

Participants: Tomasz Buchert, Sébastien Badia, Pierre-Nicolas Clauss, El Mehdi Fekari, Jens Gustedt, Lucas
Nussbaum, Martin Quinson, Cristian Rosa, Luc Sarzyniec, Sylvain Contassot-Vivier.

6.2.1. Overall Improvements of the SimGrid Framework

See 4.2.1 for the scientific context of this result.

This year was the third year of the USS-SimGrid project on the simulation of distributed applications. We are
principal investigator (see 8.2.7 ) of this project, funded by the ANR. It was prolonged until October 2012,
giving us the ability to finish properly what was started. Several improvements have therefore been added
to the framework, with numerous contributions from the ANR participants. This served as a flagship for the
whole SimGrid project and hosted several of our research efforts, detailed in the subsequent sections (up to
6.2.5 ). Also this year, the SONGS project got accepted by the ANR, paving the road for our research in this
context for the next four years. Our team also coordinates this project, devoted to the “Simulation Of Next
Generation Systems” (see 8.2.7 ).

In addition, the software quality efforts were pursued further through the second year of the INRIA ADT
project (see 8.2.1 ) to maximize the impact of our research on our user community. First, we improved
further our automated regression tests (by increasing the test coverage from below 60% to almost 80%) and
by fixing the bugs found through the automated builds conducted on the INRIA pipol infrastructure. We
also reduced the amount of possible configurations to reduce the test and maintenance burden. As usual,
performance tuning deserved a lot of our attention this year. The bindings were solidified and improved. They
are very well received by the user community. Finally, the port to the Mac architecture was improved while
the experimental port to Windows was revived.

Finally, several operations were conducted to increase our user community. A publication summarizing all
improvements made in the recent years were written and submitted [27]. The SimGrid team was represented
at SuperComputing’11 (through our partners of Lyon) to meet potential users and distribute informative leaflets
designed and printed to that extend.

6.2.2. Formal Verification of Distributed Applications

The context of this work is presented in 4.2.2 .

In 2011, we started using the model-checker integrated last year into the SimGrid framework with the goal
to evaluate its limitations. Due to its generic design, it is able to verify protocols written using several APIs
of SimGrid. We tested it on both a MPI toy program written to that extend and on an implementation of the
Chord P2P protocol. In this later case, the tested program was not written for the purpose of being model-
checked but to assess the scalability limits of the simulator. The model-checker was used to track down a bug
that was near to impossible to find with the simulator alone. This experiment and the formalism underlying
our model-checker were described in the publication [19 ]. It is also described in further detail in Cristian
Rosa’s PhD, defended this year [12 ].
A second axis of our work this year consisted in extending the semantic power of the verified properties. In the work presented above, only local assertions and invariants can be verified. We started to investigate how to improve this during the internship of Marion Guthmuller. The major difficulty is that the reduction techniques based on the transition independences that we used so far are not sufficient for vivacity properties and must be extended to deal with the visibility of atomic properties \[37\]. One of the specificity of our work is the use of actual implementations were most of the literature uses handmade abstract models. This work continued in a PhD program, but didn’t lead to any publication, yet.

6.2.3. Parallel Simulation within SimGrid

In addition to the software tuning and improvement described in 6.2.1, we tackled the issue of running SimGrid simulators in parallel. Our work differs from the state of the art, because we do not aim to parallelize the simulation kernel itself but the execution of the user code processes running on top of the simulated system. Interestingly enough, this benefits greatly from the work on formal verification introduced in the previous section, and particularly of the new network abstraction layer that was added. It greatly reduced the code locations where the global state is modified, making the parallel execution possible.

This allowed for example the simulation of up to 2 million Chord hosts on a single computer. This work was described in \[33\] and a publication in a major conference is under preparation. Since the available memory constitutes the main scalability limit now, we will work on distributing the simulation to leverage the memory of several computers at the same time.

6.2.4. Simulating MPI Applications

The final goal of SMPI is to simulate a C/C++/FORTRAN MPI program designed for a multi-processor system on a single computer without any source code modification. This addresses one of the main limitation of SimGrid, which requires the application to be written using one of the specific interfaces atop the simulator. New efforts have been put since July 2009 in this project, hereby continuing the work initiated by Henri Casanova and Mark Stilwell at University of Hawai’i at Manoa.

Previous work included a prototype implementation of various MPI primitives such as send, recv, isend, irecv and wait. Since the project’s revival, many of the collective operations (such as bcast, alltoall, reduce) have been implemented. The standard network model used in SimGrid has also been reworked to reach a higher precision in communication timings. Indeed, MPI programs are traditionally run on high performance computers such as clusters, and this requires to capture fine network details to correctly model the program behavior. Starting from the existing, validated network model of SimGrid, we have derived for SMPI a specific piece-wise linear model which closely fits real measurements. In particular, it enables to correctly model small messages and messages above the eager/rendezvous protocol limit. This work has been published at the IPDPS conference this year \[15\].

Ongoing work is now targeting a panel of MPI applications to have a better understanding of the applicability of our proposition. Pierre-Nicolas Clauss, who has been working full-time on the project between mid-2010 and mid-2011 has left, and we plan to put new workforce on SMPI with the support of the SONGS ANR project in 2012.

6.2.5. Simulating Real Applications

This work aims at providing a solution to simulate arbitrary applications on top of SimGrid. The approach consists in intercepting the application actions at system level while they are executed on a test platform, and then replay these actions on top of the simulator.

Concerning trace capture, we continued our work on the Simterpose software, which intercepts the actions of the application and save them to file for further use by the simulator. This work, presented in a national conference \[22\], will be continued during the PhD work of Marion Guthmuller.
Concerning trace replay, we proposed a replay mechanism specific to MPI applications in collaboration with F. Suter from the Computing Center at IN2P3 together with F. Desprez and G. Markomanolis from the Graal team at INRIA Rhônes-Alpes. The originality is to rely on time-independent execution traces. This allows to completely decouple the acquisition process from the actual replay of the traces in a simulation context. We are able to acquire traces for large application instances without being limited to an execution on a single cluster. Finally, our replay framework is built directly on top of the SIMGrid simulation kernel. This work was published in [16].

6.2.6. Emulation & Distem

During the internship of Luc Sarzyniec, we re-implemented an emulator from scratch with the goal of having a more reliable basis for further developments. This new development, Distem (see 5.2), already includes support for CPU performance emulation (internship of Tomasz Buchert in 2010) and network emulation. We are currently preparing a first release of Distem, and are working on its validation.

6.2.7. Grid’5000 and ADT Aladdin-G5K

Grid’5000 is an experimental platform for research on distributed systems. Two new sites were added to Grid’5000 in 2011: Reims and Luxembourg. This should reinforce the impact of Grid’5000 in the east of France. It is worth noting that the system administrator of the Luxembourg Grid’5000 site was formerly a student in Nancy, and did a student project using Grid’5000 managed by Lucas Nussbaum. Also, more collaboration on technical aspects is expected thanks to this geographical proximity.

On the local level, power consumption sensors are being added to the graphene cluster, which will allow an accurate monitoring of energy consumption during experiments.

On the national level, Lucas Nussbaum is now mandated by the Grid’5000 executive committee to follow the work of the technical team. He contributed to two publications [23], [24] at Journées Réseaux 2011 that describe the Grid’5000 software stack. He also gave invited talks during a Grid’5000 day at RenPar, and during the Support for experimental computer science workshop as SuperComputing’11.

Local scientific contributions include the automation of the deployment of the gLite middleware on Grid’5000. That work [21] was presented at Rencontres France Grilles and received the Best Poster award. We hope that this work will serve as a basis for further collaborations with the production grids community.

We also started the ADT Kadeploy project that will continue the development of the Kadeploy software, which already plays a key role on Grid’5000.

6.2.8. Experimental cluster of GPUs

The experimental platform of SUPÉLEC for "GPGPU", see Section 4.2.6, is composed of two GPU clusters, and its electrical line has been improved in 2011.

The first cluster is currently composed of 16 PCs, each one hosting a dual-core CPU and a GPU card: a nVIDIA GeForce GT285, with 1GB of RAM (on the GPU card). The 16 nodes are interconnected across a devoted Gigabit Ethernet switch. The second cluster has 16 more recent nodes, composed of an Intel Nehalem CPU with 4 hyper-threaded cores at 2.67GHz, and a nVIDIA GTX480 ("Fermi") GPU card with 1.5GB of memory. This cluster has a Gigabit Ethernet interconnection network too. These 2 clusters can be accessed and used like one 32-nodes heterogeneous cluster of hybrid nodes. This platform has allowed us to experiment different algorithms on an heterogeneous cluster of GPUs.

The energy consumption of each node of the cluster hosting the GTX285 GPUs is monitored by a Raritan DPXS20A-16 device that continuously measures the electric power consumption (in Watts). The nodes of the cluster hosting the GTX480 are monitored by two Raritan devices, because the energy consumed by this cluster exceeds the maximum energy supported by a Raritan DPXS20A-16 device.

A set of Perl and shell scripts, developed by our team, sample the electrical power (Watt) measured by the Raritan devices and compute the energy (Joule or Watt Hour) consumed by the computation on each node and on the complete cluster (including the interconnection switch).
In 2011 we have increased the amount of electrical energy supplied to these cluster, in order to support the experiments of our new distributed American option pricer. This application achieves high performances but consumes more energy on our GPU clusters than our previous codes, and exceeded the limit of our previous electrical line.

This platform has been intensively used to get experimental performance measures introduced in 2011 meetings of the COST IC0804 about Energy efficiency in large scale distributed systems, and published in a book chapter [26].
5. New Results

5.1. Analysis of Algorithms

The following articles, conference communications and reports summarize new results in analysis of algorithms over the period: [20], [18], [17], [19], [16], [13], [4], [10], [11], [3], [5].

5.2. Computer Algebra

The following articles, conference communications and reports summarize new results in computer algebra over the period: [9], [21], [2], [8], [22], [7], [15], [1], [12], [6], [14].
6. New Results

6.1. Geometry Processing

Participants: Laurent Alonso, Alejandro Galindo, Phuong Ho, Samuel Hornus, Bruno Lévy, David Lopez, Kun Liu, Vincent Nivoliers, Nicolas Ray, Dmitry Sokolov, Rhaleb Zayer.

- **Sampling:** In the frame of the Goodshape project, we continued developing new techniques for sampling shapes optimally, based on the notion of Centroidal Voronoi Tesselations. We developed a new technique for computing clipped 3D Voronoi diagrams, suitable to volumetric meshing [23], and an accelerated GPU-based centroidal Voronoi tesselation [20]. We developed an optimization technique to suppress obtuse triangles [21]. We also studied periodic boundary conditions [29], suitable to some numerical simulations.

- **Geometric modeling and computational geometry:** Dobrina Boltcheva joined the team, with her expertise on simplicial homology [10]. Vincent Nivoliers published a L-system based knot insertion rules [19] that he developed during his master in Gipsa lab. We also studied furthest polygon Voronoi diagrams [15].

- We gave an invited course on geometry processing at SIGGRAPH Asia [24]

6.2. Computer Graphics

- **Foundations of Computer Graphics:** We developed new algorithms and data structures for spatial caching and hashing on the GPU [16]. We continued our work on noise generation based on Gabor convolution and proposed several improvements [17] (see Figure 5). We also studied the fundamental problem of interpolating functions and developed an algorithm based on optimal transport theory [11].

- **Applications:** We developed an algorithm to change the lighting in images that contain trees [12] (with REVES, see Figure 6).
Figure 6. Relighting photos of canopies.

Figure 7. Unified visualization of atomic bounds and molecular surfaces.
Figure 8. Left: flow lines between injectors (black squares) and well (center square). Right: Adapted Voronoi grid.

Figure 9. Fitting a spline surface (bottom) to a triangle mesh (top) starting from an initial template (center). Data courtesy of Distene.
6.3. Scientific Visualization and scientific computing

Participants: Samuel Hornus, Bruno Jobard, Bruno Lévy, Romain Merland, Vincent Nivoliers, Jeanne Pellerin, Nicolas Ray, Dmitry Sokolov, Rhaleb Zayer.

- **Molecular visualization**: We continued the development of our Micromegas software, and developed several improvements [13], [14] (see Figure 7).

- **Geo-Modeling and geo-visualization**: In the frame of our partnership with the Gocad consortium, we developed an evaluation of multi-valued data depiction techniques [22]. We also developed several meshing tools dedicated to the numerical simulation of oil exploitation [28], [26], [25] (see Figure 8).

- **Reverse engineering**: We developed methods to convert mesh surfaces and point sets into parametric splines, using either a global parameterization technique [18] or an approximation of surface-to-surface distance based on Voronoi diagrams [27] (see Figure 9).
ALPAGE Project-Team

6. New Results

6.1. Advances in symbolic parsing with DyALog/FRMG

Participant: Éric Villemonte de La Clergerie.

Within the team is developed a wide-coverage French meta-grammar (FRMG) and an efficient hybrid TAG/TIG parser based on the Dyalog logic programming environment [127] and on the Leff morphological and syntactic lexicon [118]. It relies on the notion of factorized grammar, themselves generated from a representation that lies at a higher level of abstraction, named Meta-Grammars [129]. At that level, linguistic generalizations can be expressed, which in turn makes it possible to transfer meta-grammars from one language to a closely related one. The hybrid TAG/TIG parser generator itself implements all kinds of parsing optimizations: lexicalization (in particular via hypertags), left-corner guiding, top/bottom feature analysis, TIG analysis (with multiple adjoining), and others.

Éric de La Clergerie has continued to improve the coverage, quality and efficiency of the French meta-grammar FRMG. On the EasyDev corpus (around 4000 sentences), parsing times have improved over 2011 from an average of 1.03s per sentence to 0.28s, coverage (in terms of sentences with full parses) has improved from 72.5% to 82.6%, and accuracy (in terms of f-measure over relations) from 64.54% to 68.28%.

A part of the accuracy gains comes from the addition of a new output format for FRMG, namely the CONLL format, allowing us to use the CONLL-based dependency version of the French Treebank (around 12K sentences) for training and evaluation. We also used new machine learning techniques to improve FRMG’s disambiguation algorithm, allowing us to combine heuristic based disambiguation rules (with manually provided weights) with more standard parsing features associated with automatically learned weights. More precisely, the idea was to study the efficiency of the disambiguation rules over the French treebank and to favor (resp. penalize) well-working (resp. bad working) rules by adjusting their weight, taking into account additional (and more standard) features. Using these techniques, on ftb6_3 test part, FRMG improved from a base accuracy of 82.31% (in terms of CONLL Labeled Attachment Score) to 84.54%. These gains resulting from a training over the French TreeBank have also been observed (with however a lesser impact) on the EasyDev corpus (using a different format and using a different evaluation metric).

6.2. Task-based evaluation of syntactic lexica: coupling FRMG with various resources

Participants: Éric Villemonte de La Clergerie, Benoît Sagot.

The FRMG symbolic parser was used for comparing the performances of various syntactic lexicons as sources of information for parsing. The idea is to convert syntactic lexica other than the Leff into the Leff’s format, i.e., turn them into Alexina lexicons, and then use the resulting lexica together with the FRMG grammar for producing several parsers. These parsers only differ by the lexical information they rely on. Preliminary results had already been obtained in 2009 [119], but were restricted to one external lexicon, namely Lexicon-Grammar tables, and only to verbal entries (other entries were gathered from the Leff when using Lexicon-Grammar-based verbal entries). However, conversion tools for other resources, such as Dicovalence [136], had already been developed, in the context of the development and improvement of the Leff. Moreover, the development of a new version of the Leff verbal entries
Task-based evaluation results have been obtained on parsing with FRMG, showing that the Leff performs better than both Lexique-Grammaire and DICOVALENCE (after conversion to the Alexina formalism) [48], [49]. The new version of the Leff, mentioned above, leads for now to lower results than the current version, but its results are better than with Lexique-Grammaire or DICOVALENCE data, despite a significant increase of the average amount of entries per lemma. These results are satisfying both because they show that the Leff is a useful resource for symbolic parsing, but also because they illustrate the relevance of converting other resources into the Alexina formalism, in order to merge the valuable linguistic information they contain — as done in the last years for improving the Leff [85], [84], [86], [111], [87], [112].

6.3. Information extraction from corpora parsed with FRMG

Participants: Yayoi Nakamura-Delloye, Rosa Stern, Éric Villemonte de La Clergerie, Benoît Sagot.

Following previous experiments, in particular in the context of the FUI-funded project Scribo that ended in 2010 [4], work has been achieved for extracting information from corpora parsed with FRMG.

In the context of the EDyLex project, we have proposed two pattern-based named entity extraction methods for ontology enrichment [36], [35]. The proposed methods are characterized by the use of entity relation patterns obtained by our unsupervised extraction method. These patterns correspond to syntactic paths that connect two named entities in dependency trees produced by FRMG. This work aims to take advantage of parsing benefits and also offers solutions for parsing disadvantage. The proposed methods are characterized by the use of entity relation patterns obtained by our unsupervised extraction method. These patterns correspond to syntactic paths that connect two named entities in dependency trees. This work aims to take advantage of parsing benefits and also offers solutions for parsing disadvantage.

We also developed a mechanism for integrating the results into a domain ontology, namely the ontology under deployment at the Agence France-Presse [37].

6.4. Advances in statistical parsing

Participants: Marie Candito, Benoît Crabbé, Djamé Seddah, Enrique Henestroza Anguiano.

6.4.1. Improving statistical dependency parsing

Alpage has provided state-of-the-art results for French statistical Parsing, adapting existing techniques for French, a richer morphological language than English, either for constituency parsing or dependency parsing. The Bonsai tool (see section 5.4) is available, that gathers preprocessing tools and models for dependency parsing French. We have innovated in the tuning of tagsets and the handling of unknown words. In the last years, Alpage has then contributed on four main points:

- conversion of the French Treebank [59] used as constituency training data into dependencies [72], the resulting treebank being used by several teams for dependency parsing;
- an original method to reduce lexical data sparseness and include coverage and robustness by replacing tokens by unsupervised word clusters or morphological clusters [69], [121], [73]; all of our morphological clustering approaches were integrated into our parsing chains; data driven lemmatization required the adaptation of a state-of-the-art part-of-speech tagger and lemmatizer (Morfette [77]) based on a data-driven joint model benefiting from the inclusion of external lexica such as the Leff [121].
- a parser-agnostic postprocessing step, developed this year, which uses specialized models for dependency parse correction [30]: dependencies in an input parse tree are revised by selecting, for a given dependent, the best governor from within a small set of candidates, using a discriminative linear ranking model that includes a rich feature set that encodes syntactic structure in the input parse tree; the parse correction framework can correct attachments using either a generic model or specialized models tailored to difficult attachment types like coordination and pp-attachment; our
experiments have shown that parse correction, combining a generic model with specialized models for difficult attachment types, can successfully improve the quality of predicted parse trees output by several representative state-of-the-art dependency parsers for French.

- an adaptation of the above-mentioned technique of word clustering to the problem of adapting statistical parsers to different text domains [25]. We show that in order to parse texts from a different domain than the one a statistical parser is trained on (namely to parse target domain text using a parser trained on indomain treebank), word clusters computed over a bridge corpus that couples indomain and target domain raw texts do improve parsing performance on target domain, without degrade performance on indomain texts (contrary to previous domain adaptation techniques). To evaluate these experiments, we use as target domain biomedical texts. We have supervised the manual syntactic annotation of a test corpus from the biomedical domain (European Public Assessment Reports concerning the marketing authorization of medicinal products).

Besides this line of work, it should be noted that two parsing models built around Stochastic Tree Insertion Grammars are currently under investigation: experiments have been conducted on Spinal TIGs [122]. Moreover, we are still improving the TIG-based dependency parser MICA, developed in collaboration with University of Marseilles, Columbia university and AT&T [61] (see section 5.5).

6.4.2. Functional labelling

Alpage worked towards the improvement of a functional labeller to be used as a post-parsing tool on an unfolded parse forest (as outputted e.g. by the Berkeley parser in the Bonsai architecture) using CRF models of various orders thereby extending the previous maximum entropy labeller designed in the team. The use of CRFs for modelling triggered a collaboration with Isabelle Tellier and JP Prost (LIFO, Orleans). The labeller implementation has been considerably improved and the accuracy of the labeller has improved as well on correct treebank trees. However we found out that the feature engineering work outweights the formal improvements since we were able to show that the use of higher order graphical models were not contributing significantly to improve an unstructured model. Our modest gains come mostly from feature engineering. Moreover we notice that combined with a constituent parser the labeller does not improve at all on constituent parsing output. The reason being that our current architecture for the Bonsai parser is sequential (which is unsatisfactory). Following experiments on n-best parsing outputs, we observe that the labeller can drastically improve on better parses where its input is indeed correct. This suggest investigating formulating constituent parsing and functional labelling as a joint task requiring to address serious efficiency issues. We intend to tackle the two drawbacks of our current architecture (sequential process, parse forest unfolding) by formulating constituent parsing as a joint task with functional labelling in the next few months.

6.4.3. Parsing spontaneous oral text

Alpage also got involved in parsing spontaneous oral text taken from ESTER 3 data (with overlaps) generated in the ANR ETAPE project in collaboration with A. Abeillé (LLF) with the aim of preannotating a seed for a future treebank of oral French which would considerably support work in experimental linguistics led in the Labex. He has also a collaboration set up with A. Abeillé, C. Gardent and C. Cerisara for ensuring interoperability across ongoing efforts for producing oral treebanks for French. The way to carry out the task was by using a form of preprocessing of oral text to simulate a written entry to the Bonsai parser trained on written text. In the next few months we intend to test semi-supervised learning techniques to speed up the annotation process made by the LLF lab.

6.5. Named Entity Recognition and Entity Linking

Participants: Rosa Stern, Benoît Sagot.
Identifying named entities is a widely studied issue in Natural Language Processing, because named entities are crucial targets in information extraction or retrieval tasks, but also for preparing further NLP tasks (e.g., parsing). Therefore a vast amount of work has been published that is dedicated to named entity recognition, i.e., the task of identification of named entity mentions (spans of text denoting a named entity), and sometimes types. However, real-life applications need not only identify named entity mentions, but also know which real entity they refer to; this issue is addressed in tasks such as knowledge base population with entity resolution and linking, which require an inventory of entities is required prior to those tasks in order to constitute a reference.

6.5.1. Improvements of the Aleda entity database

Within the Alexina framework, we develop since 2012 the entity database Aleda [124], aimed at constituting such a reference. Aleda was first developed for French but is under development for English. Aleda is extracted automatically from Wikipedia and Geonames. It is used among others in the SxPipe processing chain and its NP named entity recognition, as well as in the Nomos named entity linking system.

In 2011, major efforts have been made for improving the coverage, precision and richness of the French Aleda: improvements in the tool for creating an XML almost-raw-text version of the wikipedia, new method for identifying and typing entities among wikipedia articles, based on infoboxes and wikipedia categories, richer database structure for storing more detailed information about each entity, and many other improvements. A paper about these advances has been submitted to LREC 2012.

6.5.2. Cooperation of symbolic and statistical methods for named entity recognition and typing

Named entity recognition and typing is achieved both by symbolic and probabilistic systems. We have performed an experiment [24] for making the rule-based system NP, SxPipe’s high-precision named entity recognition system developed at Alpage on AFP news corpora and which relies on the Aleda named entity database, interact with LIANE, a high-recall probabilistic system developed by Frédéric Béchet and trained on oral transcriptions from the ESTER corpus. We have shown that a probabilistic system such as LIANE can be adapted to a new type of corpus in a non-supervised way thanks to large-scale corpora automatically annotated by NP. This adaptation does not require any additional manual annotation and illustrates the complementarity between numeric and symbolic techniques for tackling linguistic tasks.

6.5.3. Nomos, a statistical named entity linking system

For information extraction from news wires, entities such as persons, locations or organizations are especially relevant in a knowledge acquisition context. Through a process of named entity recognition and entity linking applied jointly, we aim at the extraction and complete identification of these relevant entities, which are meant to enrich textual content in the form of metadata. In order to store and access extracted knowledge in a structured and coherent way, we aim at populating an ontological reference base with these metadata. We have pursued our efforts in this direction, using an approach where NLP tools have early access to Linked Data resources and thus have the ability to produce metadata integrated in the Linked Data framework. In particular, we have studied how the entity linking process in this task must deal with noisy data, as opposed to the general case where only correct entity identification is provided.

We use the symbolic named entity recognition system NP, a component of SxPipe, and use it as a mention detection module. Its output is then processed through our entity linking system, which is based on a supervised model learnt from examples of linkings. Since our named entity recognition is not deterministic, as opposed to other entity linking tasks where the gold named entity recognition results are provided, it is configured to remain ambiguous and non-deterministic, i.e., its output preserves a number of ambiguities which are usually resolved at this level. In particular, no disambiguation is made in the cases of multiple possible mentions boundaries (e.g., \{Paris\}+\{Hilton\} vs. \{Paris Hilton\}). In order to cope with possible false mention matches, which should be discarded as linking queries, the named entity recognition output is made more ambiguous by adding a not-an-entity alternative to each mention detection. The entity linking module’s input therefore consists in multiple possible readings of sentences. For each reading, this module must perform entity linking on every possible entity mention by selecting their most probable matching entity. Competing readings are
then ranked according to the score of entities (or sequence of entities) ranked first in each of them. The reading with no entity should also receive a score in order to be included in the ranking. The motivation for this joint task lies in the frequent necessity of accessing contextual and referential information in order to complete an accurate named entity recognition; thus the part where named entity recognition usually resolves a number of ambiguities is left for the entity linking module, which uses contextual and referential information about entities.

We have realized a first implementation of our system, as well as experiments and evaluation results. In particular, when using knowledge about entities to perform entity linking, we discuss the usefulness of domain specific knowledge and the problem of domain adaptation.

6.6. Extending wordnets

**Participants:** Benoît Sagot, Marianna Apidianaki, Valérie Hanoka.

The WOLF (see section 5.9) is a freely available, automatically created wordnet for French, the biggest drawback of which has until now been the lack of general concepts that are typically expressed with highly polysemous vocabulary that is on the one hand the most valuable for applications in human language technologies but also the most difficult to add to wordnet accurately with automatic methods on the other. In collaboration with Darja Fišer (University of Ljubljana), we have developed a self-training-like technique for acquiring a classifier that is able to assign appropriate synset ids (i.e., senses) to new words, extracted from non-disambiguated multilingual sources of lexical knowledge, such as Wiktionaries and Wikipedia [39], [40]. Automatic and manual evaluation shows high coverage as well as high quality of the resulting lexico-semantic repository. Another important advantage of the approach is that it is fully automatic and language-independent and can therefore be applied to any other language still lacking a wordnet. Indeed, it was applied to Slovene as well.

Other techniques were used as well and are the basis of various submitted conference papers. They rely, among others, on morphological derivation, on graph-based representation of highly multilingual lexicons extracted from numerous wiktionaries, and on automatically induced sense clusters.

6.7. Unsupervised lexical semantics

**Participant:** Marianna Apidianaki.

6.7.1. Unsupervised word sense induction and disambiguation

Word sense induction (WSI) is the task aimed at automatically identifying the senses of words in texts, without the need for handcrafted resources or annotated data. Up till now, most WSI algorithms extract the different senses of a word ‘locally’ on a per-word basis, i.e. the different senses for each word are determined separately. In collaboration with Tim van de Cruys, at Alpage in 2010, now at University of Cambridge [19], [50], we have compared the performance of such algorithms to a new algorithm that uses a ‘global’ approach, i.e. the different senses of a particular word are determined by comparing them to, and demarcating them from, the senses of other words in a full-blown word space model. The induction step and the disambiguation step are based on the same principle: words and contexts are mapped to a limited number of topical dimensions in a latent semantic word space. The intuition is that a particular sense is associated with a particular topic, so that different senses can be discriminated through their association with particular topical dimensions; in a similar vein, a particular instance of a word can be disambiguated by determining its most important topical dimensions. We evaluated our model on the SemEval-2010 word sense induction and disambiguation task. All systems that participated in this task use a local scheme for determining the different senses of a word. We obtain state-of-the-art results.
6.7.2. Unsupervised cross-lingual lexical substitution

Cross-Lingual Lexical Substitution (CLLS) is the task that aims at providing for a target word in context several alternative substitute words in another language. The proposed sets of translations may come from external resources or be extracted from textual data. In 2011, we have introduced a new approach for this task [18], namely the use of an unsupervised cross-lingual word-sense induction method. This method identifies the senses of words by clustering their translations according to their semantic similarity. We evaluated the impact of using clustering information for CLLS on the SemEval-2010 CLLS data set. Our system performs better on the ‘out-of-ten’ measure than the systems that participated in the SemEval task.

Participants: Pierre Magistry, Benoît Sagot.

For most languages using the Latin alphabet, tokenizing a text on spaces and punctuation marks is a good approximation of a segmentation into lexical units. Although this approximation hides many difficulties, they do not compare with those arising when dealing with languages that do not use spaces, such as Mandarin Chinese. Many segmentation systems have been proposed, some of them use linguistically motivated unsupervised algorithms. However, standard evaluation practices fail to account for some properties of such systems. New results [33] have shown that a simple model, based on an entropy-based reformulation of a language-independent hypothesis put forward by Harris in 1955, allows for segmenting a corpus and extracting a lexicon from the results. Tested on the Academia Sinica Corpus, our system allows for inducing a segmentation and a lexicon with good intrinsic properties and whose characteristics are similar to those of the lexicon underlying the manually-segmented corpus. Recent unpublished work using a slightly different model have improved these results. In parallel, preliminary experiments on other languages (Hindi, Sinhalese, Tamil, French) and original visualization techniques have already led to promising results.

6.9. Computational morphology

Participants: Benoît Sagot, Géraldine Walther.

Although computational morphology has been a topic of interest for Alpage for several years now, several new research topics have received attention in 2011, often in collaboration with morphologists from the Laboratoire de Linguistique Formelle (University Paris 7).

6.9.1. Inflectional morphology

Non-canonical inflection (suppletion, deponency, heteroclisis...) is extensively studied in theoretical approaches to morphology. However, these studies often lack practical implementations associated with large-scale lexica. Yet these are precisely the requirements for objective comparative studies on the complexity of morphological descriptions. We have shown [16], [43] how the Parsli model of inflectional morphology [132], which can represent many non-canonical phenomena, as well as a formalisation and an implementation thereof can be used to evaluate the complexity of competing morphological descriptions. After illustrating the properties of the model with data about French, Latin, Italian, Persian and Sorani Kurdish verbs and about noun classes from Croatian and Slovak we have conducted experiments on the complexity of four competing descriptions of French verbal inflection. The complexity is evaluated using the information-theoretic concept of description length. We show that the new concepts introduced in the model by the Parsli model enable reducing the complexity of morphological descriptions w.r.t. both traditional or more recent models.

6.9.2. Derivational morphology

This year, in relation with the ANR project EDyLex (see section 8.2.2), work has started targeted towards the acquisition of lexical information at the level of derivational morphology, both using semi- and non-supervised techniques.
Semi-supervised techniques have been used in a work dedicated to French denominal adjectives, for which we have implemented an automatic technique based on large-scale lexicons and corpora for extracting derivation links between base nouns and derived adjectives based on the same stem [46]. The resulting derivational lexicon, which is freely available, has already been partially manually validated. Future work include a full validation and adding denominal adjectives with a suppletive base.

Unsupervised techniques have been used for extraction of derivational links that appear more systematically, although their definition is less linguistically motivated as such [51].

### 6.9.3. Morphological issues concerning loan words

Also in the context of the ANR project EDyLex (see section 8.2.2), we have carried out a preliminary study on the morphological issues raised by borrowing phenomena, concerning in particular French nouns and verbs borrowed from English [52]. Using techniques that are similar to those used on derivational morphology, we have extracted a significant amount of loan words from a large raw corpus. We have proposed a model of the borrowing phenomenon, that takes into account graphemic (spelling), phonetic and morphological variability.

### 6.10. Allophony and word segmentation in language acquisition models

**Participants:** Luc Boruta, Benoît Crabbé.

Allophonic rules are responsible for the great variety in phoneme realizations. Infants can not reliably infer abstract word representations without knowledge of their native allophonic grammar. We have explored the hypothesis that some properties of infants’ input, referred to as indicators, are correlated with allophony. First, we provide an extensive evaluation of individual indicators that rely on distributional or lexical information. This evaluation relies on a phonetically transcribed corpus, generated automatically from a phonemically transcribed English, French and Japanese child-directed corpus. As such corpora do not exist as such, we used automatically extracted allophonic grammars of various sizes leading to various granularity levels, using our own allophonic rule extraction algorithm [57]. Then, we present a first evaluation of the combination of indicators of different types, considering both logical and numerical combinations schemes [23]. Though distributional and lexical indicators are not redundant, straightforward combinations do not outperform individual indicators.

Models of the acquisition of word segmentation are typically evaluated using phonemically transcribed corpora. Accordingly, they implicitly assume that children know how to undo phonetic variation when they learn to extract words from speech. Moreover, whereas models of language acquisition should perform similarly across languages, evaluation is often limited to English samples. Using the phonetically annotated corpora described above, that cover three typologically different languages, we evaluated the performance of state-of-the-art statistical models given inputs where phonetic variation has not been reduced. We have measured segmentation robustness across different levels of segmental variation, simulating systematic allophonic variation or errors in phoneme recognition. We have shown that these models do not resist an increase in such variations and do not generalize to typologically different languages. From the perspective of early language acquisition, the results strengthen the hypothesis according to which phonological knowledge is acquired in large part before the construction of a lexicon.

### 6.11. Modelling the acquisition of syntactic categories by children

**Participant:** Benoît Crabbé.

B. Crabbé co-supervised A. Gutman for an M2 thesis (MPRI) in collaboration with A. Christophe (LSCP/ENS) in the domain of psycholinguistic modelling. The topic was concerned with modelling and implementing psychologically motivated models of language treatment and acquisition. Contrary to classical Natural Language Processing applications, the main aim was not to create engineering solutions to language related tasks, but rather to test and develop psycholinguistic theories. In this context, the study was concerned with the question of learning word categories, such as the categories of Noun and Verb. It is established experimentally that 2-year-old children can identify novel nouns and verbs. It has been suggested that this can be done
using distributional cues as well as prosodic cues. While the plain distributional hypothesis had been tested quite extensively, the importance of prosodic cues had not been addressed in a computational simulation. We provided a formulation for modelling this hypothesis using unsupervised and semi-supervised forms of bayesian learning (EM) both offline and online.

6.12. Modelling and extracting discourse structures

Participants: Laurence Danlos, Charlotte Roze.

6.12.1. Cross-lingual lexical semantics of discourse connectives

Discourse connectives are words or phrases that indicate senses holding between two spans of text. The theoretical approaches accounting for these senses, such as text coherence, cohesion, or rhetorical structure theory, share at least one common feature: they acknowledge that many connectives can indicate different senses depending on their context. Depending on its sense, the translation of a connective into another language can vary greatly, either using an equivalent connective, or using a different construction or even no explicit connective at all.

On the basis of data provided by the bilingual concordancer TransSearch which propose statistical word alignment [64], [53] made a semi-manual annotation of the English translation of two French connectives ("en effet" and "alors que"). The results of this annotation show that the translations of these connectives do not correspond to the “transpots” identified by TransSearch and even less to the translations proposed in bilingual dictionaries.

The conclusions of this work were presented at an European workshop organized by the project COMTIS5, and some members decide to use our technic for other connectives and other aligned corpora (e.g. Europarl).

6.12.2. Discourse relations inference rules

In 2011 we have developed a new methodology for building discourse relations inference rules, to be integrated into an algebra of these relations [54], [38]. The construction of such an algebra has as main objective the improvement of the comparison of discourse structures within the evaluation of discourse annotations and the creation of a gold-standard corpus. The inference rules can also help detecting inconsistencies in discourse structures, in order to improve human or machine annotation. The premises of rules already studied lead to the formulation of inference rules, established by the theoretical definition of discourse relations, manually constructed data and extracted data. By manually annotating discourses, we also compute inference probabilities. We have illustrated the adopted methodology taking as theoretical background the Segmented Discourse Representation Theory [60].

6.12.3. Discourse structure and factivity

Discursive annotations proposed in theories of discourse such as RST (Rhetorical Structure Theory) or SDRT (Segmented Representation Theory Discourse) have the advatange of building a global discourse structure linking all the information in a text. Discursive annotations proposed in PDTB (Penn Discourse Tree Bank) have the advatange of identifying the "source" of each information – thereby answering to questions such as who says or thinks what?

In collaboration with Owen Rambow (Columbia University), we have proposed [26], [28] a unified approach for discursive annotations combining the strengths of these two streams of research. This unified approach relies crucially on factivity information, as encoded in the English corpus FactBank. We intend to pursue this avenue of research by initiating in 2012 the development of a French FactBank.

6.13. Modelling and extracting temporal structures

Participants: Pascal Denis, Philippe Muller.

5 http://www.idiap.ch/project/comtis
Temporal information has been the focus of recent attention in information extraction. An elegant approach to learning temporal orderings from texts is to formulate this problem as a constraint optimization problem, which can be then given an exact solution using Integer Linear Programming. This works well for cases where the number of possible relations between temporal entities is restricted to the mere precedence relation, but becomes impractical when considering all possible interval relations.

We have proposed this year two innovations [29], inspired from work on temporal reasoning, that control this combinatorial blow-up, therefore rendering an exact ILP inference viable in the general case. First, we propose to translate the network of constraints from temporal intervals to their end-points, to handle a drastically smaller set of constraints, while preserving the same temporal information. Second, we have show that additional efficiency is gained by enforcing coherence on particular subsets of the entire temporal graphs. We evaluate these innovations through various experiments on TimeBank 1.2 using standard evaluation metrics, and compare our ILP formulations with various baselines and oracle systems.

The evaluation of temporal information extraction, i.e., the comparison of two annotations of a given text, is also a scientific challenge. This is because relations between events in a story are intrinsically interdependent and cannot be evaluated separately. A proper evaluation measure is also crucial in the context of a machine learning approach to the problem. Finding a common comparison referent at the text level is not obvious, and we have argued, in collaboration with Xavier Tannier (LIMSI), in favor of a shift from event based measures to measures on a unique textual object, a minimal underlying temporal graph, or more formally the transitive reduction of the graph of relations between event boundaries [15].

**Participants:** Emmanuel Lassalle, Pascal Denis.

Bridging descriptions are a special kind of anaphora whose interpretation requires not only identifying an antecedent, but also inferring a specific relation linking it to the anaphor. The resolution of bridging anaphora represents a very challenging task in discourse processing. It is considerably much harder than standard coreferential anaphora resolution for which shallow predictors (like distance, string matching, or morphosyntactic agreement) have been shown to be rather effective. Part of the challenge is due to an important information bottleneck. Lexical resources like WordNet are still too poor and uneven in coverage to provide a realistic solution. In turn, more recent approaches to bridging resolution have turned to web-based extraction methods. To date, the most complete and best-performing approach combines focus and lexical distance predictors using machine learning techniques [105].

We have focused on mereological bridging anaphora (that is, cases wherein the inferred relation is a part-whole relation). Moreover, we have worked on French, a language for which current lexical resources have a very low coverage. The system, presented in [32] is similar to a system developed for English [105], but it was enriched to integrate meronymic information extracted automatically from both web queries and raw text using syntactic patterns. Through various experiments on the DEDE corpus [78], we show that although still mediocre the performance of our system compare favorably to those obtained for English by the above-mentioned system. In addition, our evaluation indicates that the different meronym extraction methods have a cumulative effect, but that the text pattern-based extraction method is more robust and leads to higher accuracy than the Web-based approach.

### 6.15. Statistical models of word order in French

**Participants:** Juliette Thuilier, Benoît Crabbé.

We study the problem of choice in the ordering of French words using statistical models along the lines of [66] and [67]. This work aims at describing and model preferences in syntax, bringing additional elements to Bresnan’s thesis, according to which the syntactic competence of human beings can be largely simulated by probabilistic models. We previously investigated the relative position of attributive adjectives with respect to the noun.

---

6 An illustrative English example is is the following discourse: *The car will not move. The engine is broken.*
This year, we mainly studied the problem of the relative ordering of postverbal complements. The focus of this investigation is the relative order of direct object and indirect object of French ditransitive verbs. The first part of this work is based on corpora data that we extracted from two journalistic corpora (French Tree Bank and Est-Républicain) and a radio corpus (ESTER). These data were manually annotated and validated for semantic categories (animacy and semantic class of the ditransitive verb). Based on these data, we built statistical models showing that the relative length of complements and verbal lemmas are the most important factors, and that, differently from English or German, categories as animacy or definiteness seem to play no role in the relative ordering.

In collaboration with Anne Abeillé (Laboratoire de Linguistique Formelle, Université Paris 7), we extended our corpora study with psycholinguistic questionnaires, in order to show that statistical models are reflecting some linguistic knowledge of French speakers. The preliminary results confirm that animacy is not a relevant factor in ordering French complements.

As regards to corpus work, we are extending the database with spontaneous speech corpora (CORAL-ROM and CORPAIX) and a wider variety of verbal lemmas, in order to enhance sample representativeness and statistical modelling. In a crosslinguistic perspective, we plan to strengthen the comparison with the constraints observed in other languages such as English or German.

As can be seen from the outline above, this line of research brings us closer to cognitive sciences. We hope in the very long run that these investigations will bring new insights on the design of probabilistic parsers or generators. In NLP the framework that is closest to implementing construction grammar is Data Oriented Parsing.

6.16. Assessing the Amazon Mechanical Turk plateform

Participant: Benoît Sagot.

In collaboration with Gilles Adda and Joseph Mariani from LIMSI and with Karën Fort from INIST, we have assessed some crowdsourced microworking systems and especially Amazon Mechanical Turk, the use of which has been steadily growing in language processing in the past few years [41], [17]. According to the mainstream opinion expressed in the articles of the domain, this type of on-line working platforms allows to develop very quickly all sorts of quality language resources, for a very low price, by people doing that as a hobby or wanting some extra cash. We have demonstrated that the situation is far from being that ideal, be it from the point of view of quality, price, workers’ status or ethics and bring back to mind already existing or proposed alternatives. Our goal was threefold:

- to inform researchers, so that they can make their own choices with all the elements of the reflection in mind,
- to ask for help from funding agencies and scientific associations, and develop alternatives,
- to propose practical and organizational solutions in order to improve new language resources development, while limiting the risks of ethical and legal issues without letting go price or quality.

6.17. Finite state formalisms for Egyptian Hieroglyphic transliteration

Participant: François Barthélémy.

The task of transliterating an Egyptian Hieroglyphic text into the latin alphabet was studied [20], as a model problem to compare two finite-state formalisms: the first one is a cascade of binary transducers; the second one is a class of multitape transducers expressing simultaneous constraints, implemented using the Karamel language [62]. The two systems were compared regarding their expressivity and readability.

The first system tends to produce smaller machines, but is more tricky. On the other hand, the Karamel language provides a more abstract description of the forms, using an explicit tree structure and separating the different pieces of information on different tapes, according to semantic criteria. But the Karamel machine is much larger. Karamel is a high-level declarative formalism whereas non contextual rewrite rules are an efficient low-level language.
AMAZONES Team

6. New Results

6.1. SouthBound results

6.1.1. L4 micro kernels

As part of our investigations about what software architectures were the best candidates to base our Ambient Middleware Stack upon, we studied different micro-kernel operating systems such as CodeZero [33], OKL4, and L4/Fiasco. The objective here is to try and quantify the development effort that would be needed before being able to execute a Java application on top of a micro-kernel. These studies included, in addition to a lot of bibliographic research, several technical experiments such as booting each of these various micro-kernel systems in QEmu, as well as on real hardware. We use a BeagleBoard as a representative example of the kind of hardware platforms typically encountered in Ambient Intelligence scenarios.

6.1.2. Virtual machines

In parallel to our study of micro-kernel architectures, we worked on virtual machines as well, in the perspective of bridging the gap between the two. The basic question here is: what does it takes to to cut down a Java virtual machine into pieces so as to run each of these pieces as a separate software component in the system. We ran two actions in order to investigate this question. First, we ported the JamVM virtual machine to run on top of the Genode operating system framework [37]. This provided us with better understanding of what are the real requirements of a Java virtual machine in terms of underlying operating systems support. Second, we focused on one particular service of the virtual machine, the garbage collector, and we precisely identified and studied the coupling between this component and all other parts of the virtual machine (bytecode interpreter, scheduler, etc). This work was done as part of a student summer internship (Yann Chevalier, INSA-Lyon 3IF). Removing a garbage collector at runtime, and “plugging in” another one dynamically proved to be vastly harder than expected. Still, this work provided us with great insights about the coupling relationships between different OS components.

6.1.3. HiKoB

Antoine Fraboulet (Amazone team), Guillaume Chelius (D-NET team) and Christophe Braillon (INRIA SED) started a new company called HiKob http://openlab.hikob.com/ in July 2011. HiKoB is a development project following several successful research projects completed these last 6 years at INSA Lyon and INRIA. HiKoB hardware and software products help in building complex, large-scale and distributed applications in the domains of: motion capture, biomechanical study, biologging study, building instrumentation and many more applications targeting wireless sensor network solutions for distributed and embedded measurement. HiKoB business model is built on two major directions: complete solutions for industrial applications and software and hardware tools for research and innovation in the fields of sensor networking and embedded wireless measure. HiKoB is supported by IT-Translation and INSAValor.

6.1.4. Service-Oriented Tainted Object Propagation

Many Java technologies allow the execution of code provided by multiple parties. Service-oriented platforms based on components such as OSGi are good examples of such a scenario. Those extensible component-based platforms are service-oriented, as components may directly interact with each other via the services they provide. However, even robust languages such as Java were not designed to handle safely code interaction between trusted and untrusted parties.

In [38], we show how basic Java interactions can break encapsulation or execution safety and why the Java security layers’ threat coverage is incomplete. We also review flaws in the Java access control design that can allow untrusted code to bypass restrictions by exploiting vulnerabilities in trusted code.
As component-based platforms become more and more integrated to our daily life, we improved our Service-Oriented Tainted Object Propagation technique to find such vulnerabilities and used it on several open-source components to further demonstrate the real exposure that those vulnerabilities bring to the fore.

6.2. NorthBound results

Another key issue in the Amazones architecture was to bring together formal methods and service oriented programming such as OSGi/Java approach. We developed the Logos framework that observes and records communications that occurs between an OSGi client and a corresponding server. This architecture is developed in the LISE ANR project, and we made various improvements to the architecture.

6.2.1. Amazones Protocol

It aims at building automata from running and observing applications. The logos framework observes a running application at builds at run-time an automata that represents the application behavior. Julien Ponge wrote the corresponding Scala code.

6.2.2. Monitored oriented programming

Another Logos extension integrates Monitored Oriented architectures such as JavaMOP and Larva. We are currently using and working with the larva people. Each time we intercept a call, it is transfered to the Larva automata manager.

6.2.3. Real time SOA

Admission control for service oriented application in real time infrastructure. This work led by Lionel Morel tries to bring together real time architecture configuration and component based architectures. The deal is to find a better way of managing the dynamicity of applications in real time context.

6.2.4. B Model Slicing to Generate Tests

In a model-based testing approach as well as for the verification of properties, B models provide an interesting modelling solution. However, for industrial applications, the size of their state space often makes them hard to handle. To reduce the amount of states, an abstraction function can be used. The abstraction is often a domain abstraction of the state variables that requires many proof obligations to be discharged, which can be very time consuming for real applications.

we propose a contribution to this problem that complements an approach based on domain abstraction for test generation, by adding a preliminary syntactic abstraction phase, based on variable elimination. We define a syntactic transformation that suppresses some variables from a B event model, in addition to three methods that choose relevant variables according to a test purpose. This way, we propose a method that computes an abstraction of a source model \( M \) according to a set of selected relevant variables. Depending on the method used, the abstraction can be computed as a simulation or as a bi-simulation of \( M \). With this approach, the abstraction process produces a finite state system. We apply this abstraction computation to a Model Based Testing process. We evaluate experimentally the impact of the model simplification by variables elimination on the size of the models, on the number of proof obligations to discharge, on the precision of the abstraction and on the coverage achieved by the test generation.

This work is based on a B model approach. However, in the context of AMAZONES, one of our objectives is to extend it, in order to consider models automatically generated from the usage a the tested service on a particular context.

6.2.5. Distributed Data Centric Programs Verification

Netlog is a language designed to describe distributed programs. It has a precise semantics, provides a high-level of abstraction thanks to its datalog flavor and benefits from an efficient implementation. This makes it a very interesting target language for proofs of distributed programs. In [34], with the Coq proof assistant, we formalized the distributed computation model based on message passing with either synchronous or
asynchronous behaviors; built the translation of Netlog programs; modeled the embedded machine evaluating Netlog programs, and thus established a framework to formally verify properties of distributed programs in Netlog. To test the framework, we proved the correctness of a concrete distributed program for constructing spanning trees over connected graphs.

6.2.6. Managing dynamic service substitution at runtime

The service oriented approach is a paradigm allowing the introduction of dynamicity in developments. If there are many advantages with this approach, there are also some new problems associated to service disappearance. The particular case of service substitution is often studied and many propositions exist. However, proposed solutions are mainly server-side in the context of web-services.

In this work, we propose a client side API-based approach to allow service substitution without any restart of the client and without any assumption on external services. Our proposition is based on a transactional approach, defined to authorized substitutions of services dynamically, by preserving the current run and collected data.

We designed a framework organized by Julien Ponge [14].

6.3. Application domain results

An emerging trend into Amazones team is to apply our northBound/southBound approach to the InternetOfThing wave. We try to apply our architectures to the IoT application domain.

6.3.1. Data Centric Applications Distribution

Peer to peer systems have been widely used to alleviate the burden of servers by transferring to peers in a network tasks that do not require a centralization of the information. A wide range of applications are now emerging over peer-to-peer, such as social networking, multiplayer games, mobile messaging, etc. Most of these applications are essentially data-centric, they rely on exchange of data between peers, and can be expressed by queries over the database.

We propose a tool that allows for such applications, programmed as a collection of queries over a database, to be ported seamlessly without changing the initial queries from a client/server system to peer-to-peer system. The distribution is done with overlays network defined by declarative data centric programs specified in the Netlog language, thus resulting in a fully data centric modeling of the peer-to-peer application. The communication between peers relies on implicit addresses which can be evaluated on the fly to ensure the persistence of data.

We demonstrate the technique on a multiplayer online game, written in SQL, with players who connect to a mobile ad hoc network through their portable devices. The overlay is defined by a combination of an ad hoc routing protocol, DSDV, together with a DHT. The application runs on the QuestMonitor system, which allows to monitor the communication between peers, the evolution of the local data stores, as well as the execution of the declarative code.

6.3.2. Service Deployment in Disrupted Networks

OLD / REMOVE ? Ambient environments classically use wireless connections that suffers from frequent disconnections. The hard research point is to ensure service continuity. This disconnection problem has been widely tackled for application data with proxy and prefetching approaches. For services, disconnections are more difficult to anticipate, since service calls are only solved at run-time.

We are currently working on service deployment and invocations in disrupted networks with a network coding approach. This research is a joint work with the Swing team and with Aline Viana (INRIA Saclay @ TU Berlin). The main idea is to study how social-oriented applications, that need inter-dependent services and updates to be distributed to all or part of the mobile users community, could benefit from a network coding approach. The project aims at assessing for the first time the performance, in terms of latency, energy efficiency and capacity, of standard network coding techniques in presence of realistic user mobility and service demands.
Building on these results, we plan to propose original social-aware network coding techniques that take advantage of the heterogeneous nature of the opportunistic network to reduce delays and energy consumption, in presence of multiple concurrent service flows targeting either all users or specific groups of interests.

These performance issues tackle at the same time the overall network capacity optimizations, as well as the overall software stack optimizations of a device with local and autonomous network coding strategies.

An INRIA ARC project proposal, entitled SoCool, has been submitted jointly with INRIA AMAZONES, INRIA SWING, INRIA MAESTRO, INRIA Saclay, University of Nice, TU Berlin and Fordham University.
AMIB Project-Team

5. New Results

5.1. RNA structures

5.1.1. RNA secondary structures: folding, design and evolution

In a collaboration with J. Waldispuhl (McGill, Canada) (Presented at the RECOMB’11 conference [32]), we used weighted grammatical models, introduced by members of the group [2], to perform an efficient exploration of the mutational landscape of RNA. We proposed an adaptive sampling algorithm, where weights were used to compensate an identified bias toward regions of higher GC-content within sampled sequences, thereby allowing for the exploration of more relevant portions of the evolutionary landscape. These adaptive sampling principles can be adapted into a method for the RNA design following similar principles. This constitutes a competitive alternative to local search strategies used by all existing tools for this problem. This work is ongoing as a collaboration with B. Berger group (MIT) and J. Waldispuhl (McGill, Canada), and a manuscript was recently submitted.

5.1.2. RNA knowledge-based potentials and 3D studies

We used the curated database of biologically interesting structures we have set up to perform a statistical analysis and developed knowledge-based potentials. The database server is available at http://csb.stanford.edu/rna.

We obtained RNA knowledge-based potentials that now performs well at different representation levels. They can be used in three well-known Molecular Dynamics (MD) and modeling software suites ENCAD [44], GROMACS (v3 and 4) [45] and MOSAICS [41] and are available for the community. The study we performed on a large number of new decoys showed that our potential outperforms Rosetta RNA scoring function [37] which is the gold standard. We show that not having correction terms for base-stacking and pairing can be of advantage when modelling loops at high resolution. The study was welcomed by the RNA community and published in RNA Journal (IF 6.5) [8].

We also refined the mixture model strategy we developed for building knowledge-based potentials. In collaboration with O. Schwander at LIX, we compared different mixture models: Dirichlet Process Mixture models (DPM), Kernel Density Estimation (KDE) models, Expectation Maximization models (MM) with different number of components (including a simplified version based on a post-processing step using K-Means). We showed that the Dirichlet Process Mixtures (DPM) is a good tradeoff despite its longer precomputation time as it provides a smooth potential having relatively few components. This study was presented at the MCMMB’11 conference and was submitted as a journal paper.

This work was done in collaboration with A. Sim, X. Huang an M. Levitt (Stanford University - GNAPI Associate team).

5.2. Proteins structures

5.2.1. Protein sequence alignment

In comparative protein modeling, the quality of a template model depends heavily on the quality of the initial alignment between a given protein with unknown structure to various template proteins, whose tertiary structure is available in the Protein Data Bank (PDB). Although pairwise sequence alignment has been solved for more than three decades, there remains a large discrepancy between the accuracy of the best sequence alignment between two amino acid sequences, as produced by the Needleman-Wunsch or Smith-Waterman algorithms, and that of the best structural alignment between two protein X-ray structures, as produced by the software DALI, CE, TOPFRET, etc. To improve the quality of initial alignments in template modeling, one can integrate valuable information from an ensemble of generated suboptimal alignments, that is alignments whose score is below the best possible score. In a collaboration with P. Clote (Boston College/DIGITEO) [26], we presented a novel algorithm to produce suboptimal pairwise alignments.
5.2.2. Protein-protein interaction:

A protein-protein docking procedure traditionally consists in two successive tasks: a search algorithm generates a large number of candidate solutions, and then a scoring function is used to rank them in order to extract a native-like conformation. We have already demonstrated that using Voronoi constructions and a defined set of parameters, we could optimize an accurate scoring function. However, the precision of such a function is still not sufficient for large-scale exploration of the interactome.

Another geometric construction was also tested: the Laguerre tessellation. It also allows fast computation without losing the intrinsic properties of the biological objects. Related to the Voronoi construction, it was expected to better represent the physico-chemical properties of the partners. In , we present the comparison between both constructions.

We also worked on introducing a hierarchical analysis of the original complex three-dimensional structures used for learning, obtained by clustering. Using this clustering model we can optimize the scoring functions and get more accurate solutions. This scoring function has been tested on CAPRI scoring ensembles, and an at least acceptable conformation is found in the top 10 ranked solutions in all cases. This work was part of the thesis of Thomas Bourquard, defended in 2009.

A strong emphasis was recently made on the design of efficient complex filters. To achieve this goal, we focused on the use of collaborative filtering methods state of the art machine learning approaches combined with our genetic algorithm [9].

We have also proposed an approach that improves the predictions made by HEX, a state-of-the-art docking tool developed by INRIA Nancy. We applied Voronoi fingerprint to the output of HEX and learn how to rank them, and we have tested new ranking strategies. The obtained ranking improved the initial ranking of HEX [33], [23].

We also decided to extend these techniques to the analysis of protein-nucleic acid complexes. The first preliminary developments and tests were performed by Adrien Guilhot during his M1 internship for two months.

5.2.3. Transmembrane β-barrels:

We have recently proposed an algorithm [31] that classifies Transmembrane β-Barrel Proteins (TMB) and predicts their structure. It first uses a simple probabilistic model to filter out the proteins and strands which are not beta-barrel. Then, we build a graph-theoretic model to fold into the super-secondary structure via dynamic programming. This step runs in $O(n^3)$ time for the common up-down topology, and at most $O(n^5)$ for the Greek key motifs, where $n$ is the number of amino acids. Finally a predicted three-dimensional structure is built from the geometric criteria. If the pseudoenergy is insufficient, the protein is classified as a non-TMB protein.

We have tested this approach on TMB and non-TMB proteins for classification and structure prediction. We tested classification on a dataset of 14238 proteins including 48 TMB and 14190 non-TMB proteins. Our classification results are very accurate and comparable to other algorithms [21], [5]. Especially, our PPV, MCC and F-Scores are second only to a very recent algorithm by Freeman and Wimley [39], which relies heavily on training data. We also tested the structure prediction on 42 proteins from the TMB and compared to other existing algorithms. The results are comparable to existing algorithms, the accuracy ranges from 85-93%, depending upon the parameter used. This is very promising given that other algorithms rely heavily on homology and training datasets and may be overfitting. Our approach can be further improved by refining the energetic model, especially on turns and loops.

In addition, we have developed consensus methods to combine multiple secondary structures into one more reliable solution. Our results show that our technique can be used to combine multiple solutions to produce structures that are more than any of the input structures. These methods are based mainly on social choice theory and known properties of TMB proteins. In addition, we are working on methods for combining information on the super-secondary structures, and using them to augment the supersecondary structure provided by our approach.
5.3. Combinatorics and Annotation

5.3.1. Word counting and random generation

Cis-Regulatory modules (CRMs) of eukaryotic genes often contain multiple binding sites for transcription factors, or clusters. Formally, such sites can be viewed as words co-occurring in the DNA sequence. This gives rise to the problem of calculating the statistical significance of the event that multiple sites, recognized by different factors, would be found simultaneously in a text of a fixed length. A long-term research on word enumeration has been realized by the team. An extension to Hidden Markov Models has been realized recently in a collaboration with M. Roytberg (IMPB, Puschino, Russia). It relies on a new concept of overlap graphs that efficiently overcomes the main difficulty - overlapping occurrences - in probabilities computation. This is part of E. Furletova’s thesis, to be defended soon. An implementation is available at http://server2.lpm.org.ru/bio. This algorithm provides a significant space improvement over a previous algorithm, AHO PRO developed with our former associate team MIGEC. M. Régnier and S. Sheikh have addressed combinatorial problems on clumps that should allow further space decrease and large deviation results were presented at MCCMB’11.

An other application of word combinatorics has been started this year. During his internship, L. Pei (Paris-Sud 11 U.) provided a pipeline that simulates a random generation of reads and assembles them using MIRA software. This work will be pursued by D. Iakovishina in her thesis. It is a collaboration with MAGNOME at INRIA-BORDEAUX and IOGENE in Moscow.

A previous work [36], published in 2010, generalized Boltzmann samplers to multivariate objects, allowing for the efficient random generation achieving a fixed or approximate composition for context-free languages. However, the performances of such algorithms were only guaranteed in the case of strongly-connected context-free grammars. In a recent collaboration with O. Bodini, H. Tafat and C. Banderier (LIPN, Paris-XIII) we are working on characterizing the distributions arising from simply connected grammars. In a short paper accepted for presentation at the ANALCO’12 conference [24], we showed that: i) a large class of distributions can be reached for the number of occurrence of a single letter, arguably the simplest observable pattern; ii) simple grammars/regular expressions can be built that realize these distributions; iii) Classic Boltzmann samplers remain largely unaffected by this diversity.

Our work on random generation has applications in software testing and model-checking, in a collaboration with the Fortesse group at LRI [13], [29].

5.3.2. RNA combinatorics

Pseudoknots are usually ignored by popular software for RNA prediction. This means that, even under the daring assumptions of an unique and well-defined fold for RNA, coupled with a perfectly accurate energy model, the real structure of RNA will not be recovered perfectly. In a collaboration between AMIB members and S. Janssen (Universität Bielefeld), we investigated the practical implications of such a limitation. We used RNAFOLD, a popular software for the prediction of RNA structure on representative sequences of the RFAM database, which groups known RNA sequences into about 2000 functional families. We observed that 12% of RFAM families exhibited a total absence of overlap between predicted structures and manually-curated structures, derived from experimental or evolutionary data. Combination of RFAM annotations, a survey of literature, and a newly developed predictive method for the presence of a functional pseudoknots, we were able to validate that a large majority of the mispredicted families featured evidence of pseudoknots in the functional conformation. Preliminary results were presented by B. Raman at the Fifth Indo-French Bioinformatics Meeting [34].

In 2004, Condon and coauthors gave a hierarchical classification of exact RNA structure prediction algorithms according to the generality of structure classes that they handle. In [19], we completed this classification by adding two recent prediction algorithms. More importantly, we precisely quantified the hierarchy by giving closed or asymptotic formulas for the theoretical number of structures of given size n in all the classes but one. This allows to assess the tradeoff between the expressiveness and the computational complexity of RNA structure prediction algorithms.
Similar decompositions can be used for the design of algorithms that include tractable subclasses of pseudo-knots. In [30] Y. Ponty and C. Saule extended a unifying framework introduced by Roytberg and Finkelstein to design ensemble RNA algorithms. This framework uses a family of hypergraphs to describe the conformation space, allowing for a clear separation between the search space, i.e. the set of admissible conformations, and the intended application (Minimal Free-Energy folding, partition function, statistical sampling...). We illustrated the promises of such an approach by explicitly rephrasing three major search spaces within the framework, and introduced an algorithm for computing the moments of any additive feature in the Boltzmann distribution.

By comparing empirical observations with the expected behavior of a model, combinatorial methods can be used to identify an evolutionary pressure weighing on RNA. In a collaboration with P. Clote (Boston College/DIGITEO) [11], we used analytic combinatorics to study the expected distance between both ends of an RNA molecule, or 5′-3′ distance. Postulating a Boltzmann distribution on all secondary structures, we showed that this parameter is bounded by a – typically small – constant value when the sequence length goes to the infinity. Computing this quantity on a database of experimentally-determined secondary structures, we observed that the 5′-3′ distances take larger values than those predicted from the model. Furthermore, quite surprisingly, this quantity was shown to correlate positively with the length. We concluded by hypothesizing that the secondary structure of RNA may be under evolutionary pressure to fold in a modular way, creating independent domains on the exterior face.

5.3.3. Data integration

Recent years have seen a revitalization of Data Integration research in the Life Sciences. But the perception of the problem has changed: While early approaches concentrated on handling schema-dependent queries over heterogeneous and distributed databases, current research emphasizes instances rather than schemas, tries to place the human back into the loop, and intertwines data integration and data analysis. In this domain, the contribution of AMIB in 2011 has been three folds: First, we have followed our collaboration with Ulf Leser (invited in the AMIB group at LR1 during 6 months in 2010) and have worked on the review of the past and current state of data integration for the Life Sciences and discussed recent trends in detail, which all pose various challenges for the database community in [28]. Additionally, we have worked on a vision of what should be done by workflow systems to make it possible to search, adapt, and reuse scientific workflows, the complete state-of-the-art on this domain has been provided [12]. Second, in close collaboration with oncologists from the Institut Curie and the Children’s Hospital of Philadelphia we have worked on the problem of ranking genes of interest associated to a given disease. The software GENEVALORIZATION has been designed and developed in this context and is able to provide a concise view of the literature available associated to a list of genes [10]. A second aspect of this research has been the design of a consensus ranking method, BioConsert, able to make the most (ie underline common points) of a set of established rankings [27]. This last point has been done in close collaboration with Sylvie Hamel invited professor in our group in 2010 (2 months). Third, we have presented a simple logical query language called RL for expressing different kinds of rules, especially well-suited to express association rules for transcriptomic data. In that context the challenge is to find out relationships between genes that reflect observations of how expression level of each gene affects those of others. The conjecture that association rules could be a model for the discovery of gene regulatory networks has already been partially validated. Nevertheless, several different kinds of rules between genes could be useful with respect to some biological objectives and we have designed a framework in which biologists may define their “own customized semantics” for rules with regard to their requirements. We have studied how the RL language behaves with respect to the well-known Armstrong’s axioms [22]. The main contribution of this paper is to exhibit a restricted form of RL-queries, yet with a good expressive power, for which Armstrong’s axioms are sound. From this result, this sublanguage turns out to have structural and computational properties which have been shown to be very useful in data mining, databases and formal concept analysis.

5.4. Systems Biology
In her thesis, M. Behzadi has developed a know-how on the behaviour of biological systems along a cooperation with an INSERM-INRA team based in Clermont-Ferrand. In the methodology that was developed, one computes the equations’ parameters from the experimental data in systems that can be considered at equilibrium. It was proved mathematically that some sub-domains are intrinsically stable and that their behaviour is not much affected by the initial conditions [4] for phospholipids biosynthesis. A review for carbome toxicity can also be found in [15]. Software Analyser software (MPSA) are currently under development by L. Paulevé.

Elementary flux mode is a fundamental concept as well as a useful tool in metabolic pathway analysis. However, when the networks are complex, the determination of elementary flux modes leads to combinatorial explosion of their number which prevents from drawing simple conclusions from their analysis. To deal with this problem, a biclustering method has developed [18] based on the Agglomeration of Common Motifs (ACoM). It was applied to the central carbon metabolism in Bacillus subtilis and to the yeast mitochondrial energy metabolism. It helped to give biological meaning to the different elementary flux modes and to the relatedness between reactions.

Once molecules and complexes participating in the signalling network have been identified, the relations between them (enzymatic reactions, activations, inhibitions, etc.) have to be deduced from experimental and literature data to build the influence graph. Partners INRA-BIOS and AMIB have started the development of a knowledge-based method, which uses the solver SOLAR, developed by NII (Tokyo), that allows automating this data integration task. We have already formalized the knowledge necessary for inferring the signalling network triggered by the FSH receptor, one famous GPCR. Preliminary results of this project ASAM are very encouraging.
5. New Results

5.1. New results in the theory of factorization of boundary value problems

Participants: Jacques Henry, Fadhel Jday, Maria Orey.

We are pursuing the development of the theory of factorization of boundary value problems as described in 3.1. Maria Orey who suspended her PhD thesis for a while due to health reason, has resumed her work on extending the method of factorization to the analogous in infinite dimension of the QR algorithm for matrices. This passes through the factorization of the normal equation for the least squares problem. This problem is solved and this allows a clear definition of the $Q$ and $R$ operators. She will defend her thesis in 2012.

F. Jday has obtained also a clear formulation for the factorization of the Stokes equation.

A progress has been made in the attempt to extend the factorization method to parabolic evolution equation. It appears that it is not the evolution problem that can be factorized with respect to space but the evolution operator $S(t)$ that transfers the solution from time 0 to $t$. The corresponding Riccati equation has been obtained but a full mathematical justification remains to be done.

5.2. Data completion problems for elliptic equations using the theory of factorization

Participants: Jacques Henry, Fadhel Jday.

F. Jday is continuing his thesis co-supervised by A. Ben Abda and J. Henry. The use of the method of factorization for the data completion problem has been presented in a paper in Inverse Problems when the domain is a cylinder, both Dirichlet and Neumann data are known on one face and are to be estimated on the other. Dirichlet boundary conditions were assumed on the lateral boundary. In relation to the inverse problem in electrocardiology one has to take into account more complex geometries. F. Jday considered the domain limited by two concentric spheres. The method still applies considering the family of concentric spheres deduced by homothey.

5.3. Modeling the activity of populations of neurons: study of synchronization

Participants: Jacques Henry, Gregory Dumont, Oana Tarniceriu.

During the second year of his PhD thesis G. Dumont continued to develop and refine a simulator of a population of leaky integrate and fire neurons, with a finite jump of potential response to a synaptic stimulation in order to compare with the results from another approach, the Fokker-Planck approach. It would be interesting to show that the Fokker Planck approach can be seen as a limiting case, for high frequency small jump of potential, of the one of B. Knight, L. Sirovich and L. Omurtag. At least it is suggested by the simulations. The second year focused on the study of mathematical aspects of the equation. The methods were inspired by the book of Benoit Perthame: Transport equation in biology. With these tools, the mathematical properties of the model of population density have been established: the existence and uniqueness of a solution. G. Dumont has also been able to establish that in special cases the equation has no solution, or more precisely that the solution blows up, assuming that there is no conduction delay of the spikes within the considered population. This blow up can be related to a synchronization. In case of a conduction delay the condition of existence of a solution are much larger. The situation of inhibiting synapses has also been studied. This has been submitted to the Journal of Mathematical Biosciences.

Using the principles of entropy, G. Dumont has shown that under certain circumstances the solution of the equation converges to a stationary solution and this can be interpreted as the desynchronization of the population of neurons.
Similar studies have been done on the thetaneuron model which accounts for self spiking neurons. The question of the synchronization of a population of neurons is also studied in collaboration with O. Tarniceriu. We consider a population of identical self firing neurons that are weakly coupled and we study the long term evolution of the reaporation of phases. We are now focusing to a population of 1D leaky integrate and fire neurons and we expect more precise results for this simple model.

5.4. Modeling in electrocardiology

Participants: Bedr’Eddine Ainseba, Jacques Henry, Yves Coudière, Simon Labarthe, Alejandro Lopez Rincon.

5.4.1. Modeling the electrical activity of the atria

The first year of the PhD thesis of Simon Labarthe has been dedicated to three main activities:

- a review of medical and mathematical literature about anatomy and physiology of atria and atrial fibrillation, numerical simulation of cardiac activity, mathematical analysis of cardiac models.
- the numerical implementation of simulation tools has been developed: the software is able to take into account a real 3D or 2D manifold geometry with realistic fibre orientation to simulate the bidomain or monodomain problem. Geometrical tools facilitating the fibre orientation construction have been added.
- numerical and theoretical studies of the modeling and the influence of fibre orientation in the atria and the pulmonary veins have been initiated.

5.4.2. Inverse problem in electrocardiology

The PhD thesis of Alejandro Lopez is devoted to improving the resolution of the inverse problem to recover the potential map on the heart from the measured potentials on the torso.

To have a best solution of the inverse problem many steps were taken. First, a software to solve the finite element method in 3d for the Poisson equation was created, and compared to an analytical solution. Also a software for the heat equation was created to prepare the monodomain equation. The improvement of the forward solution helps to improve the inverse solution. An article explaining the software was included in the book “VEHÍCULOS AEROESPACIALES” (aerospace vehicles) published by the Sociedad Mexicana de Ciencia y Tecnología Aeroespacial (Mexican Society of Aerospace Science, and Technology) [19].

The second step was to develop a static solution of the inverse problem constructing a transfer matrix (heart to thorax), and solving with conjugate gradient. An article describing this software was accepted in the 22nd International Conference on Electronics, Communications and Computers.

As a third step the boundary element method was implemented to see the advantages and disadvantages in comparison with the finite element method.

The next step was to implement the monodomain model of the heart, to try to solve the problem of identification of parameters (in progress).

5.5. Invasion processes and modeling in epidemiology

Participants: Jean-Baptiste Burie, Arnaud Ducrot.

We have derived a homogenized version of our model of a fungal of disease of vine (see [7]) that takes into account the periodic row structure of vineyards. We used two-scale homogenization of Nguentseng and Allaire (see e.g. [20]): the macroscopic scale is the vineyard scale while the microscopic one is the plant scale. We have proved a result of convergence towards the homogenized model and numerical simulations have demonstrated a significant gain in computing time and stability.

These results have been presented at ECMTB2011 in Krakow (and also, at the Exploratory Workshop on Emerging Infectious Diseases and Mathematical Modelling, Barcelona 2011 and seminars at Franche-Comté University, Tamkang and National Taiwan University).

An article is to be submitted in SIAM J. Multiscale Modeling and Simulation in early 2012.
6. New Results

6.1. Logical time in Model-Based embedded design

Participants: Charles André, Frédéric Mallet, Julien Deantoni, Robert de Simone, Marie-Agnès Peraldi Frati, Régis Gascon, Calin Gliția, Kelly Garces Pernett, Benoît Ferrero, Nicolas Chleq, Arda Goknil.

The foundational basis of our approach to modeling and analysis of embedded systems using logical time and logical clock specification constraints (CCSL) is recalled in 3.2, and was surveyed in [2]. This year we conducted a number of works exploiting this approach and promoting its introduction to various application domains.

Charles André presented the general approach in an invited lecture at the French Summer School on Real-Time, in Brest [21].

The HDR manuscript of Frédéric Mallet, where the MARTE Time Model is deeply considered, also in relation with other standards such as AADL, was published in book format [39].

In the article [19] we showed how CCSL observers could be encoded in the synchronous language Esterel, using crucial features of simultaneity, and how otherwise simultaneity could be obtained in simulation. This work was also presented internally as deliverable of the FUI Lambda project (see 8.2.3).

We drew a definite link with our activities on Process Network analysis (see 6.3), by showing how the CCSL primitives could be used to provide the loose timing semantic constraints of exiting PN models such as SDF (Synchronous Data-Flow domain of UC Berkeley’s Ptolemy), and its Multi-Dimensionla extension (MD-SDF). This resulted in a journal publication [38]. Existing static schedules can then be obtained by analysis with K-Passa 5.2, or simulated using TimeSquare 5.1 (with an ASAP strategy).

In a collaboration with researchers at East China Normal University (ECNU Shanghai), we showed how CCSL constraints could be translated towards the PROMELA language implemented in the SPIN model-checker, which once again raises the issues of faithfully modeling simultaneity. This work resulted in a communication at the ICECCS conference [33]. Following this work one of our co-author, Yin Ling, earned a one-year scholarship from the Chinese government to visit us as part of her PhD.

The usage of CCSL expressions in the role of predicate property formulas, and their comparison with the more classical temporal formalisms such as PSL (Property Specification Language), was investigated in [24]. A longer internal report version can be found at [42].

In [23] we tackle the issue of recovering global information from multiple execution traces living in distinct logical time bases, with polychronous constraints relating them. The use for efficient debug of embedded systems from distributed traces is examplified on a case study of terrestrial robot. This work was conducted in the framework of the ANR RT-Simex project, see 8.2.1.

A case study in modeling with logical time and CCSL, from requirements to implementation, based on an automotive spark ignition system, is provided in [31]. We worked more generally on the introduction of our approach to existing formalism in the automotive domain, such as EAST-ADL2 and AutoSar, as part of our contribution to the new ITEA2 Timmo2U project. Premises of this effort are described in [32].

The use of CCSL constraints in general requirement engineering was also studied and demonstrated in a conference article, jointly with colleagues at ECNU Shanghai, presented at APSEC’2011 [22].

The use and modeling of priorities amongst timed events (i.e., logical clock ticks), which has strong impacts on efficient logical clock based simulations and scheduling (as the choice of next event), is still a topic of ongoing work. Several advanced considerations are to be found as part of jean-François Le Tallec PhD thesis, to be defended in January 2012 [16].
6.2. Model-Based approaches to SoC design

Participants: Charles André, Robert de Simone, Benoît Ferrero, Carlos Gomez Cardenas, Jean-François Le Tallec.

The main practical goal of this work was to combine in a sensible way the various formalisms SystemC, IP-XACT, UML MARTE, and UPF (for power consumption representation) (see 4.1 for further descriptions). There were true motivations for this: SystemC is a de-facto standard for SoC simulation at various levels, but currently lacks any sort of formal description so that systems can be analysed, reasoned about for correctness and optimized (and it becomes even more so with newer draft standard evolutions). IP-XACT was introduced as an ADL to ease composition and assembly of IP components (written in SystemC or not), but again it currently fails short of its goal, and in particular does not allow standard decoration of model attributes in prominent non-functional domains such as timing/performance and low-power/energy consumption. These could be provided with the help of dedicated features in UML MARTE, and aligned on the UPF standard for power management modeling.

While the intended design flow would take the UML MARTE and UPF to IP-XACT to SystemC direction, it was important to extract IP-XACT and MARTE structural representation from existing SystemC programs, both to populate the flow with existing legacy models, and to explore better the requirements for complete and consistent modeling towards IP block assembly. This work was conducted in Jean-François Le Tallec PhD, to be defended in January 2012 [ 16 ]. Together with Benoît Ferrero he defined and realized a software tool named SCiPX (SystemC to IP-XACT translator), originally based on the PinaVM tool by VERIMAG and the DoxyGen syntactic analyzer.

SCiPX is available in prototype version from our site http://www-sop.inria.fr/aoste/index.php?page=software/scipx. It can be combined with the former software transformation modules IPXACT2Marte and Marte2IPXACT developed previously. These results were partly supported by the ID/TL-M contract with ST Microelectronics (see 7.1 ), and the ANR HeLP project (see 8.2.2 ), and were presented in [ 26 ], [ 25 ]

As part of his PhD thesis, Carlos Gomez Cardenas described a subset of UPF standard as a metamodel inside UML MARTE. He also considered compatibility and interconnections with the industrial environments AcePlorer (by Docea Power), and Synopsys Virtualizer (formerly CoWare), provided to us in the context of the CIM PACA tool farm 8.1.1. Preliminary results were presented in [ 36 ]. This work was also presented during internal meetings of the ANR HeLP project, and coordinated with work conducted in the team of Michel Auguin at CNRS UMR LEAT (also in Sophia-Antipolis).

6.3. Process Network analysis

This year we comforted the type of analysis on regular static scheduling and routing in dedicated process network models such as studied in the successive PhD thesis of Julien Boucaron, Jean-Vivien Millo, and Anthony Coadou, and recently surveyed in [ 5 ]. This resulted mainly in further implementation upgrades of our K-Passa tool (see 5.2 ), performed first by Anthony Coadou (before he left on a postdoc internship), then continued by Jean-Vivien Millo (on a return postdoc position with us).

In a work mostly conducted while member of the Alchemy EPI in Saclay, but which draws a clear link to our past and present activities in the subject, Sid-Ahmed-Ali Touati studied efficient heuristics to the general problem of one-dimensional periodic task scheduling under storage requirements, using a modeling framework akin to Process Networks. This resulted in a journal article accepted once the author had become attached to the Aoste EPI [ 17 ].

6.4. Correct and efficient implementation of polychronous formalisms

Participants: Thomas Carle, Manel Djemal, Virginia Papailiopoulou, Dumitru Popot Butucaru, Robert de Simone, Yves Sorel.
Existing analysis techniques for synchronous and polychronous languages, such as clock calculi, are meant to extract relations of simultaneity (time inclusion) and exclusiveness (time exclusion) between the various computations and communications. This approach is well-suited when targeting sequential processors. For distributed or multi-threaded implementations, further independence relations are needed to express potential concurrency. This resulted in a general theory of endochronous systems, meant to support this additional analysis [11].

Last year we completed a first prototype tool implementation for weak endochrony checking. This was completed this year in two directions:

- connecting our tool with Signal as input language, and interface it in practice to the Polychrony/SME environment developed by the Espresso EPI;
- Improving algorithmic complexity and internal data representation, so that our tool can now handle reasonable size Signal programs.

This work was of course conducted in collaboration with Espresso members. Experimental results were presented at the ESLsyn 2011 conference [30]. We are currently expanding the framework in order to take modes/states into account in the program specifications. Effective generation of multi-threaded GALS wrappers for Signal programs is also under way.

We worked at extending the AAA methodology for polychronous processes by providing a better integration of clock analysis in the various phases of the implementation process (allocation, scheduling, pipelining, etc.). We also considered a wider range of implementation targets (time-triggered, MPSoC). We defined a dedicated software pipelining algorithm to match conditional scheduling/reservation tables such as used in SynDex, with the goal of improving throughput with the same duration of individual computation cycles (as is the goal of any pipelining techniques). The originality here is to make logical clocks of polychronous systems act as triggers for the predicated executions as used in traditional software pipelining. First results have been presented during the Synchron 2011 workshop and in a research report [41].

Further work on time-triggered systems was submitted inside the FUI Parsec 8.2.4 and P 8.2.5 projects, including real-time implementation methods for the IMA/ARINC 653 avionics platforms. In particular we conducted experiments to replace the scheduling policy of the second-level scheduler (L1 in the standard) from dynamic priority-driven to dynamic Time Division time triggered (TT-IMA). Preliminary results are under way, and were informally presented at the yearly Synchron seminar.

An important emerging trend in target MPSoC platforms is that On-chip networks are progressively introduced to cope with the bottleneck of inter processor communications. Correct implementation of polychronous systems in this context thus relies on efficient routing of data in such networks, and ultimately may assume that on-chip NoC routers may be programmed in one way or another to behave predictably according to the global application distributed on the cores. We started a collaboration on this topic with the "Embedded Systems-on-Chips" department of the LIP6 laboratory, one of the main site of expertise for SoC/NoC design and Hardware/software codesign. This collaboration first materialized with the co-supervision of M. Djemal’s PhD thesis. A generic MPSoC architecture is being defined, which includes a 2D mesh network-on-chip with programmable routers, on which static routing schedules such as synthesized by our tools may be implemented and run.

6.5. Uniprocessor Real-time Scheduling

Participants: Laurent George, Mohamed Marouf, Daniel de Rauglaudre, Yves Sorel.

6.5.1. Strict periodic harmonic tasks

This year, we focused our work on scheduling of strict periodic tasks to the particular case of harmonic tasks [28]. After transforming the scheduling problem into a bin-packing problem, we performed a schedulability analysis and proposed schedulability conditions in each sub-case of harmonic tasks: we proposed a necessary and sufficient condition in the case where all tasks periods are distinct, and we proposed a sufficient condition in the case where some tasks have the same period. Finally, we proposed a scheduling algorithm based on the bin-packing problem resolution.
6.5.2. Combination of strict periodic and sporadic tasks

Non-preemptive strict periodic tasks are harder to schedule than preemptive ones. One can hope to extend schedulability results when combining non-preemptive strict periodic tasks with preemptive sporadic one.

We proposed in [27] a schedulability analysis for a combination of strict periodic and sporadic tasks. We considered all tasks with fixed priorities, where the highest priorities are given to strict periodic tasks and the lower priorities are given to sporadic tasks. First, we scheduled strict periodic tasks using our former scheduling algorithm. Then, we computed the critical instants which maximize the response time of a sporadic task. We proved that the critical instants are contained in the permanent phase of strict periodic tasks, and are given by the start times of strict periodic jobs in a hyper-period. We also proved that we can reduce critical instants by eliminating some of them. Then, we gave the analytic expression of the computing time \( W_i(t) \) at any time \( t \) necessary for the execution of a task \( \tau_i \) taking in consideration all the tasks with higher priorities. That allows the computation of the response time \( r_i \) by solving the equation \( W_i(t) = r_i \). Therefore, for a sporadic task, if its response time \( r_i \) is less of equal to its deadline for all critical instants, then this latter task is schedulable, else it is not schedulable. We proceed similarly for all sporadic tasks to prove that a tasks set is schedulable or not.

6.5.3. Exact cost of RTOS

It is important to determine the exact cost of the real-time operating system (RTOS) when preemptive scheduling is used for better processor utilization compared to non preemptive scheduling [43]. Indeed, in this case it is possible to trust the schedulability conditions when they include that cost, and also to avoid waste resources. This year we developed a generic RTOS modelled with Petri nets and we determined its exact cost on an ARM9 processor. We used Petri nets on the one hand to choose through simulations the best structure of that scheduler, and on the other hand to verify non blocking properties. In order to obtain its exact cost the scheduler was programmed in assembly language, and coded such as it is deterministic, i.e. its cost does not depend on alternative statements but only on the number of tasks which is known a priori. Using this RTOS we experimented simple task sets on the ARM9 processor for which we were able to include the exact RTOS cost in the schedulability conditions.

6.5.4. Formal proofs of real-time scheduling theorems

Scheduling involves numerous models and theorems, sometimes dated of several decades, but never formally proved. We made a formal proof in Coq (proof assistant developped at Inria) to check a classical theorem giving a schedulability condition for a set of real-time strictly periodic tasks (about 1500 lines of Coq). This work was published in a paper accepted for publication in the conference JFLA 2012.

A second proof is actually being carried now, dealling with response time of a set of fixed priority real-time preemptive tasks. The theorem states that the worst case of this response time occurs when all tasks start simultaneously. A step in the original argument by Jane W. S. Liu [55] involves the proof of a function whose fixpoint computes the response time of the first instance of the least priority task. This specific step is now formally proved in Coq (3500 lines of Coq), and we are now working on the completion of the full theorem.

6.6. Multiprocessor Real-time Scheduling

Participants: Laurent George, Maxence Guesdon, Mohamed Marouf, Falou Ndoye, Simon Nivault, Yves Sorel, Cécile Stentzel.

6.6.1. Partitioned scheduling with exact RTOS cost

In the case of partitioned scheduling we propose a greedy heuristic to solve the real-time scheduling problem of periodic preemptive tasks on a multiprocessor architecture while taking into account the exact RTOS cost. This is achieved by combining an allocation heuristic, of “best fit” type, and a schedulability condition based on the operation \( \oplus \) which takes into account the exact RTOS cost [43]. The allocation heuristic minimizes the makespan (total execution time of the tasks executed on the multiprocessor taking into account inter-processor communication costs). A first version of that work was presented in [29].
6.6.2. Semi-partitioned scheduling

In [18] we study two cases of semi-partitioned scheduling of sporadic tasks with constrained deadlines on homogeneous multi-processor: (i) the case where the Worst Case Execution Time (WCET) of a job can be portioned, each portion being executed on a dedicated processor, according to a static pattern of migration and using for solving the local assignment problem a linear programming approach ; (ii) the case where the jobs of a task are released on a processor, 1 time out of p, where p is an integer less than or equal to the number of processors, according to a Round-Robin migration pattern. The first approach has been investigated in the state-of-the-art by migrating a job at its local deadline, computed from the deadline of the task it belongs to.

6.6.3. Fault tolerance on electric vehicles

We consider applications composed of a real-time task set running on the distributed heterogeneous architecture of the CyCab (electric vehicle developed in the IMARA team-project) based on dsPICs processors, MPC555 micro-controllers, and an embedded PC all together connected through CAN (Controller Area Network) buses. For hardware reasons we suppose that only dsPICs and CAN buses can fail. Our goal is to find a fault-tolerant software solution to tolerate such failures while the applications satisfy the real-time constraints. Because extra hardware for error detection is expensive in such electric vehicle, we proposed a software error detection based on watchdogs. We solved separately two different problems: buses and dsPICs fault-tolerance. In both cases we use active redundancy policies. For buses fault-tolerance, we assume that all processors are reliable, and all but one bus can fail. The same data is sent through all the CAN buses. If a CAN bus fails then the data is sent by the other CAN buses. For processors fault-tolerance, we assume that all communication media are reliable and at least one processor can fail. The first step consists in performing active redundancy for all the tasks of the application. A task and their redundant tasks are assigned to different processors. If processor fails then the data which are not sent by tasks running on that faulty processor, are actually sent by the redundant tasks. All the tasks with their redundant counterparts are scheduled according to the schedulability analysis proposed in [28].

6.6.4. Scicos/SynDEx gateway and code generation for multi-core

This work was carried out in the Openprod project (see 8.3.2.2). The gateway between Scicos and SynDEx has been updated to deal with the last Scicos data structures and the last version of SynDEx. Besides, this gateway has been improved and partially rewritten to support as much Scicos blocks as possible. We use the gateway to automatically produce from a control model specified and simulated in Scicos a real-time executable running on a multi-core platform. The latter platform is described according to the shared memory model defined last year. In order to generate real-time executable code we had to develop a new SynDEx executive kernel based on Windows-RTX which supports shared memory communications and multi-core parallel execution. That executive kernel is used with the macro-code generated by SynDEx to produce the real-time executable code.

6.6.5. SynDEx updates

We continued the developments of future version 8 of SynDEx which will feature a new software architecture to allow better functionality evolutions and maintenance. On the other hand in the COTROS ADT ("Génération de code temps réel distribué optimisé et sûr"), we achieved the new automatic code generator for the current version 7 of SynDEx. This generator creates intra and inter-processor synchronizations according to well defined rules, checks deadlock absence in inter-processor synchronizations, manages efficiently buffers and semaphores (declaration, naming, etc.).
6. New Results

6.1. Tralics: a LaTeX to XML Translator
Participant: José Grimm.

The major use of Tralics remains the production of the RaWeb (Scientific Annex to the Annual Activity Report of Inria). The software is described in [65], [68], [67], [66]. Other applications of Tralics consist in putting scientific papers on the Web; for instance Cedram (http://www.cedram.org, Centre de diffusion de revues académiques mathématiques), that publishes the Journal de théorie des nombres de Bordeaux, uses Tralics for the abstracts and plans to translate full papers. Tralics is also used by Zentralblatt for converting comments, reviews and abstracts. The Software has been presented at the DML2010 conference [69]. Tralics has been used for the HTML+MathML documentation of the open TURNS software http://trac.openturns.org/.

6.2. Inverse problems for elliptic operators

6.2.1. Boundary value problems for Laplace equation in 3-D
Solving overdetermined Cauchy problems for the Laplace equation on a spherical layer (in 3-D) in order to process incomplete experimental data is a necessary ingredient of the team’s approach to inverse source problems, in particular for applications to EEG since the latter involves propagating the initial conditions from the boundary to the center of the domain where the singularities (i.e., the sources) are sought after. Here, the domain is typically made of several homogeneous layers of different conductivities.

Such problems offer an opportunity to state and solve extremal problems for harmonic fields for which an analog of the Toeplitz operator approach to bounded extremal problems [45] has been obtained in [2]. Still, a best approximation on the subset of a general vector field generated by a harmonic gradient under a $L^2$ norm constraint on the complementary subset can be computed by an inverse spectral equation for some Toeplitz operator. Constructive and numerical aspects of the procedure (harmonic 3-D projection, Kelvin and Riesz transformation, spherical harmonics) and encouraging results have been obtained on numerically simulated data.

Issues of robust interpolation on the sphere from incomplete pointwise data are also under study in order to improve numerical accuracy of our reconstruction schemes. Spherical harmonics, Slepian bases and related special functions are of special interest (thesis of A.-M. Nicu), while splines, spherical wavelets, cubature techniques should be considered as well.

It turns out that Slepian functions are eigenfunctions of truncated Toeplitz operators in the complex plane (the framework of 2-D problems). These properties will be used in order to quantify the robustness properties of our resolution schemes for $L^2$ bounded extremal problems [45], and to establish error estimates.
The analogous problem in $L^p$, $p \neq 2$, is quite important to get tighter control on pointwise approximation. However, it is considerably more difficult. In a collaborative effort with the university of Orléans, within the framework of the ANR project AHPI, we set ourselves the goal of understanding the case $p = \infty$ better. Namely, connections between the BMO $^2$ distance of a bounded vector field on the sphere to a BMO harmonic gradient and the spectral properties of a “big” Hankel-like operator acting on $L^2$ harmonic gradients and valued in its orthogonal space are currently being investigated. We obtained a generalization of the Hodge decomposition (we call it the Hardy-Hodge decomposition) for $\mathbb{R}^n$-valued vector fields on $\mathbb{R}^{n-1}$ (resp. $\mathbb{S}^{n-1}$) which stands analog to the Hardy direct sum decomposition in dimension 1. In this decomposition, the analytic part becomes the trace of the gradient of a harmonic function in the half-space (resp. the ball) whose BMO-norm on parallel hyperplanes (resp. concentric spheres) is uniformly bounded. The two main difficulties facing a generalization of Nehari’s theorem are the absence of a constructive derivation of Coifman-Rochberg weak factorizations and Wolff’s phenomenon that a harmonic gradient (even $C^1$-smooth) is not determined by its values on a set of positive measure on $\mathbb{R}^n$ (resp. $\mathbb{S}^n$). This last point is the only obstacle to establish uniqueness and constancy-of-modulus properties. We shall concentrate on these two items in the future.

The above issue is also interesting in $L^p$, $1 \leq p < \infty$, where it leads to analyze particular solutions to the the $p$-Laplacian on the sphere. This aspect is not pursued in depth at the moment.

6.2.2. Sources recovery in 3-D domains, application to MEEG and geophysics

The problem of sources recovery can be handled in 3-D balls by using best rational approximation on 2-D cross sections (disks) from traces of the boundary data on the corresponding circles (see section 4.1 ). In 3-D, functional or clinical active regions in the cortex are often represented by pointwise sources that have to be localized from measurements on the scalp of a potential satisfying a Laplace equation (EEG, electroencephalography). In the work [7] it was shown how to proceed via best rational approximation on a sequence of 2-D disks cut along the inner sphere, for the case where there are at most 2 sources. A long-haul research on the behaviour of poles of best rational approximants of fixed degree to functions with branch points was completed this year [19], which shows that the technique carries over to finitely many sources.

In this connection, a dedicated software “FindSources3D” (see section 5.7 ) has been developed, in collaboration with the team Athena. Further, it appears that in the rational approximation step of these schemes, multiple poles possess a nice behaviour with respect to the branched singularities (see figure 4 ). This is due to the very basic physical assumptions on the model (for EEG data, one should consider triple poles). Though numerically observed, there is no mathematical justification so far why these multiple poles have such strong accumulation properties, which remains an intriguing observation. This is the topic of [30].

Also, magnetic data from MEG (magneto-encephalography) will soon become available, which should enhance the accuracy of source recovery algorithms.

This approach also appears to be interesting for geophysical issues, namely discretizing the gravitational potential by means of pointwise masses. This is one topic of A.-M. Nicu’s PhD thesis. Magnetic sources localization from observations of the field away from the support of the magnetization is an issue under investigation in a joint effort with the Math. department of Vanderbilt University and the Earth Sciences department at MIT. The goal is to recover the magnetic properties of rock samples (meteorites) from fine measurements extremely close to the sample that can nowadays be obtained using SQUIDs (supraconducting coil devices).

The magnetization operator is the Riesz potential of the divergence of the magnetization, When the latter has bounded variation, we already described the kernel of this operator (the so-called silent magnetizations or silent source distributions) in terms of measures whose balayage on the boundary of the sample vanishes. This however, is not so very effective, computationally.

\footnote{bounded mean oscillation}
The case of a thin slab (the magnetization is then modeled as a vector field on a portion of the plane) has proved more amenable. We have shown that that silent sources from above or below can be characterized via the Hardy-Hodge decomposition mentioned in section 6.2.1. The smoothness assumptions have been weakened considerably to accommodate magnetizations that may be any distribution with compact support, more generally any finite sum of partial derivatives of any order of $L^p$ or $BMO$ functions. Silent unidirectional and bi-directional magnetizations demonstrably reduce this way to certain divergence free tangential vector fields. In particular, no nonzero compactly supported unidirectional magnetization exists. In the $L^2$ setting, equivalent magnetizations of minimal $L^2$-norm can be computed using the Hardy-Hodge decomposition (which is orthogonal in this case), and an uncertainty principle relating the support of a magnetization and the support of its minimum-norm equivalent magnetization has been obtained. A paper is being written on these results.

Meanwhile, the severe ill-posedness of the reconstruction challenges discrete Fourier methods, one of the main problems being the truncation of the observations outside the range of the SQUID measurements. A next step will be to develop the extrapolation techniques initiated by the project team, using bounded extremal problems, in an attempt to overcome this issue.

6.2.3. Boundary value problems for 2-D conductivity equations, application to plasma control

In collaboration with the CMI-LATP (University Marseille I) and in the framework of the ANR AHPI, the team considers 2-D diffusion processes with variable conductivity. In particular its complexified version, the so-called conjugate or real Beltrami equation, was investigated. In the case of a smooth domain, and for Lipschitz conductivity, we analyzed the Dirichlet problem for solutions in Sobolev and then in Hardy classes [8].

Their traces merely lie in $L^p$ ($1 < p < \infty$) of the boundary, a space which is suitable for identification from pointwise measurements. Again these traces turn out to be dense on strict subsets of the boundary. This allows us to state Cauchy problems as bounded extremal issues in $L^p$ classes of generalized analytic functions, in a reminiscent manner of what was done for analytic functions as discussed in section 3.1.1.

This year we generalized the construction to finitely connected Dini-smooth domains and $W^{1,q}$-smooth conductivities, with $q > 2$ [43]. The case of an annular geometry is the relevant one for the application to plasma shaping mentioned below [17]. The application that initially motivated this work came from free boundary problems in plasma confinement (in tokamaks) for thermonuclear fusion. This work was initiated in
collaboration with the Laboratoire J. Dieudonné (University of Nice) and is now the topic of a collaboration with two teams of physicists from the CEA-IRFM (Cadarache).

In the transversal section of a tokamak (which is a disk if the vessel is idealized into a torus), the so-called poloidal flux is subject to some conductivity equation outside the plasma volume for some simple explicit smooth conductivity function, while the boundary of the plasma (in the Tore Supra tokamak) is a level line of this flux [53]. Related magnetic measurements are available on the chamber, which furnish incomplete boundary data from which one wants to recover the inner (plasma) boundary. This free boundary problem (of Bernoulli type) can be handled through the solutions of a family of bounded extremal problems in generalized Hardy classes of solutions to real Beltrami equations, in the annular framework. Such approximation problems also allow us to approach a somewhat dual extrapolation issue, raised by colleagues from the CEA for the purpose of numerical simulation. It consists in recovering magnetic quantities on the outer boundary (the chamber) from an initial guess of what the inner boundary (plasma) is.

In the particular case at hand, the conductivity is $\frac{1}{x}$ and the domain is an annulus embedded in the right half-plane. We obtained a basis of solutions (exponentials times Legendre functions) upon separating variables in toroidal coordinates. This may be viewed as a generalization to the annulus of the Bessel type expansions derived in [21] for simply connected geometries. This provides a computational setting to solve the extremal problems mentioned before, and was the topic of the PhD thesis of Y. Fischer [17], [22]. In the most recent tokamaks, like Jet or ITER, an interesting feature of the level curves of the poloidal flux is the occurrence of a cusp (a saddle point of the poloidal flux, called an X point), and it is desirable to shape the plasma according to a level line passing through this X point for physical reasons related to the efficiency of the energy transfer. We established well-posedness of the Dirichlet problem in weighted $L^p$ classes for harmonic measure on piecewise smooth domains without cusps, thereby laying ground for such a study. This issue is next in line, now that the present approach has been validated numerically on Tore Supra data.

On the half-plane, the conductivity $\frac{1}{x}$ is severely unbounded but the analysis of this test case is quite important for the convergence of extrapolation algorithms to recover magnetic quantities on the chamber. Additive decompositions into Hardy solutions inside the outer boundary and outside the inner boundary, with controlled vanishing on the imaginary axis, have been obtained as part of the PhD work of S. Chaabi. The latter developed this year a multiplicative parameterization of Hardy-smooth solutions by holomorphic functions for the conjugate Beltrami equation, a result which is both subtler and weaker than the classical Stoilow factorization for solutions to the complex Beltrami equation. This factorization is of considerable numerical interest in situations where conductivity is little or not known.

6.3. Rational Approximation for fitting Non Negative EPT densities

Participants: Martine Olivi, Bernard Hanzon [Univ. Cork], Conor Sexton [Univ. Cork], Fabien Seyfert.

We explored this year a new application field for our rational approximation methods. We studied the problem of fitting a probability density function from a large set of financial data. The class of density function that we considered is that of non negative EPT (Exponential-Trigonometric-Polynomials) functions that seems to provide a very relevant framework for probabilistic calculations. Parseval’s theorem implies that approximating the rational transform is equivalent to approximating the density itself. During his visit, Conor Sexton (a PHD student of Bernard Hanzon) adapted and ran the RARL2 software on this problem. The results were encouraging albeit the major problem of imposing positivity is still under study.

6.4. Orthogonal rational functions and non-stationary stochastic processes

Participants: Laurent Baratchart, Stanislas Kupin [Univ. Bordeaux 1].
The theory of orthogonal polynomials on the unit circle is a most classical piece of analysis which is still the object of intensive studies. The asymptotic behaviour of orthogonal polynomials is of special interest for many issues pertaining to approximation theory and to spectral theory of differential operators. Its connection with prediction theory of stationary stochastic processes has long been known \[ 64 \]. Namely, the \( n \)-th orthonormal polynomial with respect to the spectral measure of the process yields the optimal regression coefficients of a linear one-step ahead predictor from the \( n - 1 \)-st last values, in the sense of minimum variance of the error. Likewise, the (inverse of) the dominant coefficient of the polynomial gives the prediction error. In particular, asymptotics for the dominant coefficient determine the asymptotically optimal prediction error from the past as time goes large.

As compared to orthogonal polynomials, orthogonal rational functions have not been much considered up to now. They were apparently introduced by Dzrbasjan but the first systematic exposition seems to be the monograph by Bultheel et al. \[ 57 \] where the emphasis is more on the algebraic side of the theory. In fact, the asymptotic analysis of orthogonal rational functions is still in its infancy.

We recently developed an analog of the Kolmogorov-Krein-Szegö theorem \[ 18 \] for orthogonal rational functions which is first of its kind in that it allows for the poles of these functions to approach the unit circle, generalizing previously known results for compactly supported singular set. Dwelling on this asymptotic analysis of orthogonal rational functions, we developed a prediction theory for certain, possibly nonstationary stochastic processes that we call Blaschke varying processes. \[ 44 \]. These are characterized by a spectral calculus where time shift corresponds to multiplication by an elementary Blaschke product (that may depend on the time instant considered). This class of processes contains the familiar Gaussian stationary processes, but it contains many more that exhibit a much more varied behaviour. For instance, the process may be asymptotically deterministic along certain subsequences and nondeterministic along others. The optimal predictor is constructed from the spectral measure via orthogonal rational functions, and its asymptotic behaviour is characterized by the above-mentioned generalization of the Kolmogorov-Krein-Szegö theorem. In the same vein, we also developed prediction theory for another class of nonstationary processes, the so-called Cauchy-processes, that may be characterized as stationary processes fedind in turn a sequence of varying filters of degree 1. Their covariance matrices can be charaterized via Nevanlinna-Pick interpolation. The issue of characterizing covariance sequences of Blaschke processes is still open. Their identification raises the problem of constructing optimal Schur rational approximants to a given Schur function.

### 6.5. Rational and meromorphic approximation

**Participants:** Laurent Baratchart, Herbert Stahl [TFH Berlin], Maxim Yattselev.

We demonstrated in a recent past, under mild smoothness assumptions, the possibility of convergent rational interpolation to Cauchy integrals of complex measures on analytic Jordan arcs and their strong asymptotics \[ 14 \], \[ 13 \]. Subsequently, we started investigating the case of Cauchy integrals on so-called symmetric contours for the logarithmic potential. These correspond to functions with more than two branched singularities, like those arising in the slicing method for source recovery in a sphere when there is more than one source (see section 6.2.2 ). Recently we obtained weak asymptotics in this case, and dwelled on them to elucidate the asymptotic of poles of best \( L^2 \) meromorphic approximants of given degree to a function with branched singularities on a curve encompassing them. Namely, the counting measure of the poles converges weak-star, when the degree goes large, to the Green equilibrium distribution of the set with minimum Green capacity inside the curve, outside of which the function is single-valued. The technical core of this contribution is an existence and uniqueness result, along with a differential characterization, of the compact of minimum weighted capacity outside of which the function is single-valued \[ 19 \]. This teams up with results from \[ 63 \] to produce the results.

We presently study strong asymptotics, limiting ourselves at present to a threefold geometry, and to the case of Padé approximants (interpolation at a single point with high order). The result is that uniform convergence can only take place if the weights of the branches of the threefold with respect to the equilibrium distribution are rational. If they are rationally dependent, a spurious pole clusters to certain curves within the domain of analyticity, and if they are rationally independent, exactly one pole exhibits chaotic behaviour in the complex
plane. Moreover, we have shown that the chaotic situation is generic, in a measure theoretic sense, with respect to the location of branchpoints. This generalizes and sharpens results of Suetin for Cauchy integrals on disconnected pieces of a smooth symmetric contour. It is the first time that a branched contour is analyzed with respect to general densities. A paper is being written to report these results.

6.6. Circuit realisations of filter responses: determination of canonical forms and exhaustive computations of constrained realisations

Participants: Smain Amari [Royal Military College, Kingston, Canada], Jean Charles Faugère [EPI SALSA, INRIA Rocquencourt], Giuseppe Macchiarella [Politecnico di Milano, Milan, Italy], Uwe Rosenberg [Design and Project Engineering, Osterholz-Scharmbeck, Germany], Matteo Oldoni [Politecnico di Milano, Milan, Italy], Fabien Seyfert.

We pursued our work on circuit realisations of filter responses with mixed type (inductive or capacitive) coupling elements and constrained topologies [1]. We now focus on the use of resonating couplings in the design of asymmetric filter’s characteristics without the use cross-coupling in order to simplify the practical implementation. In parallel, efforts are being payed to improve the synthesis method for higher order filters, having in mind application to diplexers with high number of symmetrically located transmission zeros.

6.7. Synthesis of compact multiplexers and de-embedding of multiplexers

Participants: Martine Olivi, Fabien Seyfert, Stéphane Bila [Xlim, Limoges, France], Hussein Ezzedin [Xlim, Limoges, France], Damien Pacaud [Thales Alenia Space, Toulouse, France], Giuseppe Macchiarella [Politecnico di Milano, Milan, Italy], Matteo Oldoni [Politecnico di Milano, Milan, Italy].

6.7.1. Synthesis of compact multiplexers

Our work on the synthesis problem for diplexers has continued this year. Based on the polynomial structure highlighted last year [39], a synthesis algorithm was devised and allowed the effective synthesis of multiplexer characteristics (see figure 5). As opposed to other synthesis algorithms [74] the latter only involves polynomial computations on the sub-filters of the overall multiplexer, allowing its application to synthesis problems relative to devices with a numerous number of ports. The latter is based on the recursive solving of an extended Nevanlinna-Pick problem, first introduced in [62]. The convergence of this fixed point procedure is under study as well as its extension to the synthesis of general multiplexer.

![Figure 5. Diplexer's characteristic computed with an algorithm based on the recursive solving of extended Nevanlinna-Pick interpolation problems.](image-url)
6.7.2. De-embedding of multiplexers

While we presented our work on the de-embedding diplexers at [26] we extended the latter to general multiplexers. The multiplexer de-embedding problem we study is the following. Let $S$ be the measured scattering matrix of a multiplexer composed of a $N$-port junction with response $T$ and $N-1$ filtering devices with responses $F_1, \cdots, F_{N-1}$ as depicted by Figure 6.

![Figure 6. Multiplexer made of a junction $T$ and filtering devices $F_1, F_2, \cdots, F_N$.](image)

The de-embedding question is the following: given $S$ and $T$, is it possible to derive the $F_k$'s? We derived some rather important and surprising characteristics of this general problem:

- When stating the de-embedding problem in terms of chain rather that scattering matrices, the latter becomes linear,
- For a generic junction the de-embedding problem has a unique solution for $N = 2$ and $N > 3$ while it is degenerated for $N = 3$,
- Degeneracy depends on the junction’s response and can be explained by the occurrence of filtering responses that hide behind the junction. These are responses $F_1, \cdots, F_{N-1}$ such that when chained to the junction, the response $T$ remains unchanged.

In the light of these theoretical results the tractability of the practical problem is currently under investigation. For example, it appears that in practice the $T$ responses can not be considered as generic as they are often build by chaining several 3-junctions together. Moreover, while theoretically uniqueness of the de-embedding solution seems to be guaranteed for large values of $N$, the sensitivity of the latter with respect to measurements errors grows dramatically with $N$. Therefore approaches that entail additional hypotheses, such as rationality of the responses $F_k$ are being studied. This work is pursued in collaboration with Thales Alenia Space and the Politecnico di Milano.

6.8. Averaging in control

**Participants:** Bernard Bonnard, Jean-Baptiste Pomet, Jana Nemcova.

A reference paper on the construction and properties of an “average control system”, has been submitted [27]; it is based on Alex Bombrun’s doctoral work [54] (defended in 2007). It connects properties of convergence of solutions of highly oscillating control systems to those of an average control system, when the frequency of oscillation goes high. Likewise, it details (on a time-interval that goes to infinity) the properties of solutions
of a conservative system with small controls in relation to those of an average system as the magnitude of control goes to zero. It also gives many properties of this average control system that has “more controls” than the original system, and yields, when this number of new controls is maximal, a Finsler metric on the state manifold. It is however difficult to compute explicitly and is never twice differentiable.

In [33], we study into details this average system arising from low-thrust orbital transfer, in the restricted “meridian” co-planar case, and prove that its trajectories for minimum time never leave the “elliptic domain” where averaging is valid. This gives some ground to using it as a limit to describe transfer from an elliptic orbit to another.

More exploration on this average system and the corresponding Finsler metric is planned.

6.9. Optimal transport

Participants: Bernard Bonnard, Ahed Hindawi, Jean-Baptiste Pomet, Ludovic Rifford.

In [23], we provide results on existence and continuity of the optimal transport map between absolutely continuous measures (with respect to Lebesgue measure) for a point-to-point cost coming from controllable linear-quadratic optimal control. This is the simplest case of a cost coming from a system with drift; it bears some interest because the cost can be explicitly computed. A. Hindawi’s PhD also aims at more general systems. It will be defended in 2012.

6.10. Detection of the instability of amplifiers

Participants: Laurent Baratchart, Sylvain Chevillard, Martine Olivi, Jean-Baptiste Pomet, Fabien Seyfert.

A new collaboration with the CNES and the University of Bilbao began this year. The goal is to help the development of amplifiers, in particular to detect unstability at an early stage of the design.

Currently, Electrical Engineers from the University of Bilbao, under contract with CNES (the French Space Agency), use heuristics to diagnose instability before the circuit is physically implemented. We intend to set up a rigorously founded algorithm instead, based on properties of transfer function of such amplifiers which belong to particular classes of analytic functions.

We completed the first stage of this collaboration, in that we now have a formal definition of stability within these classes: a stable function is one which, when connected in parallel with a large resistor, yields a $H^\infty$ transfer function (in this context transfer functions might have infinitely many poles). We also obtained a characterization of transfer functions that may actually be realized in terms of elementary electric components (i.e., resistors, self, capacities, LEDs, and transmission lines): they are the rational functions in the variable and the exponentials thereof.

6.11. Tools for numerically guaranteed computations

Participant: Sylvain Chevillard.

This work has been performed in collaboration with members of the teams Arénaire in Lyon and Caramel in Nancy. The overall and long-term goal is to enhance the quality of numerical computations. Several aspects are studied:

- A first topic is the development of software code for the multiprecision evaluation of elementary and special functions. Developing such codes is a long and error-prone task. It is hence relevant to automatically generate such codes whenever possible. A first step has been to design an algorithm that automatically generates multiprecision code for the evaluation of constant expressions with an a priori guaranteed error [25]. This is usually necessary for the evaluation, e.g., of the first terms of a Taylor series.
Another topic consists in the design of algorithms that allow developers of double precision mathematical libraries (so-called libm) to certify their library. In the process of developing a libm, one usually replaces the function \( f \) to be evaluated by a good polynomial approximation \( p \). In order to certify the quality of the library, it is then necessary to give a rigorous mathematical proof that the relative error \( \varepsilon = (p - f)/f \) between \( p \) and \( f \) is bounded by a small constant. This turns out to be equivalent to the problem of computing a sharp yet certified upper bound of the supremum norm of \( \varepsilon \). An efficient algorithm has been designed for this purpose [20] (this work is the publication of a work initially begun in the Arénaire team and continued in the Caramel team).

Finally, a more general endeavor is to develop a tool that helps developers of libms in their task. This is performed by the software Sollya, which has originally been developed in the Arénaire team, in collaboration with C. Lauter and M. Joldeș. A new release has been performed this year [32].
6. New Results

6.1. Hardware Arithmetic and Architecture

Participants: Florent de Dinechin, Hong Diep Nguyen, Bogdan Pasca, Honoré Takeugming, Álvaro Vázquez Álvarez, Nicolas Brunie, Sylvain Collange.

6.1.1. FPGA-specific arithmetic

Reconfigurable computing has the opportunity of using exotic operators that would not make sense in a general-purpose microprocessor [43], for instance the constant dividers studied in 6.1.2. Such operators must be also be matched to the precision and performance needed by applications. F. de Dinechin and B. Pasca described the FloPoCo framework that assists the construction of correct pipelines and the automatic testing of such operators [28]. For this context, B. Pasca, with H. D. Nguyen, now at U.C. Berkeley, and T. Preusser, from T. U. Darmstadt, described improved architectures for short-latency adders on modern FPGAs [39]. With Ch. Alias and A. Plesco (Compsys project-team), he studied the integration in of deeply pipelined arithmetic datapath in high-level synthesis tools [51].

6.1.2. Multiplication by Rational Constants versus Division by a Constant

Motivated by the division by 3 or by 9 appearing in some stencil kernels, F. de Dinechin investigated how the periodicity of the binary representation of a rational constant could be exploited to design an architecture multiplying by this constant [26]. With L. S. Didier, this approach was then compared to a specialisation of divider architectures to the division by small integer constants, which is shown to match well the fine structure of FPGAs [44].

6.1.3. Elementary Functions

A. Vázquez worked with J. Bruguera, from U. Santiago de Compostella, on hardware architectures for evaluating $q$-th roots [66]. Their solution composes digit-recurrence operators for reciprocal, logarithm, multiplication and exponential.

6.1.4. Extensions of the fused-multiply-and-add operator

With B. de Dinechin, from Kalray, N. Brunie and F. de Dinechin proposed to extend the classical fused-multiply-and-add operator with a larger addend and result. This enables higher-precision computation of sums of products at a cost that remains close to that of the classical FMA [56].

6.1.5. Emerging throughput-oriented architecture

On massively multi-threaded processors like GPUs, neighbor threads are likely to operate on similar data. S. Collange showed with A. Kouyoumdjian how it is possible to take advantage of this inter-thread value correlation at the hardware level with a hardware cache-compression technique on GPUs [59]. With D. Sampaio, R. Martins, and F. Magno Quintão Pereira (U. Minas Gerais), he then addressed this question also at the compiler level using a compiler stage to identify statically data patterns in GPGPU programs [65].

Current GPU architectures require specific instruction sets with control-flow reconvergence annotations, and only support a limited number of control-flow constructs. S. Collange and N. Brunie, with G. Diamos (NVIDIA) generalized dynamic vectorization to arbitrary control flow on standard instruction sets with no compiler involvement [46], [57], [54]. In addition, this technique allows divergent branches to be executed in parallel, as a way to increase the throughput of parallel architectures [55].
6.2. Efficient Floating-Point Arithmetic and Applications

6.2.1. Correctly Rounded Sums

P. Kornerup (Odense Univ., Denmark), V. Lefèvre, N. Louvet and J.-M. Muller have given a study of some basic blocks needed in the design of floating-point summation algorithms. In particular, in radix-2 floating-point arithmetic, they have shown that among the set of the algorithms with no comparisons performing only floating-point additions/subtractions, the 2Sum algorithm introduced by Knuth is minimal, both in terms of number of operations and depth of the dependency graph. They have investigated the possible use of another algorithm, Dekker’s Fast2Sum algorithm, in radix-10 arithmetic. Under reasonable conditions, they have also proven that no algorithms performing only round-to-nearest additions/subtractions exist to compute the round-to-nearest sum of at least three floating-point numbers. Starting from an algorithm due to Boldo and Melquiond, they have also presented new results about the computation of the correctly-rounded sum of three floating-point numbers [21].

6.2.2. Error of an FMA

The fused multiply-add (FMA) instruction, specified by the IEEE 754-2008 Standard for Floating-Point Arithmetic, eases some calculations, and is already available on some current processors such as the Power PC or the Itanium. S. Boldo (EPI Proval) and J.-M. Muller first extended an earlier work on the computation of the exact error of an FMA (by giving more general conditions and providing a formal proof). Then, they presented a new algorithm that computes an approximation to the error of an FMA, and provide error bounds and a formal proof for that algorithm [16].

6.2.3. Accurate computation of \( ad - bc \) with an FMA

C.-P. Jeannerod, N. Louvet, and J.-M. Muller have provided in [60] a detailed rounding error analysis of Kahan’s FMA-based algorithm for the computation of expressions of the form \( ad - bc \). They showed that Kahan’s algorithm is always highly accurate, and under mild assumptions on the radix and the precision gave an optimal bound on the absolute error and an asymptotically optimal bound on the relative error. They also studied how the relative error varies as a function of the relative order of magnitude of the two products \( ad \) and \( bc \). Finally, they investigated whether the error bounds can be improved in special cases like sums of squares and discriminants.

6.2.4. Performing Arithmetic Operations on Round-to-Nearest Operations

During any composite computation, there is a constant need for rounding intermediate results before they can participate in further processing. Recently, a class of number representations denoted RN-Codings were introduced, allowing an unbiased rounding-to-nearest to take place by a simple truncation, with the property that problems with double-roundings are avoided. P. Kornerup (Odense Univ., Denmark), J.-M. Muller and A. Panhaleux first investigate a particular encoding of the binary representation. This encoding is generalized to any radix and digit set; however, radix complement representations for even values of the radix turn out to be particularly feasible. The encoding is essentially an ordinary radix complement representation with an appended round-bit, but still allowing rounding-to-nearest by truncation, and thus avoiding problems with double-roundings. Conversions from radix complement to these round-to-nearest representations can be performed in constant time, whereas conversion the other way, in general, takes at least logarithmic time. Not only is rounding-to-nearest a constant time operation, but so is also sign inversion, both of which are at best log-time operations on ordinary two’s complement representations. Addition and multiplication on such fixed-point representations are first analyzed and defined in such a way that rounding information can be carried along in a meaningful way, at minimal cost. The analysis is carried through for a compact (canonical) encoding using two’s complement representation, supplied with a round-bit. Based on the fixed-point encoding, it is shown possible to define floating-point representations, and a sketch of the implementation of an FPU is presented [22].
6.2.5. Augmented Precision Square Roots, 2-D Norms, and Discussion on Correctly Rounding

\[ \sqrt{x^2 + y^2} \]

Define an “augmented precision” algorithm as an algorithm that returns, in precision-\(p\) floating-point arithmetic, its result as the unevaluated sum of two floating-point numbers, with a relative error of the order of \(2^{-2p}\). Assuming an FMA instruction is available, N. Brisebarre, M. Joldeş, P. Kornerup (Odense University, Denmark), E. Martin-Dorel and J.-M. Muller perform a tight error analysis of an augmented precision algorithm for the square root, and introduce two slightly different augmented precision algorithms for the 2D-norm \(\sqrt{x^2 + y^2}\). Then they give tight lower bounds on the minimum distance (in ulps) between \(\sqrt{x^2 + y^2}\) and a midpoint when \(\sqrt{x^2 + y^2}\) is not itself a midpoint. This allows them to determine cases when their algorithms make it possible to return correctly-rounded 2D-norms [30].

6.2.6. Midpoints and exact points of some algebraic functions in floating-point arithmetic

When implementing a function \(f\) in floating-point arithmetic, if we wish correct rounding and good performance, it is important to know if there are input floating-point values \(x\) such that \(f(x)\) is either the middle of two consecutive floating-point numbers (assuming rounded-to-nearest arithmetic), or a floating-point number (assuming rounded toward \(\pm \infty\) or toward 0 arithmetic). In the first case \(f(x)\) is a midpoint, and in the second case it is an exact point. In [20] C.-P. Jeannerod, N. Louvet, J.-M. Muller, and A. Panhaleux have studied whether such midpoints and exact points exist for some usual algebraic functions and various floating-point formats. When midpoints or exact points exist, they have been characterized or, when possible, listed exhaustively. The results and the techniques presented in this paper can be used in particular to deal with both the binary and the decimal formats defined in the IEEE 754-2008 standard for floating-point arithmetic.

6.3. Correct Rounding of Elementary Functions

**Participants:** Florent de Dinechin, Vincent Lefèvre, Jean-Michel Muller, Bogdan Pasca, Serge Torres.

6.3.1. FPGA Acceleration of the Search For Hardest-to-Round Cases

The IEEE 754-2008 standard for floating-point arithmetic recommends (yet does not dictate) that some elementary functions should be correctly rounded. That is, given a rounding function \(\circ\), (e.g., round to nearest even, or round to \(\pm \infty\)), when evaluating function \(f\) at the floating-point number \(x\), the system should always return \(\circ(f(x))\).

Building a fast correctly rounded library for some target floating-point (FP) format requires preliminarily solving a problem called the table maker’s dilemma. This requires very large computations which may use environments and formats totally different from the target environment and format. F. de Dinechin, V. Lefèvre, J.-M. Muller, B. Pasca and A. Plesco suggest performing these computations on an FPGA. Their paper [45] won the best paper award at the ASAP2011 conference.

6.3.2. Hierarchical Polynomial Approximation of a Function by Polynomials

Algorithms used to search for the hardest-to-round cases of a function requires the approximation of the function by small-degree polynomials on small intervals. This can be done efficiently by a hierarchical polynomial approximation. Work is being done to improve this method by replacing interval arithmetic (as partly used in the current tools) by static error bounds. This will allow us to better control the precision needed to compute the coefficient of the polynomials. The implementation will also be simpler.

6.4. Validation and Automation

**Participants:** Nicolas Brisebarre, Florent de Dinechin, Claude-Pierre Jeannerod, Jingyan Jourdan-Lu, Mioara Joldeş, Vincent Lefèvre, Nicolas Louvet, Christophe Mouilleron, Hong Diep Nguyen, David Pfannholzer, Nathalie Revol, Philippe Théveny, Gilles Villard.
6.4.1. Efficient Implementation of Algorithms for Interval Linear Algebra

H.-D. Nguyen and N. Revol proposed an algorithm to solve linear systems with interval coefficients. The same approach can be used to verify the solution of a linear system with floating-point coefficients, i.e. to compute an interval enclosing the error between the exact solution and an approximate solution. The goal is twofold: on the one hand the accuracy of the solution is desired up to the last bit of the floating-point solution, on the other hand the efficiency of the implementation is obtained through the use of optimized BLAS3 routines [48]. The PhD thesis of H.-D. Nguyen [13] contains in particular the algorithm [24] and its properties. Its complexity has been established [47] and its potential use for symbolic-numeric computations has been discussed [50].

6.4.2. Standardization of Interval Arithmetic

We contributed to the creation, and now chair, the IEEE 1788 working group on the standardization of interval arithmetic http://grouper.ieee.org/groups/1788/. The main discussion topics of this working group [49], for the year 2011, were exception handling (via decorations). An emerging topic is the repeatability and reproducibility of interval computations. on the same platform or across different platforms.

6.4.3. Formal Proofs of the Arithmetic on Polynomial Models

Using as starting point [9], the calculus with polynomial models, such as Taylor models, based on floating-point coefficients and floating-point operations, has been formalized and checked in Coq [18]. This calculus is at the core of Ariadne, an environment for the study of hybrid systems: the idea is to prove the environment itself, instead of using model-checking on the systems.

6.4.4. Formal Proof Generation for Elementary functions

The proof of the correct rounding property for an elementary function requires tight bounds on the error involved in the function code. F. de Dinechin, with Ch. Lauter (LIP6) and G. Melquiond (INRIA Proval) have described the use of the Gappa proof assistant to compute such tight bounds rigorously [27].

6.4.5. Code Generation for Polynomial Evaluation

A given arithmetic expression may be evaluated on a computer in several ways, depending on the parenthesization and the ordering of terms in use. Among all the possible evaluations, one may want to choose one that is as fast and accurate as possible. In [12] Ch. Mouilleron introduced a set of algorithms in order to generate all these possible evaluations, to count them, and to find an optimal or nearly optimal one according to a given criteria. Thanks to this work, several sequences related to numbers of evaluations have been discovered and added to Sloane’s on-line encyclopedia of integer sequences (OEIS). Moreover, this allowed to show experimentally that an algorithm by Paterson and Stockmeyer for the evaluation of a polynomial \( p \) at a matrix point is optimal for small degrees of \( p \). Finally, this work has led to the revamping of the software tool CGPE presented in [38] (see also § 5.5).

6.5. Arithmetic and Algorithms

Participants: Guillaume Hanrot, Claude-Pierre Jeannerod, Adeline Langlois, Ivan Morel, Christophe Mouilleron, Andrew Novocin, Xavier Pujol, Damien Stehlé, Gilles Villard.

6.5.1. Faster Lattice Reduction

Andrew Novocin, Damien Stehlé and Gilles Villard [40] designed an algorithm, \( \tilde{L}^1 \), with the following specifications: It takes as input an arbitrary basis \( B \) in \( \mathbb{Z}^{d \times d} \) of a lattice \( L \); It computes a basis of \( \tilde{L} \) which is reduced for a mild modification of the Lenstra-Lenstra-Lovász reduction; It terminates in time \( O(d^4 \beta + d^{r+1} \beta) \) where \( \beta = \log \| B \| \) (and \( \omega \) is a valid exponent for matrix multiplication). This is the first LLL-reducing algorithm with a time complexity that is quasi-linear in the bit-length beta of the entries and polynomial in the dimension \( d \). A critical ingredient for achieving this result was the study of the effect of small perturbations on the LLL-reducedness of a lattice basis [17].
6.5.2. Computing Short Lattice Vectors

Among all known lattice reduction algorithms, BKZ provides the best trade-off between run-time and smallness of the computed lattice basis. Guillaume Hanrot, Xavier Pujol and Damien Stehlé [32] showed that BKZ can be terminated long before its completion, while still providing bases of excellent quality. More precisely, if it is terminated within a polynomial number of calls to a lower-dimensinal Shortest Vector Problem solver, then the bounds on the output quality are as close as desired to the bounds that can be obtained by letting BKZ run until completion.

Guillaume Hanrot, Xavier Pujol and Damien Stehlé also surveyed the known algorithms for solving the Shortest Vector Problem [31].

6.5.3. Lattice-Based Cryptography

NTRUEncrypt is the fastest known lattice-based encryption scheme. Its moderate key-sizes, excellent asymptotic performance and conjectured resistance to quantum computers could make it a desirable alternative to factorisation and discrete-log based encryption schemes. Damien Stehlé and Ron Steinfeld [41] showed how to modify NTRUEncrypt to make it provably resistance to Chosen Plaintext Attacks, under the assumed quantum hardness of standard worst-case lattice problems restricted to a family of lattices related to some cyclotomic fields.

6.5.4. Lattices and Communication Theory

Cong Ling, Shuiyin Liu, Laura Luzzi and Damien Stehlé studied and optimized lattice algorithms that are relevant for MIMO communications [23], [37]. These algorithms tackle the Bounded Distance Decoding Problem: Given a point within a small prescribed distance to a given lattice, find the lattice vector closest to it.

6.5.5. Other Applications of Lattice Reduction Algorithms

In [35] Jürgen Klüners, Mark van Hoeij, and Andrew Novocin showed how to use the LLL lattice reduction algorithm for computing a compact representation of the set of all subfields of any given number field. William Hart (Warwick Mathematics Institute, UK), Mark van Hoeij (Florida State University, USA) and Andrew Novocin exploited the very latest progress in lattice reduction to propose a fine-tuned cutting-edge implementation of a polynomial factorization algorithm.

6.5.6. Polynomial Arithmetic

With William Hart and Mark van Hoeij, A. Novcin proposed in [33] a state of the art algorithm for factoring polynomials in Z[x]. The algorithm is fast in practice, saving in a large class of common examples, without sacrificing performance on worst-case polynomials. The presented algorithm is structured along the lines of algorithms with the best theoretical complexity. In [34] William Hart and A. Novcin proposed an efficient algorithm for computing the composition of two univariate polynomials. Their work builds upon the Brent-Kung algorithm.

6.5.7. Exact Linear Algebra

Transforming a matrix over a field to echelon form, or decomposing the matrix as a product of structured matrices that reveal the rank profile, is a fundamental building block of computational exact linear algebra. For such tasks the best algorithms available so far were either rank sensitive (i.e., of complexity expressed in terms of the exponent of matrix multiplication and the rank of the input matrix) or in place (i.e., using essentially no more memory that what is needed for matrix multiplication). In [61] C.-P. Jeannerod, Clément Pernet (U. Joseph Fourier, Grenoble), and Arne Storjohann (U. Waterloo, Canada) have proposed algorithms that are both rank sensitive and in place. These algorithms are based on a new matrix factorization, namely $A = CUP$ with $C$ a column echelon form revealing the row rank profile of $A$, $U$ a unit upper triangular matrix, and $P$ a permutation matrix.
6. New Results

6.1. Optical imagery for remote sensing

6.1.1. Phase Field-Higher Order Active Contours for Object Modelling and Image Segmentation

Participants: Ikhlef Bechar, Josiane Zerubia [contact].

This work is done in collaboration with Dr Ian Jermyn of Durham University (United Kingdom) and was funded by a contract with the EADS foundation [http://www-sop.inria.fr/ariana/Ikhlef.Bechar/hoacs/index.html].

The problem of object segmentation from imagery is an essential preliminary task for many applications (target recognition, automated navigation, organ segmentation in medical imaging, etc). The problem of adding prior knowledge about objects to the image segmentation process has received a lot of interest since recently, and active contours [38] provide us with such a tool.

We consider a new class of active contours called Higher Order Active Contours (HOACs) introduced initially in [41], and which consider an optimal contour as the one which minimizes an energy involving three additive terms; namely the length of a contour, its area and a term of interaction between all possible pairs of its points via an interaction function $\Psi(t)$. The three terms being weighed by means of three scalar parameters. The main advantage of HOACs over traditional segmentation methods is that they offer an unprecedented means for including shape prior about an object via the interaction function $\Psi(t)$.

The HOAC set up has been applied successfully to various object extraction problems such as the extraction of networks [40], circular shapes [37], etc, using a specific family of the $\Psi(t)$'s. Our main task in the framework of this project is to extend their work to more general shapes.

Our contributions so far have been in the numerical computation of the optimal HOAC parameters for a given shape. We have shown indeed that the HOAC energy can be fully made linear with respect to $\Psi(t)$, which then makes it easy to solve for $\Psi(t)$ numerically (cf. Fig. 6). This is achieved by first choosing a linear basis to represent $\Psi(t)$ and using K-K-T (Karush-Kuhn-Tucker) optimality criteria to express the fact that a target contour is a local minimum of the energy. Consequently, looking for the optimal values of the coefficients for a given shape amounts first to solve an eigen value problem, and second, to find the linear combinations of the found eigen vectors that satisfy both K-K-T minimality criteria. The computation being carried out in the Fourier domain for sake of computational efficiency. We are currently testing the proposed model on simple shapes such as the butterfly one shown in figure 6.

6.1.2. Optimization of the compression-restoration chain for satellite images

Participants: Mikael Carlavan, Laure Blanc-Féraud [contact].

This project involves the French Space Agency (CNES) and the CESBIO, on collaboration with TAS and I3S (Marc Antonini).

This work concerns the study of the optimal imaging chain in the context of satellite imaging. The main goal of this study is to propose a new method to address the problem of decoding-deconvolution-denoising and consists in a characterization and optimization of the compression/restoration processes considering the instrumental characteristics (FTM, noise, sampling). A theoretical study first showed that current processes of compression and restoration are better fitted if the restoration is performed on-board before the compression. Indeed, current restoration algorithm is designed to remove the blur and the instrumental noise but does not take into account the coding noise, and it is well-known that compression algorithms do not perform
Figure 6. An example of estimation of the $\Psi$ function for a given shape. (a) An example of a butterfly-like shape; (b) The numerical estimation of its optimal $\Psi$ function; (c) The result of a gradient descent algorithm on the HOAC energy with $\Psi$ of figure (b) until convergence (in black the original shape, and in red the shape found by the gradient descent algorithm). One can see that the estimated $\Psi$ makes the HOAC energy achieve a local minimum at a shape which is very close to the target shape of figure (a).
properly on noisy data. More generally, we concluded that the image should be the closest possible to the real image before the step of coding, encouraging, thus, to move the restoration step on-board before the compression. Figure 7 shows the global distortion w.r.t. the coding rate if the restoration step is done either before (on-board) or after (on-ground) the compression. We see that using an on-board restoration leads to a quality improvement of the final image regardless the coding rate. For example, at the usual coding rate of 2.5 bits/pixel, using an on-board restoration improves the quality of the final image about 0.5 dB.

![Figure 7](image.png)

**Figure 7.** Global distortion w.r.t coding rate. The solid line is the global distortion with the restoration step done on-ground after the compression and the dashed line is the global distortion if the restoration is performed on-board before the compression.

### 6.1.3. Aerial Image Restoration

**Participants:** Daniele Graziani, Laure Blanc-Féraud [contact].

This project involves as partners: ATE, Coreti, and Gilles Aubert from the J.A.D. Laboratory at the University of Nice Sophia Antipolis.

The goal of the project is to build an airborne camera system, and our part is to process aerial images provided by ATE: restoration, microscanning, video, color images. We investigate a convex variational framework to compute high resolution images from a low resolution video. We analyze the image formation process to provide a well designed model for warping, blurring, downsampling and restoration. The microscanning is modeled as a convex minimization problem, which is solved with a domain decomposition technique based on the recent work of M. Fornasier, A. Langer and C. Schonlieb. ("A convergent overlapping decomposition method for total variation Minimization", Numeriske Math. to appear), which allows parallel computing and a realization of a real time algorithm.

### 6.1.4. Contribution of object recognition on forest canopy images to the building of an allometric theory for trees and natural, heterogeneous forests

**Participants:** Jia Zhou, Xavier Descombes, Josiane Zerubia [contact].

This work is done in collaboration with Dr. Pierre Couteron and Christophe Proisy at IRD, UMR AMAP, Montpellier.
Individual tree detection methods are more and more present, and improve, in forestry and silviculture domains with the increasing availability of satellite metric imagery. Automatic detection on these very high spatial resolution images aims to determine the tree positions and crown sizes. The mathematical model based on marked point processes has showed advantages w.r.t. several individual tree detection algorithms for plantations. We used this detection method to analyze natural mangrove forests in French Guiana, eucalyptus plantations in Brazil, and other types of tropical forests. The simulated optical images were also used to improve the method and calibrate the detection parameters. To analyze a eucalyptus plantation in Brazil [23], we used 2 optical images acquired by the WorldView-2 satellite. A tentative detection simultaneously with 2 images of different dates (multi-date) was tested for the first time, which estimates individual tree crown variation during these dates. In this work, we tried to find the trees localizations and crown sizes in order to provide a plantation map, and estimate the tree crown growth during the period between 2 images, and compared these results with the field measurements and expected dynamics of corresponding populations. An example of multi-date detection result is showed in figure 9.

The detection method was also applied on simulated optical DART (Discrete Anisotropic Radiative Transfer) images, where exact field inventory could be provided on large surfaces. We assessed the detection results with these "ground-truth" maps.

6.2. SAR imagery for remote sensing

6.2.1. Stochastic modeling for very high resolution SAR image processing

Participants: Aurélie Voisin, Vladimir Krylov, Josiane Zerubia [contact].

This work is done in collaboration with DIBE, University of Genoa, with Dr Gabriele Moser and Prof. Sebastiano B. Serpico [http://spt.dibe.unige.it/] with partial financial support of the French Defense Agency, DGA [http://www.defense.gouv.fr/dga/] with partial financial support of the French Defense Agency, DGA [http://www.defense.gouv.fr/dga/]. The data are provided by the Italian Space Agency, ISA [http://www.asi.it/en].
Figure 9. Results of a multi-date detection on 2 images at different dates: in May (left) and in August (right)

We deal with the environmental risk assessment by addressing the problem of classifying SAR images of urban areas. Several difficulties need to be considered to address the SAR classification problem. The first one is related to the inherent multiplicative noise known as speckle, which degrades appreciably the registered imagery. Another difficulty is the heterogeneity of urban areas on very high resolution (VHR) images that leads to heterogeneous statistical modeling, reflecting the different ground materials such as asphalt, concrete, metal, etc. We propose a hierarchical statistical Bayesian supervised classification approach that consists of two steps. The first step deals with the SAR amplitude statistical modeling for each target class (e.g. vegetation, urban, etc.) by using a finite mixture model, estimated by resorting to a dictionary-based stochastic expectation maximization (DSEM) algorithm. More specifically, the SAR amplitude probability density functions (PDFs) are assumed to be mixtures of $K$ PDFs automatically chosen inside a predefined dictionary of SAR-specific distribution families. Such mixtures are intended to take into account the above mentioned VHR SAR statistics heterogeneity. We further consider an additional source of information obtained by extracting a textural feature map from the original SAR image in order to optimize the detection of urban areas. Typically, the textural feature is generated by using a Grey Level Co-occurrence Matrix (GLCM)-based method. The marginal PDFs of the original SAR image and the textural feature are combined via copulas, leading to a joint PDF for each class. On the second step the classification map is generated, using the joint copula-based statistics. To improve the robustness with respect to speckle noise, we consider a contextual model based on Markov random fields (MRFs), and, more specifically, a hierarchical MRF, which offers the possibility to take into account the multi-scale information and to deal with multi-resolution imagery [28]. A variety of algorithms were proposed to estimate the labels on hierarchical graphs. The consideration of a specific graph, here a quad-tree, allows to benefit from its good properties (e.g. causality) and to apply non iterative algorithms. Among the different algorithms employed in the literature, we chose to take into account an exact estimator of the marginal posterior mode (MPM). The cost function associated to this estimator offers the possibility to penalize the errors according to their number and the scale at which they occur: an error at the coarsest scale is stronger penalized than an error at the finest scale. Moreover, we introduce a prior estimation update that experimentally leads to improved results and is less affected by speckle noise when compared to a predefined prior [35]. The challenge of the problem considered here is that our given input is a single-polarized SAR image at a single resolution. To improve the classification, we extract an extra information in the form of a multi-scale wavelet decomposition from the initial image. Then, at each level, the textural feature map is obtained from each image in the decomposition stack. Finally, at each level, the wavelet image is combined with the textural image by using copulas, as described previously in Ariana activity reports. The hierarchical method was tested on real COSMO-SkyMed images. We illustrate the obtained results with an example of a SAR acquisition of the Port-au-Prince quay (Haiti). Spatially disjoint training and test areas were manually annotated. The classification is done following 3 classes: urban areas, natural landscape and wet areas. The
results are shown qualitatively in figure 10. The computation of numerical results gives an average accuracy of 95.65 percent for the considered test areas.

Our previous work was based on single-scale MRF, thus the hierarchical approach is a direct extension. Part of our work was dedicated to the comparison of these two methods [35], [28], and we also compared the MRF-based model to a novel products of experts approach [18].

6.2.2. Parameter estimation procedures for HR SAR image classification

Participants: Vladimir Krylov, Josiane Zerubia [contact].

This work is conducted in collaboration with DIBE, University of Genoa with Dr. Gabriele Moser and Prof. Sebastiano Serpico [http://spt.dibe.unige.it/] with the support of the Italian Space Agency, ASI [http://www.asi.it/en].

Parameter estimation of probability density functions is one of the major steps in the mainframe of statistical image and signal processing. We have explored the properties and limitations of the recently proposed method of logarithmic cumulants (MoLC) parameter estimation approach which is an alternative to the classical maximum likelihood (ML) and method of moments (MoM) approaches. We have derived the general sufficient condition of strong consistency of MoLC estimates which represents an important asymptotic property of any statistical estimator [33]. We have demonstrated the strong consistency of MoLC estimates for a selection of widely used distribution families originating (but not restricted to) synthetic aperture radar (SAR) image processing. We have then derived the analytical conditions of applicability of MoLC to samples generated from several distribution families in our selection. We have conducted various synthetic and real data experiments to assess the comparative properties, applicability and small sample performance of MoLC notably for the generalized gamma and $K$ family of distributions. The synthetic-data experiments have demonstrated a competitive accuracy of MoLC estimates and a reliable behavior of this estimator for small samples which is a critical issue in applications. We have performed real-data image processing experiments to the problem of supervised classification applied to high resolution satellite SAR imagery. These experiments confirmed the stability of MoLC estimator with respect to sample size and at the same time illuminated the critical side of MoLC given by applicability restrictions. The experiments suggested the efficiency of use of the MoLC estimator for finite-mixture estimation problems [3], [19], and ML-based classification approaches [4], [28], [35].
6.2.3. Unsupervised amplitude and texture based classification of SAR images with multinomial latent model

**Participants:** Koray Kayabol, Aurélie Voisin, Vladimir Krylov, Josiane Zerubia [contact].

The participants would like to thank the Italian Space Agency (ASI) for providing the COSMO-SkyMed images. The TerraSAR-X images are provided from http://www.infoterra.de/.

We combine both amplitude and texture statistics of the Synthetic Aperture Radar (SAR) images using Products of Experts (PoE) approach for classification purpose. We use Nakagami density to model the class amplitudes and a non-Gaussian Markov Random Field (MRF) texture model with \( t \) distributed regression error to model the textures of the classes. A non-stationary Multinomial Logistic (MnL) latent class label model is used as a mixture density to obtain spatially smooth class segments. The Classification Expectation-Maximization (CEM) algorithm is performed to estimate the class parameters and to classify the pixels [18]. Determining the necessary number of classes to represent the data and initialization are some drawbacks of the EM type algorithms. In [17] and [32], we combine hierarchical agglomeration, CEM and Integrated Classification Likelihood (ICL) criterion to get rid of the drawbacks of EM. We obtained some classification results of water, land and urban areas in both supervised and unsupervised cases on TerraSAR-X, as well as COSMO-SkyMed data [18], [17], [32]. The proposed unsupervised ATML-CEM (Amplitude and Texture density mixtures of MnL with CEM) method provides significantly better results, see Fig. 12, compared to the corresponding results obtained with K-MnL and its performance is close to supervised ATML-CEM.

6.3. 3D-modelling of urban scenes

6.3.1. Building reconstruction from aerial LiDAR data

**Participants:** Yannick Verdie, Florent Lafarge [contact], Josiane Zerubia.

The generation of 3D representations of urban environments from aerial and satellite data is a topic of growing interest in image processing and computer vision. Such environments are helpful in many fields including urban planning, wireless communications, disaster recovery, navigation aids, and computer games. Laser scans have become more popular than multiview aerial/satellite images thanks to the accuracy of their measurements and the decrease in the cost of their acquisition. In particular, full-waveform topographic LiDAR constitutes a new kind of laser technology providing interesting information for urban scene analysis. We study new
Figure 12. (a) The original SAR image (COSMO-SkyMed, ©ASI), (b), (c) and (d) classification maps obtained by K-MnL, supervised and unsupervised ATML-CEM methods. Blue, red and green colors represent water, urban and land areas, respectively.
stochastic models for analysing urban areas from LIDAR data. We aim to construct concrete solutions to both urban object classification (i.e., detecting buildings, vegetation, etc.) and the 3D reconstruction of these objects. Probabilistic tools are well adapted to handling such urban objects, which may differ significantly in terms of complexity, diversity, and density within the same scene. In particular, jump-diffusion based samplers offer interesting perspectives for modelling complex interactions between the various urban objects. We investigated a first approach aiming at producing accurate, watertight and compact meshes from planar patches under planar constraint especially designed for urban scenes. The LiDAR point cloud is classified through a non-convex energy minimization problem. The planar structures are extracted and connected to generate a compact, and watertight mesh of the building. Experiments highlight the potential of our method in term of performance, compactness, and accuracy. This work has been published in [22]. We illustrated our results in figure 13.

![Figure 13. Results of 3D urban reconstruction by the framework described in [22].](image)

6.3.2. Modeling large urban environments from unstructured point clouds

**Participant:** Florent Lafarge [contact].

We present a robust method for modeling cities from unstructured point data. Our algorithm provides a more complete description than existing approaches by reconstructing simultaneously buildings, trees and topologically complex grounds. Buildings are modeled by an original approach which guarantees a high generalization level while having semantized and compact representations. Geometric 3D-primitives such as planes, cylinders, spheres or cones describe regular roof sections, and are combined with mesh-patches that represent irregular roof components. The various urban components interact through a non-convex energy minimization problem in which they are propagated under arrangement constraints over a planimetric map. We experimentally validate the approach on complex urban structures and large urban scenes of millions of points as illustrated on Figure 14.

6.3.3. Parallel Monte Carlo sampler for point processes

**Participants:** Yannick Verdie, Florent Lafarge [contact], Ioan Dragan.

We designed a new parallel scheme for Markov point processes. These probabilistic models exploit random variables whose realizations are configurations of parametric objects, each object being assigned to a point positioned in the scene. The number of objects is itself a random variable. Another strength of Markov point processes is their ability to take into account complex spatial interactions between the objects and to impose global regularization constraints. Moreover, we proposed to use space-partitioning tree such as quadtree (for 2D data) or octree (for 3D data) for non-homogeneous measure adapted to the problem. We illustrate the results in figure 15.
Figure 14. Reconstruction of the cities of Marseille and Amiens, France, from Lidar point cloud.

Figure 15. Results of the new Marked Point process on (left) 2D data, and (right) LiDAR data.
6.4. Biological imagery

6.4.1. Regularizing parameter estimation with Poisson noise

**Participants:** Mikael Carivan, Laure Blanc-Féraud [contact].

The problem is to automatically estimate the regularizing parameter in Poisson noisy image deconvolution using the $L_1$-norm regularization as a total variation or frame coefficients. This problem is addressed using the discrepancy principle. The standard weighted criterion composed of a data term and a regularization term is rewritten as a constrained minimization problem. The constraint is designed on the data term using the discrepancy principle and a new estimation of the bound is proposed as well as an efficient algorithm to solve this constrained minimization problem. This work is published in [10], [24], [9].

6.4.2. Brain vascular network segmentation

**Participant:** Xavier Descombes [contact].

*This work was conducted in collaboration with Franck Plouraboué and Abdelhakim El Boustani from IMFT Toulouse and Caroline Fonta from CerCo Toulouse. It has been partially supported by a PEP II project from CNRS.*

Micro-tomography produces high resolution images of biological structures such as vascular networks. We have proposed a new approach for segmenting vascular network into pathological and normal regions from considering their micro-vessel 3D structure only. We consider a partition of the volume obtained by a watershed algorithm based on the distance from the nearest vessel. Each region is characterized by its volume and the local vascular density. The volume and density maps are first regularized by minimizing the total variation. Then, a new approach has been proposed to segment the volume from the two previous restored images based on hypothesis testing. Results are presented on 3D micro-tomographic images of the brain micro-vascular network (see Fig. 16).

![Figure 16. Brain micro-vascular network segmentation](image)

6.4.3. Blind restoration of 3D biological image

**Participants:** Saima Ben Hadj, Laure Blanc-Féraud [contact].
Fluorescence microscopy is a powerful imaging technique providing three-dimensional images of biological living specimen. However, these images are degraded by a depth variant blur due to light diffraction phenomenon as well as refractive index mismatch between the different mediums composing the system and the biological sample. They are also distorted with noise from non-ideal imaging conditions. In order to provide biologist with more suitable images for quantitative studies, many restoration methods were developed. In most of them, the blur function, called Point Spread Function (PSF) is assumed to be piecewise constant in order to avoid the intensive computing time when using a pointwise varying PSF. However, this usually leads to blocking effect in the restored image. In our work, we extend the Space varying (SV) blur model previously proposed in [39] for 2D astronomical images to 3D microscopy images. In that model, the degraded image is a convex combination of convolutions with a space-invariant (SI) PSF. Furthermore, we fit to that model two restoration procedures which are basically developed for a SI PSF. On the one hand, we use the Richardson-Lucy method with Total Variation regularization which is carried out under Poisson noise assumption in order to restore confocal microscopy images. We employ another method with total variation regularization adapted to images with an additive Gaussian noise in order to restore Wide Field Microscopy images. For that, we rely on a fast optimization method based on a domain-decomposition technique [36]. In particular, we study its convergence properties when using the SV blur model [31], [27]. To illustrate the interest of the proposed method, we show in Fig 17 some results obtained on a simulated bead image of Wide Field Microscopy.

![Image](image_url)

**Figure 17.** (X,Z) slices of the (a) original image, (b) degraded image (c) restored image using a SV blur model, and (d) restored image with a space-invariant PSF.

### 6.4.4. Axon imaging

**Participant:** Florence Besse [contact].

During brain development, neurons extend cellular processes (dendrites and axons) to connect to specific targets and establish functional networks. Understanding how axonal processes migrate to reach their targets and how they form new branches to build up a complex axonal tree is thus key. To characterize the properties of axonal trees, we have generated a collection of confocal 3D pictures of normal and mutant single axons labeled using a fluorescent protein. To analyze the formation of axonal trees in real-time, we have developed a protocol to dynamically image growing axons within intact Drosophila brains. In this protocol, entire brains are cultured in conditions where they can undergo cell differentiation and maturation. Axons are labeled by the fluorescent molecule GFP and are imaged over 12h, with very low-photobleaching and no associated phototoxicity, using an ultra-sensitive 2-photon microscope. Several image sequences corresponding to the growth of axons in normal conditions have been acquired (see Fig. 18).

### 6.4.5. Detection of Axons in Neuronal Images

**Participants:** Alejandro Mottini, Florence Besse, Xavier Descombes [contact].
Imaging techniques such as confocal and two-photon microscopy provide an efficient way of analyzing supra-cellular structures. It is known that the precise shape of these objects provides information on their functioning and allows the characterization of pathological states. Therefore, the analysis of the morphological differences between normal and pathological structures is of paramount importance. In particular, the analysis of neuronal axon topologies allows biologists to study the causes of neurological diseases such as Fragile X Syndrome and Alzheimer’s disease. For this purpose biologists have acquired static 3D images of mature neuron axons using fluorescent confocal microscopy.

Due to the high volume of generated image data and the tortuous nature of the axons, manual processing is infeasible. Therefore, it is necessary to develop techniques for the automatic extraction and analysis of the neuronal structures. However, since both types of images present different characteristics, two different methodologies need to be developed. The main objective of the static case is the study of the length and number of bifurcation points of the two populations of neurons. On the other hand, the focus in the dynamic
case is put on the tracking of the axonal tips. The automatic extraction of axons from confocal microscope images is a key problem in the field of neuron axon analysis. In this work we propose a solution which combines algorithms for the denoising, binarization, skeletonization, gap filling, point detection and statistical analysis in a pipeline capable of extracting the axons. Furthermore, these algorithms were incorporated in a software, developed in Matlab, which includes an easy to use GUI along with functionalities to facilitate high data throughput analysis. The software was evaluated on several 3D confocal microscope images of normal and mutated axons. Our results support the potential use of the software in helping biologist perform automatic morphological analysis of axons in fluorescent confocal microscopy images.

Figure 20. Original (left) and extracted (right) normal axon image (2D maximum intensity projection).

6.4.6. Axons tracking

Participants: Alejandro Mottini, Huei-Fang Yang, Florence Besse, Xavier Descombes [contact].

This work was funded by project ARC-DADA (INRIA/CNRS/UNSA) [ http://www-sop.inria.fr/members/Xavier.Descombes/DADA/home.html ]. It is done in collaboration with Serpico team at INRIA Bretagne (C. Kervrann, P. Houllier)

To study axon growth process biologists have acquired dynamic 3D+t image sequences of developing neurons using fluorescent two-photon microscopy.

Live cell two-photon microscopy is an effective tool for the analysis of dynamical processes occurring in living samples that, when combined with fluorescence, allows the detection of objects of interest in 3D space and time. These labeled objects appear as bright spots which need to be detected. The low resolution and signal-to-noise-ratio (SNR) make this analysis difficult even for experienced biologists. As a consequence, automatic detection techniques need to be robust and flexible. To this end, the Marked Point Process (MPP) detection framework was selected. Since axonal extremities appear either as circular objects or as ending points of thin filaments, we proposed two different MPP models. These models were formulated using a Gibbs energy function and optimized with Multiple Births and Deaths, a newly proposed algorithm which guarantees a fast convergence to the global minimum. The first model is designed to detect spheres or disks and the second filaments (both in 3D). Both models were tested on several 3D static images. To evaluate the performance of the detection, results were compared against images labeled by an experienced biologist.

Figure 22 shows the results obtained on one frame of a video sequence (the shown image is a slice of the 3D frame) for the disk/sphere model. One can appreciate that the axonal tip marked by the biologist (in white, left) was detected. However, a false positive is also present.
Figure 21. Dynamic images (2D maximum intensity projection).

Figure 22. Original (left) and resulting (right) images (detected disks in pink). The true axonal tip is circled in white (original image) and red (result). In the original image, axons are labeled in white.
Figure 23 shows the result obtained on one of the slices (for the same video frame) for the filament model. Although the good filament was detected, many false positives are also present in the image. Similar results were obtained for other images.

Once the detection of the extremities in each frame of the video has been solved, the solution should be embedded into a tracking algorithm to obtain an estimation of the axon’s trajectory during the growing stage. To this end, the particle filtering technique was considered. This technique consists in estimating the posterior distribution of the current state $x_t$ of the target of interest at time $t$ based on the measurements $z_{1..t}$:

$$p(x_t|z_{1..t}) \propto p(z_t|x_t) \int p(x_t|x_{t-1}) p(x_{t-1}|z_{1..t-1}) dx_{t-1},$$

(1)

where $p(x_t|x_{t-1})$ is the transition distribution, and $p(z_t|x_t)$ is the likelihood. In the current implementation, a simple kinematic model is used for the transition distribution, and a color histogram is applied to the computation of the likelihood. Figure 24 shows the preliminary results obtained by applying the particle filtering technique on the coronal KESM (Knife-Edge Scanning Microscopy) sections of the mouse cerebellum, where the green rectangles indicate the tracked objects.

Figure 24. Tracking results on the coronal KESM sections of the mouse cerebellum. The green rectangles are the tracked objects. The user gives an initial starting region on the first image, and the algorithm tracks the region of interest in the subsequent images. Note that the images are cropped for a better view.
The next step will be to design a more sophisticated transition distribution and likelihood model that are suitable for tracking the trajectories of axons during their growth.

6.5. Dermatology

6.5.1. Statistical analysis of skin pigmentation under treatment

Participants: Sylvain Prigent, Xavier Descombes, Josiane Zerubia [contact].

This work was partially funded by a contract with Galderma R&D [http://www.galderma.com/RampD.aspx].

One of the steps to evaluate the efficiency of a therapeutic solution is to perform measurements on a series of patients who received the studied treatment. In parallel another treatment is tested on another group of people or on the same group of patients on another skin area. This second treatment is the reference one for the studied pathology or a placebo. We will call it ‘vehicle’.

For facial hyper-pigmentation, for each studied treatment, a group of $N_e$ patients receives the treatment on one cheek and the vehicle on the other. To this end, patients are selected to have the same hyper-pigmentation severity on the two cheeks. Then multi-spectral images are taken at different times $t$ along the treatment period.

We propose a methodology to estimate the efficiency of a treatment by calculating a spectral criterion that maximizes the visibility of the disease comparatively to a healthy reference area. To design such a criterion, we compare three approaches. The first one gives weights to spectral bands in order to get an equivalent of the luminance from the $CIEL^*a^*b^*$ decomposition. This is the standard measure in dermatology. We compare this spectral measurement to a spectral signature obtained by ICA (Independent Components Analysis) in a whole study, and a criterion that searches for the highest contrasted band.

Once a criterion is designed, we compute the hyper-pigmentation severity of a patient by normalizing the pathological area with the healthy area and the active treatment measurement by the vehicle. That gives severity measurement distributions from patients at different times. A Student paired test allows to determine if an active treatment has an effect between two measurement times. The experiments done on 3 treatments and their associated vehicles brought to the following conclusion: The severity measure based on the selection of an optimal band allows to detect a treatment effect sooner than the two other approaches. The severity measurements obtained by the optimal band method is illustrated in figure 25.

![Figure 25. Evolution of skin pigmentation in the time and its quantification.](image-url)
6. New Results

6.1. Introduction

The ARLES project-team investigates solutions in the forms of languages, methods, tools and supporting middleware to assist the development of distributed software systems, with a special emphasis on mobile distributed systems enabling the ambient intelligence/pervasive computing vision. Our research activities in 2011 have focused on the following areas:

- Dynamic interoperability among networked systems toward making them eternal, by way of on-the-fly generation of connectors based on adequate system models (§ 6.2);
- Pervasive service-oriented software engineering, focusing on supporting service composition in an increasingly heterogeneous and dynamic networking environment, while enforcing quality of service (§ 6.3);
- Service oriented middleware for the ultra large scale future Internet of Things (§ 6.4);
- Abstractions for enabling domain experts to easily compose applications on the Internet of Things (§ 6.5); and
- System-level support for application development in the context of mobile social ecosystems, while taking into account privacy, performance, and data interoperability (§ 6.6).

6.2. Emergent Middleware Supporting Interoperability in Extreme Distributed Systems

Participants: Emil Andriescu, Nelly Bencomo, Amel Bennaceur, Luca Cavallaro, Nikolaos Georgantas, Sneha-Sham Godbole, Valérie Issarny, Rachid Saadi, Daniel Sykes.

Interoperability is a fundamental challenge for today’s extreme distributed systems. Indeed, the high-level of heterogeneity in both the application layer and the underlying infrastructure, together with the conflicting assumptions that each system makes about its execution environment hinder the successful interoperation of independently developed systems. A wide range of approaches have been proposed to address the interoperability challenge [31]. Solutions that require performing changes to the systems are usually not feasible since the systems to be integrated may be legacy systems, COTS (Commercial Off-The-Shelf) components or built by third parties; neither are the approaches that prune the behavior leading to mismatches since they also restrict the systems’ functionality. Therefore, many solutions that aggregate the disparate systems in a non-intrusive way have been proposed. These solutions use intermediary software entities, called mediators, to interconnect systems despite disparities in their data and/or interaction models by performing the necessary coordination and translations while keeping them loosely-coupled. However, creating mediators requires a substantial development effort and a thorough knowledge of the application-domain, which is best understood by domain experts. Moreover, the increasing complexity of today’s distributed systems, sometimes referred to as Systems of Systems, makes it almost impossible to develop ‘correct’ mediators manually. Therefore, formal approaches are used to synthesize mediators automatically.
In light of the above, we have introduced the notion of \textit{emergent middleware} for realizing mediators. Our research on enabling emergent mediators is done in collaboration with our partners of the \textsc{Connect} project (§ 7.1.1). Our work during the year has more specifically focused on:

\begin{itemize}
  \item \textbf{Supporting architecture}. We have been working together with our partners in the \textsc{Connect} project on the refinement of an overall architecture supporting emergent middleware, from the discovery of networked systems to the learning of their respective behavior, and synthesis of emergent middleware enabling them to interoperate [30].
  \item \textbf{Affordance inference}. We have proposed an ontology-based formal model of networked systems based on their affordances, interfaces, behavior, and non-functional properties, each of which describes a different facet of the system [2]. However, legacy systems do not necessarily specify all of the aforementioned facets. Therefore, we are currently exploring techniques to infer the affordance by using textual descriptions of the interface of networked systems. More specifically, we rely on machine learning techniques to automate the inference of the affordance from the interface description by classifying the natural-language text according to a predefined ontology of affordances [17].
  \item \textbf{Mediator synthesis for emergent connectors}. We focus on systems that have compatible functionality, i.e., semantically matching affordances, but are unable to interact successfully due to mismatching interfaces or behaviors. We propose two approaches to enable communication between such systems:
    \begin{enumerate}
    \item A \textit{mapping based} approach, whose goal is to automatically synthesize a mediator model that ensures their \textit{safe} interaction, i.e., deadlock-freedom and the absence of unspecified receptions. Our approach combines semantic reasoning and constraint programming to identify the semantic correspondence between networked systems’ interfaces, i.e., \textit{interface mapping}. Unlike existing approaches that only tackle the one-to-one correspondence between actions, this approach handles the more general cases of one-to-many and many-to-many mappings.
    \item A \textit{goal based} approach, which enables the communication of two networked systems, so that the communication satisfies a given user goal. It aligns their actions using ontology matching. The aligned processes as well as the user goal are encoded as a satisfiability problem. It relies on model checking to determine if a feasible communication trace exists that satisfies the user goal. The model checking process is reiterated so as to discover all the feasible satisfying traces, which are finally concatenated to build the mediator.
    \end{enumerate}
\end{itemize}

The feasibility of both of our approaches has been demonstrated through prototype tools and real-world scenarios involving heterogeneous systems.

\begin{itemize}
  \item \textbf{Mediator synthesis for streaming connectors}. In the context of dynamic mediator synthesis, we have targeted the domain of mobile multimedia streaming, resulting in a first step that statically solves the hard problem of streaming interoperability across heterogeneous smartphone multimedia platforms. With the recent evolution of mobile phones, multimedia streaming is now commonly used in smartphones for purposes such as video broadcast, video conferencing and place shifting, which in turn highlights the importance of multimedia enabled applications. However, peer-to-peer solutions are difficult to implement because of increased node heterogeneity and their low processing power. Furthermore, existing mobile platforms such as Android, iOS, Blackberry and Windows Phone 7 support multimedia streaming (as resource consumers) either through platform specific APIs or system services. However, they use heterogeneous protocols and data formats, thus compromising interoperability.

  Given the challenges above, we designed \textsc{AmbiStream} [11], a lightweight middleware for heterogeneous mobile devices, capable of “on the fly” adaptation. \textsc{AmbiStream} relies on the highly-optimized multimedia software stacks provided by smartphone platforms and adds the necessary
layers to solve interoperability. More specifically, the middleware targets: a) Streaming of prerecorded or live audio/video using an intermediary real-time protocol; b) Managing streaming protocol translation and multimedia container format adaptation to the ones supported natively by each device; and c) Extensibility in order to support new multimedia streaming protocols and multimedia container formats given its plug-in based architecture. We have used a model-driven approach to generate multi-platform plug-ins from higher level descriptions in the form of a Domain Specific Language (DSL). The defined DSL takes into account multimedia specific operations such as timing, fragmenting, multiplexing, congestion control and buffering.

• **Models@run.time.** We have recently integrated the notion of Models@run.time in our research towards emergent middleware. We use Models@run.time to extend the applicability of models and abstractions to the runtime environment. As is the case for software development models, a run-time model is often created to support reasoning. However, in contrast to development models, run-time models are used to reason about the operating environment and runtime behavior, and thus these models must capture abstractions of runtime phenomena. Different dimensions need to be balanced, including resource-efficiency (time, memory, energy), context-dependency (time, location, platform), as well as personalization (quality-of-service specifications, profiles). The hypothesis is that because Models@run.time provide meta-information for these dimensions during execution, run-time decisions can be facilitated and better automated. Thus, we anticipate that Models@run.time will play an integral role in the management of extremely distributed systems.

  Our work on the use of Models@run.time has two aspects:

  – We have used Models@run.time to tackle the crucial problem of uncertainty in extremely distributed systems that are aware of their own requirements. Requirements awareness helps optimize requirements satisfaction when factors that were uncertain at design time are resolved at runtime. Using our approach, we are able to maintain goal-based models in memory while the system is running. The executing system, therefore, is able to introspect and consult it goals during runtime. Crucially, at runtime we use the notion of claims to represent assumptions that cannot be verified with confidence at design time. Such claims are attached to the goal-based runtime models. By monitoring claims at runtime, their veracity can be tested. If falsified, the effect of claim negation can be propagated to the system’s goal model and an alternative means of goal realization can be selected automatically, allowing the dynamic adaptation of the system to the prevailing environmental context.

  – In a complementary way to the mediator synthesis approaches discussed above, we further promote the use of Models@run.time to support the runtime synthesis of software that will be part of the executing system. Specifically, we focus on the use of runtime models to support the realization of emergent middleware, i.e., the synthesis of mediators that define a sequences of actions to translate semantic actions of one system developed using a particular middleware protocol to the semantic actions of another system developed using an alternate middleware built with no prior knowledge on the former. Discovery and learning enablers capture the required knowledge of the context and environment during runtime. Supported by that knowledge, a runtime model of the mediator-to-be is reified. Reification means that the knowledge is explicitly formulated and made available for computational manipulation. The form of the runtime models is based on labeled transition systems (LTSs) which offer the behavioral semantics needed to model the interaction protocols. Ontologies complement the LTSs providing semantic reasoning about the mapping between protocols. Specifically the LTS of each protocol is annotated using ontologies to support the subsequent mapping between the protocols. From the LTS-based runtime models, mediators are synthesized.

6.3. Revisiting the Abstractions of Service Oriented Computing for the Future Internet

Participants: Mohammad Ashiqur Rahaman, Dionysis Athanasopoulos, Sandrine Beauche, Nebil Ben Mabrouk, Nikolaos Georgantas, Valérie Issarny.

A software architecture style characterizes, via a set of abstractions, the types of: components (i.e., units of computation or data stores), connectors (i.e., interaction protocols) and possibly configurations (i.e., system structures) that serve to build a given class of systems. As such, the definition of a software architectural style is central toward eliciting appropriate design, development and runtime support for any family of systems. The service oriented architecture style may then be briefly defined as follows: (1) components map to services, which may be refined into consumer, producer or prosumer services; (2) connectors map to traditional client-service interaction protocols; and (3) configurations map to compositions of services through (service-oriented) connectors, e.g., choreography and orchestration structures. While the service-oriented architecture style is well suited to support the development of Internet-based distributed systems, it is largely challenged by the Future Internet that poses new demands in terms of sustaining qualities such as scalability, heterogeneity, mobility, awareness & adaptability that come in extreme degrees compared to the current Internet. Therefore, we have been working on eliciting software architectural abstractions for the Future Internet by building upon the service-oriented architecture style, as well as on applying them to system design, development and execution.

Complex distributed applications in the Future Internet will be to a large extent based on the open integration of extremely heterogeneous systems, such as lightweight embedded systems (e.g., sensors, actuators and networks of them), mobile systems (e.g., smartphone applications), and resource-rich IT systems (e.g., systems hosted on enterprise servers and Cloud infrastructures). These heterogeneous system domains differ significantly in terms of interaction paradigms, communication protocols, and data representation models, provided by supporting middleware platforms. Specifically considering interaction paradigms, the client/server (CS), publish/subscribe (PS), and tuple space (TS) paradigms are among the most widely employed ones today, with numerous related middleware platforms. In light of the above, we have aimed at eliciting abstractions that (i) leverage the diversity of interaction paradigms associated with today’s and future complex distributed systems, as well as (ii) enable cross-paradigm interaction to sustain interoperability in the highly heterogeneous Future Internet [19].

Existing cross-domain interoperability efforts are based on bridging communication protocols, wrapping systems behind standard technology interfaces, and/or providing common API abstractions. In particular, such techniques have been applied by the two widely established system integration paradigms, that is, service oriented architecture (SOA) and enterprise service bus (ESB). However, state of the art interoperability efforts do not or only poorly address interaction paradigm interoperability. Indeed, systems integrated via SOA and ESB solutions have their interaction semantics transformed to the CS paradigm. Then, potential loss of interaction semantics can result in suboptimal or even problematic system integration. To overcome the limitation of today’s ESB-based connectors for cross-domain interoperability in the Future Internet, we introduce a new connector type, called GA connector, which stands for “Generic Application connector”. The proposed connector type is based on the service bus paradigm in that it achieves bridging across heterogeneous connector types. However, the behavior of the GA connector type differs from that of classical ESB connectors by bridging protocols across heterogeneous paradigms, which is further realized by paying special attention to the preservation of the semantics of the composed protocols. Indeed, the GA connector type is based on the abstraction and semantic-preserving merging of the common high-level semantics of base interaction paradigms.

Eliciting Interaction Paradigm Abstractions: We introduce a systematic abstraction of interaction paradigms with the following features:

- First, we introduce base CS, PS and TS connector types, which formally characterize today’s core interaction paradigms. The proposed types comprehensively cover the essential semantics of the considered paradigms, based on a thorough survey of the related literature and representative
Then, we further abstract these connector types into a single higher-level one, the GA connector type. GA is a comprehensive connector type based on the abstract union of CS, PS, and TS, where precise identification of the commonalities or similarities between the latter has enabled the optimization of the former. Further, GA preserves by construction the semantics of CS, PS, and TS.

In more detail, connector types are formally specified in terms of: (i) their API (Application Programming Interface), and (ii) their roles, i.e., the semantics of interaction of the connected component(s) with the environment via the connector. Regarding the latter, the behavioral specification of roles from a middleware perspective relates to specifying the production and consumption of information in the network, while the semantics of the information are abstracted and dealt with at the application layer. The behaviors of the connector roles are then specified using Labeled Transition Systems (LTS). We precisely define the mapping of the roles implemented by the base connector types to/from the corresponding roles of the GA connector type.

For both the above abstraction transformations, we provide counterpart concretizations, which enable transforming GA connector primitives to CS, PS, or TS connector primitives and then to concrete middleware platforms primitives.

Furthermore, based on the GA abstraction, we introduce mapping transformations between any pair from the set \{CS, PS, TS\} via GA. The fine knowledge of CS, PS, and TS semantics, as embedded in GA, enables these mappings to be precise: differing semantics are mapped to each other in such a way that loss of semantics is limited to the minimum. These mappings relate to the definition of the glue process implemented by the GA connector, which defines how a pair of producer and consumer roles coordinates in the environment. The GA glue reconciles consumer and producer roles that may differ with respect to time and space coupling as well as scoping. Hence, GA connectors support interactions among highly heterogeneous services of the Future Internet, and especially across domains.

eXtensible Service Bus: We apply the above connector abstractions to introduce an enhanced bus paradigm, the eXtensible Service Bus (XSB). XSB features richer interaction semantics than common ESB implementations to deal effectively with the increased Future Internet heterogeneity. Moreover, from its very conception, XSB incorporates special consideration for the cross-integration of heterogeneous interaction paradigms. When mapping between such paradigms, special attention is paid to the preservation of interaction semantics. XSB has the following features:

- XSB is an abstract bus that prescribes only the high-level semantics of the common bus protocol. The XSB common bus protocol features GA semantics.
- Heterogeneous systems can be plugged into the XSB by employing binding components that adapt between the native middleware of the deployed system and the common bus protocol. This adaptation is based on the systematic abstractions and mappings discussed above.
- XSB, being an abstract bus, can have different implementations. This means that it needs to be complemented with a substrate which at least supports: (1) deployment (i.e., plugging) of various systems on the bus, and (2) a common bus protocol implementing GA semantics. With respect to the latter, we envision that a GA protocol realization may either be designed and built from scratch (still supposing at least an IP-based transport substrate) or be implemented by conveying GA semantics on top of an existing higher-level protocol used as transport carrier. The latter solution can be attractive, as it facilitates GA protocol realizations in different contexts and domains.

We have carried out an early realization of XSB on the PEtALS ESB. In particular, we addressed the workflow-based orchestration of heterogeneous systems, which is a preliminary step before dealing with peer-wise system integration. This work already provides a successful feasibility study of the XSB concept. This work comprises: (i) extending the BPEL workflow language with GA API primitives; (ii) introducing transformation between the GA-extended BPEL and the standard BPEL, which consists in encapsulating GA primitives into standard BPEL primitives and enables conveying GA semantics on top of BPEL primitives.
and subsequently on top of the common bus protocol primitives; (iii) providing templates for systematic and highly facilitated building of binding components; and (iv) introducing transformations between native system interface descriptions and GA-based interface descriptions.

6.4. Service Oriented Middleware facing the Challenges of the Internet of Things

Participants: Benjamin Billet, Nikolaos Georgantas, Sara Hachem, Valérie Issarny, Roberto Speicys Cardoso, Thiago Valladares Sabino Teixeira.

Over the years, the Internet has become the most important networking infrastructure, providing an integrated entity enabling sharing, contributing, creating, using, collaborating and integrating information and knowledge by all. As a result, the Internet is changing at fast pace and is expected to evolve into the Future Internet, i.e., service-aware and self-aware federated networks that provide built-in and integrated capabilities such as: contextualization, reliability, robustness, mobility, security, service support, and self-management of communication resources and services. In our vision, The Future Internet can be defined as the union and cooperation of the Internet of Content, Internet of Services, Internet of Things, and 3D interactive Internet, supported by an expanding network infrastructure foundation. In ARLES, we chose to pay special attention to the Internet of Things (IoT). IoT is characterized by the integration of large numbers of real-world objects (or “things”) onto the Internet, with the aim of turning high-level interactions with the physical world into a matter as simple as is interacting with the virtual world today. As such, two devices that will play a key role in the IoT are sensors and actuators. In fact, such devices are already seeing widespread adoption in the highly localized systems within our cars, mobile phones, laptops, home appliances, etc. In their current incarnation, however, sensors and actuators are used for little more than low-level inferences and basic services. This is partly due to their highly specialized domains (signal processing, estimation theory, robotics, etc.), which demand application programmers to also be domain experts, and partly due to a glaring lack of interconnectivity between all the different devices. Our work within that domain was focused on three related directions:

- **Challenges related to IoT:** To prepare the ground for our research on middleware for the Internet of Things, we identified the set of challenges in the IoT, namely [10]: the large scale of the Internet of Things, heterogeneity of things, unknown and dynamic network topology, unknown data-point availability, incomplete or inaccurate metadata, and conflict resolution. The scale issue arises with the millions of devices, millions of users, large amounts of data to share and services to request. The heterogeneity of the IoT is due to the fact that the network will be composed of different types of devices from different vendors with varying sensing/actuating characteristics. The unknown dynamic network topology results from the fact that devices will be mostly mobile and their availability is unknown. A related challenge is the unknown data-point availability as things, which provide the desired measurements, may leave the network or malfunction at any time. A data point is measurement of an entity of interest at a specific time. As for metadata inaccuracy, this issue is a direct result of humans, who are prone to making errors, being the main source of metadata specification. Last but not least, conflict resolution is due to the multiple stakeholders involved in the Internet of Things.

- **Middleware Requirements for the Internet of Things:** The middleware we plan on implementing should abstract things (IoT devices) as services and support dynamic service composition. To handle the IoT challenges, the middleware should also support a probabilistic discovery approach where only a subset, instead of a whole set, of devices is selected in a way that provides a good enough answer that satisfies an application’s request [10]. However, and prior to designing the middleware architecture, we extensively surveyed the literature in order to identify research challenges for service-oriented middleware design, therefore investigating service description, discovery, access and composition in the Future Internet of services [7].

- **Ontologies for the Internet of Things:** As part of our middleware architecture, we specified a set of ontologies [20] that model real-world entities as physical concepts, along with things that measure
those entities. Further, to support a smarter service composition, we also modeled mathematical formulas and physics relations as services to substitute missing thing-based services. Those services will instead compute the value of a desired measurement of an entity of interest. Finally, we also specified an ontology that describes estimation models that can be used to estimate the value of a measurement in case of a missing data point or a missing data source. Estimation models can further be used to define probabilistic discovery functions that will be executed by the middleware.

6.5. Composing Applications in the Internet of Things

Participants: Iraklis Leontiadis, Pankesh Patel, Animesh Pathak.

As introduced above, the Internet of Things (IoT) integrates the physical world with the existing Internet, and is rapidly gaining popularity, thanks to the increased adoption of smart phones and sensing devices. Several IoT applications have been reported in recent research, and we expect to see increased adoption of IoT concepts in the fields of personal health, inventory management, and domestic energy usage monitoring, among others.

An important challenge to be addressed in the domain of IoT is to enable domain experts (health-care professionals, architects, city planners, etc.) to develop applications in their fields rapidly, with minimal support from skilled computer science professionals. Similar challenges have already been addressed in the closely related fields of Wireless Sensor and Actuator Networks (WSANs) and Pervasive/Ubiquitous computing. While the main challenge in the former is the extremely large scale of the systems (hundreds to thousands of largely similar nodes, sensing and acting on the environment), the primary concern in the latter has been the heterogeneity of nodes and the major role that the user’s own interaction with these nodes plays in these systems (cf. the classic “smart home” scenario where the user interacts with a smart display which works together with his refrigerator and toaster). The upcoming field of IoT includes both WSANs as well as smart appliances, in addition to the elements of the “traditional” Internet such as Web and database servers, exposing their functionalities as Web services etc. Consequently, an ideal application development abstraction of the IoT will allow (domain expert) developers to intuitively specify the rich interactions between the extremely large number of disparate devices in the future Internet of Things.

The larger goal of our research is to propose a suitable application development framework which addresses the challenges introduced above. This will most likely be achieved by a domain specific language (DSL) that exposes specific functionalities to the domain experts. The first logical step was to construct a domain model. Towards that end, we took advantage of the CRC — Classes, Responsibility, Collaboration — technique, defining the main abstract concepts, their responsibilities, and associations that represent their relationship with each other in the IoT. Specifically, we used this technique to propose a domain model [22] that addresses the following challenges:

- **Creation of common understanding.** The different terms used by different people in the IoT domain can lead to confusion, which can be alleviated by the usage of a common lexicon, as provided by a domain model. This lexicon can then be used by researchers, system programmers, as well as domain experts.

- **Modeling invariant properties.** The domain model represents the invariant properties of the domain — concepts and relationships which do not change from one application to the other. An instance of this in the IoT domain can be the notion of a sensor attached to a device. Depending on the specific applications, the type of sensors and devices can change (e.g., a light sensor attached to a smart phone), but the inherent relationship between the types of entities they represent does not.

- **Enabling modular design.** Application needs often tend to arrive in terms of behavior, which needs to be broken down and divided among the entities in the system. A good domain model aids in this process, since the capabilities of each type of entity are clearly identified. E.g., the application requirement of “the system senses the temperature of a room and keeps it steady” can be easily broken down into an application consisting of temperature sensors, computational components, and HVAC actuators, each performing its well-known role in this sense-compute-actuate loop.
As part of a related effort with a narrower focus on the domain of sensor network macroprogramming — a technique that aims to aid the wide adoption of networked sensing by providing the domain expert the ability to specify their applications at a high level of abstraction — we have explored techniques to bring Web services in the gamut of sensor network macroprogramming. Our research addresses the challenges faced by developers of systems where sensors (e.g., RFID badge sensors in an office) interact with pre-existing larger software components exposed as Web services (e.g., the office personnel access control database). As part of our work, we have proposed extensions to the data-driven ATaG macroprogramming language using which developers can easily incorporate existing Web services in their applications.

We have incorporated our continued research in the above areas into Srijan (§ 5.5), which provides an easy-to-use graphical front-end to the various steps involved in developing an application using the ATaG macroprogramming framework.

6.6. Addressing Middleware Challenges in Large Scale Mobile Social Networks of the Future

Participants: Sara Hachem, Valérie Issarny, Animesh Pathak, Amir Seyedi.

With the increased prevalence of advanced mobile devices (the so-called “smart” phones), interest has grown in Mobile Social Ecosystems (MSE), where users not only access traditional on line Web-based social networks using their mobile devices, but are also able to use the context information provided by these devices to further enrich their interactions. In complex mobile social ecosystems of the future, the heterogeneity of software platforms on constituent nodes, combined with their intrinsic distributed nature and heterogeneity in representation of data and context, as well as user’s privacy and trust concerns, raises the need for middleware support for the development of mobile social applications. We believe that the development of mobile social applications can be greatly simplified by the presence of middleware support. To that end, we have been working on addressing the following challenges:

- **Semantic models for mobile social ecosystems.** In order to enable re-use of data between different social applications run by the same user, we have proposed an expressive and extensible model using semantic techniques to represent MSE and the interactions possible in them. This supports semantic interoperability between separately developed applications and minimizes resource-consuming operations such as data mapping and replication.

- **Efficient decentralized storage of social data.** Instead of storing the social knowledge of the whole world with a single provider — a practice performed today by common social networks such as Facebook — which can lead to privacy issues, our research endeavors to propose a middleware using which users can store their personal knowledge in a distributed manner on the devices owned by them (e.g., smart phone, home desktop, laptop). This also allows users to provide selective access to other users based on semantically defined access control policies.

- **Socially aware policies for access control.** Since social data is private and sensitive in nature, we have proposed a policy framework [21] where the user can specify both the data to be protected as well as the relevant set of peers with access to that data in a socially-aware manner (e.g., “only let my colleagues know my location during weekdays from 9 – 5”). This policy framework can be used as a guard around the user’s knowledge base, allowing access only to authorized peers. We are also working on providing end-users an easy to use editor so as to be able to specify these socially-aware policies easily.

- **Social data extraction from existing sources.** Our research includes work in enabling users to populate their social knowledge base by extracting data from their existing repositories. We have identified two types of sources of such data. The first already contain social links such as “friendship” in addition to general information, while the second do not contain social links, but may contain information which can be correlated to infer social links (e.g., call and SMS logs). We are working on a framework where adapters can be written for the former using their API to import their data; while for the latter, inference algorithms can be used to correlate data and guess/recommend social links.
• **Inferring trust from proximity.** In mobile social network, highly sensitive private data is at risk of being shared with unwanted peers, since users may not have any knowledge about the users they socially connect with. Trust management then appears as a promising decision support for mobile users in establishing social links. However, while the literature is rich in trust models, most approaches lack appropriate *trust bootstrapping*, i.e., the initialization of trust values. In [24], we address this challenge by introducing proximity-based trust initialization based on the users’ behavioral data available from their mobile devices or other types of social interactions. The proposed approach is further assessed in the context of mobile social networking using users behavioral data collected by the MIT reality mining project. Results show that the inferred trust values correlate with the self-reported survey of users relationships.

We have incorporated our research in the above areas into Yarta [25], a middleware for mobile social applications. Our prototype middleware, as discussed in §5.6, currently supports application development for laptops as well as Android-powered smart phones, providing distributed storage of semantically-modeled social knowledge guarded by a rich policy framework.
6. New Results

6.1. Perception and autonomous navigation

Participants: Patrick Rives, Pascal Morin, Andrew Comport, Alexandre Chapoulie, Gabriela Gallegos, Cyril Joly, Maxime Meilland, Glauco Scandaroli.

6.1.1. Indoor SLAM: Self-calibration of the camera frame with respect to the odometry frame

Fusing visual data and odometry information is a standard technique to improve the robustness of the SLAM solution. Odometry data is considered as an input of the motion prediction equation while the visual data constitutes the filter observation. However, such method requires that the system is well calibrated: the pose of the camera frame with respect to the odometry frame has to be known. Usually, this pose is directly obtained by an hand made measurement yielding to incorrect values. We propose a new self calibration method to get these calibration parameters automatically. In practice, the state in the SLAM formulation is augmented with the unknown camera parameters (with respect to the odometry frame). This method requires to adapt a few Jacobians with respect to the original SLAM algorithm which assumes that these parameters are known. The accuracy and the stability of the estimation scheme clearly depends on the observability and the conditioning properties of the new system.

In 2010, we presented results in the case where the camera frame location has only 3 degrees of freedom (two translations and a rotation with respect to the vertical $z$ axis). This year, these results were extended to the full calibration problem. As in the previous case, we assume that the robot is moving on a horizontal ground and observes 3D landmarks from the images delivered by the on board camera. The five parameters introduced by the calibration problem - 2 translations and 3 rotations (only 2 translations since the $z$ component is not observable due to the planar motion of the robot) - are estimated simultaneously in addition to the "classical" SLAM parameters. The implementation of the algorithm is based on a Smoothing And Mapping (SAM) approach which computes a solution by considering the whole trajectory (instead of only the current pose as with the EKF approach).

As a theoretical result, we prove that this augmented system remains observable if and only if the curvature of the robot trajectory changes. This analysis was validated on real data with our indoor robot. Fig. 2 shows the mobile platform and the camera. It can be seen that an important rotational offset was added on the camera to test the capability to deal with large rotational values (the parameters are initialized with identity). Results are provided on Fig. 3 - 4 and table 1. They show that the trajectory and the map seem consistent; moreover, the algorithm was able to correct the odometry drift (green trajectory on Fig. 3). Then, the observability analysis was validated since the estimation of the camera frame parameters begins when there is a significant change in the radius of curvature of the trajectory (see the confidence bounds on Fig. 4). Finally, the estimation of these parameters was consistent with the ground truth (table 1). These results were presented at IROS’11 conference [30].

6.1.2. Outdoor Visual SLAM

Safe and autonomous navigation in complex outdoor urban-like environment requires a precise and real time localization of the robot. Standard methods, like odometry, typically performed by wheel encoders or inertial sensors, are prone to drift and not reliable for large displacements. Low cost GPS stations are inaccurate and satellite masking effect happens too frequently due to corridor-like configurations. We develop a real time and accurate localization method based on vision only without requiring any additional sensor.

Our approach relies on a monocular camera on board the vehicle and the use of a database of spherical images of the urban scene acquired during an offline phase. This geo-referenced database allows us to obtain a robust “drift free” localization. Basically, the database is constituted of spherical images augmented by depth which are positioned in a GIS (Geographic information system). This spherical robot centered representation accurately represents all necessary information for vision based navigation and mapping ([26]). During the online navigation, the current vehicle position is computed by aligning the current vehicle camera view with the closest reference sphere extracted from the database.

A spherical augmented acquisition system has been developed and tested on our Cycab vehicle. This system is composed of six wide angle stereo cameras in overlap, which permits to extract depth information by dense correspondence. Since the depth is available, we are able to construct 360 degrees spherical images with a unique center of projection. Those 3D spheres are then used in an image-based spherical odometry algorithm to obtain the trajectory of the vehicle ([31]), fuse the spheres and construct the database.

During the online navigation, we consider a vehicle equipped with a simple camera (perspective, omnidirectional...). Here the aim is to register the current view on the closest sphere stored in the database. To achieve this we have developed a spherical image-based registration which allows efficient and accurate localization. But since the database of augmented visual spheres can be acquired under different illumination conditions than the online camera is experiencing, a robust algorithm combining model based localization and online visual odometry has been developed [32]. This method performs in real-time (45 Hz), and allows to handle large illumination changes and outliers rejection (see figure 5).

As a part of the ANR CityVIP project, the localization and mapping system has been successfully tested in Clermont Ferrand (France). A database of augmented images has been built along a learning trajectory. The aim was to automatically “replay” the learning trajectory using the database and a monocular camera. To avoid collisions and pedestrians, a laser was mounted on the front of the Cycab. The system was able to autonomously follow large scale trajectories (over 400 meters), in crowded urban environments (see figure 6).

6.1.3. Loop closure detection for spherical view based SLAM

Although more precise than the odometry computed from the wheels encoders, the visual odometry also suffers from the problem of drift when large displacements are performed. It is possible to correct this drift if the robot is capable to determine if the place it is visiting has already been visited, re-observes a scene previously observed. This is often referred as the loop closure detection problem and several methods exist in the literature using perspective cameras. We develop new methods more reliable by exploiting the peculiar properties of spherical cameras.

Standard perspective cameras have a limited field of view leading to an incapability to encompass all the surrounding environment. This limitation of the field of view drastically limits the performances of visual loop closure algorithms. We propose to use spheres of vision computed by mosaicing images from 6 wide angle cameras mounted on a ring. Such a representation offers a full 360° field of view and keeps the spherical image invariant to the changes in orientations (Figure 7).

Loop closure detection can be exploited in a SLAM context at two levels: firstly, in the metric representation to retro-propagate along the robot’s trajectory the cumulative errors due to the drift, secondly, in the topological representation, to fusion in the graph representation the nodes corresponding to a same place.

Existing algorithms are not point of view independent: loop closures are detected uniquely when a place is revisited by the robot coming from the same direction but if the robot comes back in a different direction, the algorithms fail. Our solution relies on the presented spherical view and an efficient way of information extraction from it. We extract local information describing the points of interest of the scene. We enhance this local information with a global descriptor characteristic of the distribution of the points of interest over the sphere thereby describing the environment structure. These informations are used to retrieve the already visited places. Our algorithm performs well and is robust to the point of view variation [27]. This has led to an accepted paper at OMNIVIS 2011.
Figure 7. Spherical view acquisition

The figure 8 below presents obtained results. The trajectory is corrected (drift reduction) using the loop closure constraint. Red and green dots represent the loop closing places, they are linked by a red line.

Figure 8. Loop closure detection and trajectory drift correction

6.1.4. Context-based segmentation of scenes

In a topological SLAM framework based on vision, the places are often represented by images gathered at regular time/distance intervals. It is nevertheless a meaningless representation in the context of topology. We
would prefer a definition like "in front of a building" or "entrance of the campus" instead of "image number i". Places are thus a set of images we need to group. This is what we call context based segmentation. In order to achieve this segmentation a criterion for "changing place" is needed, we propose to evaluate the environment structure using a global spatial descriptor (computed on the spherical view) called GIST. The algorithm relies on a statistical process control monitoring for an out-of-control signal involving a changing place event. The algorithm still needs to be improved for better robustness on the localization of the changing place events when we come back on previous visited paths.

The figure 9 presents the preliminary results. On the bottom left is the similarity matrix of the images GIST while on the bottom right is the segmented trajectory followed by our robot.

![Figure 9. Context-based segmentation of scenes](image)

### 6.1.5. Nonlinear observers for visual-inertial fusion with IMU-bias and camera-to-IMU rotation estimation

This work concerns the fusion of visual and inertial measurements in order to obtain high-frequency and accurate pose estimates of a visual-inertial sensor. While cameras can provide fairly accurate pose (position and orientation) estimates, the data acquisition frequency and signal processing complexity limit the capacities of such sensors in the case of highly dynamic motions. An IMU (Inertial Measurement Unit) can efficiently complement the visual sensor due to its high frequency acquisition, large bandwidth, and easy-to-process signals. IMU biases and calibration errors of the displacement between the camera frame and the IMU frame, however, can severely impair the fusion of visual and inertial data. Identification of these biases and calibration of this displacement can be achieved with dedicated measurement tools, but this requires expensive equipment and it is time consuming. We propose instead to address these issues via the design of observers. Last year, we had proposed a nonlinear observer to fuse pose and IMU measurements while identifying additive IMU biases on both gyrometers and accelerometers. We have extended this work to the self-calibration of the
rotation between the pose sensor frame (camera) and the IMU frame. Simulation and experimental results have confirmed that this calibration significantly improves the final pose estimation and allows to process motions with faster dynamics. This work has been presented at the IROS conference in October [35]. It is a joint work with G. Silveira from CTI in Brazil. We are currently extending this result to include the self-calibration of the translation displacement between both sensors.

6.2. Control of mobile robots

Participants: Claude Samson, Pascal Morin, Minh-Duc Hua [Post Doc, I3S, CNRS-Univ. of Nice-Sophia Antipolis], Daniele Pucci, Glauco Scandaroli, Luca Marchetti, Tarek Hamel [Univ. of Nice-Sophia Antipolis].

6.2.1. New developments of the Transverse Function control approach

6.2.1.1. Control of a redundant wheeled snake mechanism using transverse functions on $SO(4)$

The Transverse Function approach is applied to the control of a nonholonomic three-segments/snake-like wheeled mechanism, similar to the planar low-dimensional version of Hirose’s Active Cord Mechanism (ACM) previously studied [65], but with two additional internal degrees of freedom (d.o.f.) whose actuation yields more flexible and efficient control solutions (see figure 10). From a theoretical point of view, these complementary d.o.f. modify the Control Lie Algebra of the system so that only first-order Lie brackets of the control vector fields are needed to satisfy the Lie Algebra Rank Condition (LARC). The fact that four independent (angular velocity) control inputs are used also implies for this system the existence of Transverse Functions (TF) defined on the six-dimensional special orthogonal group $SO(4)$. Several examples of mechanisms whose control involve TF defined on $SO(3)$ have been pointed out in the past [54], [64], [65]. Beyond the specific control problem addressed here, a motivation for the present study is to illustrate for the first time how functions defined on the larger set $SO(4)$ can be determined and used for the control of a physical system. This study is complemented with recalls concerning the parametrization of $SO(4)$ by pairs of isoclinic quaternions and with the derivation of complementary differential calculus relations associated with this parametrization. The results will soon be submitted for presentation at an international conference.

6.2.1.2. Control of three hooked vehicles with off-axle hitches

An extension of the study [65] performed last year on Hirose’s Active Cord Mechanism (ACM) concerns the case when one of the wheeled-trains (the middle one, for instance) possesses actuators giving it tracting and rotating capacities (alike a unicycle-like vehicle), while the other two vehicles are passively hooked to this tracting vehicle. This type of actuation departs from the one of Hirose’s Active Cord Mechanism for which the tracting capacity of the mechanism relies exclusively on the deformation of the system of vehicles via the control of the inter-connecting angles, and it makes an important difference at the control level. This system may also be seen as a unicycle-type vehicle with two trailers and off-axle hitches. Unlike the simpler hitch-on-axle case commonly addressed in the literature, this system is not differentially flat and “complete” feedback solutions ensuring practical stabilization of any, feasible or non-feasible, trajectory remained an open issue. This actuation allows for the complete alignment of the three vehicles without going through actuation singularities, and for the asymptotic tracking of a reference frame moving along a straight line or a circle. On the other hand, in order to fully take advantage of the extra possibilities offered by it, one has to consider higher-order Lie bracket maneuvering motions that significantly complicate the feedback control design. The Transverse Function approach is applied using the fact that a dynamic extension of this two-control-inputs system is left-invariant on a 6-dimensional Lie group. Transverse functions calculated as the group product of “elementary” functions defined either on toruses or on $SO(3)$, and yielding feedback controls ensuring asymptotic stabilization of “feasible” reference trajectories under common "persistent excitation" properties (as in the case of classical feedback control solutions based on a linear approximation of the associated tracking error system) are proposed. As usual, the superiority of the transverse function solution over more classical solutions comes from that it also applies to the case of non-feasible reference trajectories for which (practical) stabilization involves complex maneuvers. The results of this study will be submitted next year for presentation at an international conference.
Figure 10. Three segments snake robot with two steering wheels. View from above
6.2.1.3. Control of an extended trident-snake vehicle

This study is part of a thesis work on the control of non-standard nonholonomic mobile robots by W. Magiera under the dual supervision of Prof. K. Tchon (Wroclaw University of Technology) and C. Samson. This collaboration involves several long term visits of the PhD student at INRIA, starting this year (2 months), and for the next two years. This year’s objective is to address a particularly challenging control problem and evaluate the possibilities offered by the Transverse Function approach to solve it. The system under consideration is based on the "common" trident snake mechanism [54] complemented with one, two, or three additional "passive" wheeled extensions, each of them subjected to the rolling-without-slipping constraint (see figure 6.2.1.3). Transverse Functions solutions tested so far involve a mixt (product) of functions defined either on the torus, or on special orthogonal groups, and future improvements may involve the search for new transverse functions.

![Figure 11. Trident-snake mechanism with passive extensions. View from above](image)

6.2.2. Control of aerial vehicles

6.2.2.1. Vehicles subjected to lift forces

The development of a general theory for the control of underactuated (ground, marine, and aerial) vehicles whose main propulsion relies on a thrust force exerted in a single (vehicle’s related) direction was continued
this year. Part of this program, more specifically devoted to aerial vehicles, is the subject of D. Pucci’s thesis research project. This year’s focus was the prolongation of the work initiated last year on the modelling of lift forces and on their effects on the flight and control of aerial vehicles. Among the new results obtained on the subject, an extension and generalization of a previous feedback control strategy developed for spherically-shaped vehicles only subjected to drag forces \[52\], based on an “ideal” generic model of lift and drag forces associated with bi-symmetric wings, has been accepted for presentation at an international conference (\[34\]). The proposed solution involves a change of thrust control input in order to render the dynamics of the transformed system independent of the angle of attack associated with the vehicle’s main wing. A weakness of the aforementioned model is that it does not account for the so-called stall phenomenon, which is an abrupt loss of lift when the angle of attack increases beyond a certain value called stall angle. Taking it into account adds considerable complexity to the vehicle’s dynamics, especially in the case of a vehicle moving within a fluid endowed with a large Reynolds number for which the stall phenomenon can no longer be neglected. We showed that, although this phenomenon never forbids the existence of an attitude equilibrium given a desired reference velocity, the uniqueness of this equilibrium is not always granted. As a consequence, modifications of the desired velocity may result in the abrupt disappearance of an equilibrium so that the asymptotic stabilization of a desired velocity profile may become an ill-conditioned problem. To avoid this complication a possibility consists in characterizing “good” velocity profiles—associated, for instance, to transition maneuvers between hovering and high-velocity cruising— for which the existence of continuously changing equilibria is ensured. First results on this topic and research direction have been submitted for presentation to an international conference.

6.2.2. Nonlinear control of VTOL UAVs with uncertain position measurements

This work concerns the feedback control of VTOL UAVs (Vertical Take-Off and Landing Unmanned Aerial Vehicles). The objective is to asymptotically stabilize a reference equilibrium configuration with a “semi-global” convergence domain, i.e. global convergence domain in position and semi-global in orientation, knowing that a global convergence domain in orientation cannot be obtained with continuous feedback laws due to the topology of the rotation space \(\text{SO}(3)\). Several solutions to this problem have been proposed in the past years, under the assumption that the pose (i.e. position and orientation) is completely known. This work concerns the case when the relation between the “position measurements” and the true position vector is uncertain. In practice, such uncertainties are related, e.g., to ill-calibrated sensors or to incomplete knowledge of the environment in the case of proximetry sensors. It is assumed that position measurements are given by \(\bar{p} = Mp\) where \(p\) is the true position error with respect to the reference position, and \(M\) is an unknown invertible matrix. As a first contribution, we propose a class of feedback laws that achieve semi-global stability of the equilibrium \(p = 0\) for any matrix \(M\) that satisfies the stability criteria \(\|M - I_3\| < \delta(k)\) where \(I_3\) is the \(3 \times 3\) identity matrix, \(\delta\) is a strictly positive function, and \(k\) is the vector of control parameters. An explicit expression of the function \(\delta\) is provided, thus relating the control parameters to the stability margin. The second contribution of this work is the application of this control approach to the visual servoing of VTOL UAVs with respect to a planar vertical structure (wall, etc). From the homography matrix that relates the current camera image to a reference image (taken at the reference pose), we derive a signal output of the form \(\bar{p} = Mp\). The matrix \(M\) typically depends on unknown parameters but we show that a very rough knowledge of them is sufficient to design a stable controller based on the above-mentioned stability criterion. These results have been submitted for publication at an international conference. This is a joint work with H. de Plinval and P. Mouyon from ONERA Toulouse.

6.2.3. Development of an autonomous shopping cart

This work, which consists in developing a shopping cart with autonomy capabilities (automatic user following, obstacle avoidance, etc), is part of the national INRIA PAL project (Personally Assisted Living) which aims at developing robotic tools for disabled persons or elders.

The architecture of “Autonomous Shopping Cart” has been developed in three layers. The first one is responsible for connecting the services layer to physical (or virtual) devices. During this year, all necessary components to access the devices have been implemented:
• the Phidgets library wraps the API of Phidgets devices and abstracts the access to the peripherals on the wheelchair robot;
• the Hannibal library wraps the interface to access the Hannibal robot (through Carmen library);
• the Simulator library wraps the simulator interface.

All of them expose a common interface to the software modules. Thus, the higher components do not have to be changed if the test platform changes.

The second level is the core of this year’s work. It is composed by the Control module and Modeling module. The Control module aims at stabilizing the trajectory of the robot w.r.t a given reference motion. In practice, this reference motion corresponds to the cart user that needs to be followed, but it could be any virtual reference motion. A first implementation of the Control module has been made using Matlab software. The result is a Control library that contains two different methods for controlling the trajectory:

• position control only;
• full-state control (position+orientation).

These methods have been implemented in Matlab language and then converted in C++. The resulting library has been utilized within the Control module deployed on the robotic platform.

The main objective of the Modeling module is to detect the cart user within the sight of the sensors. This task is generally non-trivial, due to noise in the sensor signals and variations of the environment. For this reason a Multiple Hypothesis Tracker has been used to allow for the presence of several persons in the environment. The method uses the laser scans to extract potential persons and then a Selector algorithm extracts the best hypothesis for the cart user. This hypothesis is then converted into a virtual reference point given to the Control module for trajectory tracking.

The third layer is represented by the Behavior module. This component manages the other modules, starts and stops services on request, enables the initialization procedure and so on. As for now, it starts all modules and initiates the starting procedure. In particular, it selects the first person to be tracked, among possible candidates.

Experiments have been successfully conducted both on the mobile robot Hannibal and on the wheeled walking aid ANG (Assistive Navigation Guide) developed by the EPI Coprin.
6. New Results

6.1. Lighting and Rendering

**Participants:** Mahdi Bagher, Laurent Belcour, Georges-Pierre Bonneau, Eric Bruneton, Cyrill Crassin, Jean-Dominique Gascuel, Olivier Hoel, Nicolas Holzschuch, Fabrice Neyret, Cyrill Soler, Fabrice Neyret, Charles de Rousiers, Cyrill Soler.

6.1.1. Non-linear Pre-filtering Methods for Efficient and Accurate Surface Shading

**Participants:** Eric Bruneton, Fabrice Neyret.

Rendering a complex surface accurately and without aliasing requires the evaluation of an integral for each pixel, namely a weighted average of the outgoing radiance over the pixel footprint on the surface. The outgoing radiance is itself given by a local illumination equation as a function of the incident radiance and of the surface properties. Computing all this numerically during rendering can be extremely costly. For efficiency, especially for real-time rendering, it is necessary to use precomputations. When the fine scale surface geometry, reflectance and illumination properties are specified with maps on a coarse mesh (such as color maps, normal maps, horizon maps or shadow maps), a frequently used simple idea is to pre-filter each map linearly and separately. The averaged outgoing radiance, i.e., the average of the values given by the local illumination equation is then estimated by applying this equation to the averaged surface parameters. But this is really not accurate because this equation is non-linear, due to self-occlusions, self-shadowing, non-linear reflectance functions, etc. Some methods use more complex pre-filtering algorithms to cope with these non-linear effects. In [14] we presented a survey of these methods. We have started with a general presentation of the problem of pre-filtering complex surfaces. We then present and classify the existing methods according to the approximations they make to tackle this difficult problem. Finally, an analysis of these methods allows us to highlight some generic tools to pre-filter maps used in non-linear functions, and to identify open issues to address the general problem.

6.1.2. Frequency-Based Kernel Estimation for Progressive Photon Mapping

**Participants:** Laurent Belcour, Cyrill Soler.

We have developed an extension to Hachisuka et al.’s Progressive Photon Mapping (or PPM) algorithm [32] in which we estimate the radius of the density estimation kernels using frequency analysis of light transport [29]. We predict the local radiance frequency at the surface of objects using a Gaussian approximation, and use it to drive the size of the density estimation kernels, in order to accelerate convergence (see Figure 3). The key is to add frequency information to a small proportion of photons: frequency photons. In addition to contributing to the density estimation, they will provide frequency information. This work has been published in [20].

6.1.3. Efficiently Visualizing Massive Tetrahedral Meshes with Topology Preservation

**Participant:** Georges-Pierre Bonneau.
Figure 3. In this figure we compare against progressive photon mapping with our algorithm for the convergence of an indirectly lit part of the scene. In the closeup, we show that our algorithm produces a lower varying estimate at an earlier stage of its execution. The images were produced using 100,000 photons per pass and 25% of frequency photons to make timing comparable.

Figure 4. Left: Variable resolution visualization of a volume mesh with multiple linear features. The topology of the substructures is guaranteed to be preserved. Right: Snapshot of the multiresolution visualization tool to explore simulation data with embedded structures on a desktop PC.
This work is the result of a collaboration with S. Hahmann from the EVASION team-project and Prof. Hans Hagen partly done during a sabbatical of G.-P. Bonneau in the University of Kaiserslautern, Germany. Interdisciplinary efforts in modeling and simulating phenomena have led to complex multi-physics models involving different physical properties and materials in the same system. Within a 3d domain, substructures of lower dimensions appear at the interface between different materials. Correspondingly, an unstructured tetrahedral mesh used for such a simulation includes 2d and 1d substructures embedded in the vertices, edges and faces of the mesh. The simplification of such tetrahedral meshes must preserve (1) the geometry and the topology of the 3d domain, (2) the simulated data and (3) the geometry and topology of the embedded substructures. This work focuses on the preservation of the topology of 1d and 2d substructures embedded in an unstructured tetrahedral mesh, during edge collapse simplification. We derive a robust algorithm, based on combinatorial topology results, in order to determine if an edge can be collapsed without changing the topology of both the mesh and all embedded substructures. Based on this algorithm we have developed a system for simplifying scientific datasets defined on irregular tetrahedral meshes with substructures, illustrated in Figure 4. We presented and demonstrated the power of our system with real world scientific datasets from electromagnetism simulations in the Springer book chapter [27].

6.1.4. Real-Time Rough Refraction
Participants: Nicolas Holzschuch, Charles de Rousiers.

We have developed an algorithm to render objects of transparent materials with rough surfaces in real-time, under distant illumination. Rough surfaces cause wide scattering as light enters and exits objects, which significantly complicates the rendering of such materials. We present two contributions to approximate the successive scattering events at interfaces, due to rough refraction: First, an approximation of the Bidirectional Transmittance Distribution Function (BTDF), using spherical Gaussians, suitable for real-time estimation of environment lighting using pre-convolution; second, a combination of cone tracing and macro-geometry filtering to efficiently integrate the scattered rays at the exiting interface of the object. We demonstrate in I3D paper [24] the quality of our approximation by comparison against stochastic raytracing. This work is illustrated in Figure 5.
6.1.5. Interactive Indirect Illumination Using Voxel Cone Tracing  
**Participants:** Cyril Crassin, Fabrice Neyret.

Indirect illumination is an important element for realistic image synthesis, but its computation is expensive and highly dependent on the complexity of the scene and of the BRDF of the involved surfaces. While off-line computation and pre-baking can be acceptable for some cases, many applications (games, simulators, etc.) require real-time or interactive approaches to evaluate indirect illumination. We present in the Pacific Graphics paper [16] a novel algorithm to compute indirect lighting in real-time that avoids costly precomputation steps and is not restricted to low-frequency illumination. An illustration is given in Figure 6. It is based on a hierarchical voxel octree representation generated and updated on the fly from a regular scene mesh coupled with an approximate voxel cone tracing that allows for a fast estimation of the visibility and incoming energy. Our approach can manage two light bounces for both Lambertian and glossy materials at interactive framerates (25-70FPS). It exhibits an almost scene-independent performance and can handle complex scenes with dynamic content thanks to an interactive octree-voxelization scheme. In addition, we demonstrate that our voxel cone tracing can be used to efficiently estimate Ambient Occlusion. A primer of this work has been published as a poster (Best Poster Award [22]). Insights of the method were given in the Siggraph Talk 2011 [23].

The publication [22] has received the Best Poster Award at I3D’2011.

6.1.6. Fast multi-resolution shading of acquired reflectance using bandwidth prediction  
**Participants:** Mahdi Bagher, Laurent Belcour, Nicolas Holzschuch, Cyril Soler.

Shading complex materials such as acquired reflectances in multi-light environments is computationally expensive. Estimating the shading integral involves stochastic sampling of the incident illumination independently at several pixels. The number of samples required for this integration varies across the image, depending on an intricate combination of several factors. Ignoring visibility, adaptively distributing computational budget across the pixels for shading is already a challenging problem. In the paper [28] we present a systematic approach to accelerate shading, by rapidly predicting the approximate spatial and angular variation in the local light field arriving at each pixel. Our estimation of variation is in the form of local bandwidth, and accounts for combinations of a variety of factors: the reflectance at the pixel, the nature of the illumination, the local geometry and the camera position relative to the geometry and lighting. An illustration is given in Figure 7. The speed-up, using our method, is from a combination of two factors. First, rather than shade every pixel, we use this predicted variation to direct computational effort towards regions of the image with high local variation. Second, we use the predicted variance of the shading integrals, to cleverly distribute a fixed total budget of shading samples across the pixels. For example, reflection off specular objects is estimated using fewer samples than off diffuse objects.
Figure 7. The technique developed by Mahdi Bagher allows to predict in real time the local bandwidth of the image obtained by shading a measured material with all frequency distant illumination (See inset colored top-right image). This information allows a drastic economy of samples in the computation of the integrals that are needed to produce an accurate image. In particular this allows to perform multi-sampling anti-aliasing in a deferred shading pipeline with much less image-space samples than the brute-force solution.
6.2. Expressive Rendering and Visualization

Participants: Pierre Bénard, Georges-Pierre Bonneau, Alexandre Coninx, Joëlle Thollot.

6.2.1. Temporal Coherence for Stylized Animation

Participants: Pierre Bénard, Joëlle Thollot.

![Image](image.png)

Figure 8. In our state-of-the-art report we review and carefully compare Temporal Coherence techniques for stylized animations.

Non-photorealistic rendering (NPR) algorithms allow the creation of images in a variety of styles, ranging from line drawing and pen-and-ink to oil painting and watercolor. These algorithms provide greater flexibility, control and automation over traditional drawing and painting. Despite significant progress over the past 15 years, the application of NPR to the generation of stylized animations remains an active area of research. The main challenge of computer generated stylized animations is to reproduce the look of traditional drawings and paintings while minimizing distracting flickering and sliding artifacts present in hand-drawn animations. These goals are inherently conflicting and any attempt to address the temporal coherence of stylized animations is a trade-off. We have published the state-of-the-art report [15] motivated by the growing number of methods proposed in recent years and the need for a comprehensive analysis of the trade-offs they propose. We formalize the problem of temporal coherence in terms of goals and compare existing methods accordingly. We propose an analysis for both line and region stylization methods and discuss initial steps toward their perceptual evaluation. The goal of our report is to help uninformed readers to choose the method that best suits their needs, as well as motivate further research to address the limitations of existing methods.

6.2.2. Visualization of data with uncertainty using perceptually guided procedural noise

Participants: Alexandre Coninx, Georges-Pierre Bonneau.

This work is the result of a collaboration with EdF R&D and Jacques Droulez, Director of Research at CNRS in Collège de France. In his PhD work, Alexandre Coninx has introduced a new method to visualize uncertain scalar data fields by combining color scale visualization techniques with animated, perceptually adapted Perlin noise. The parameters of the Perlin noise are controlled by the uncertainty information to produce animated patterns showing local data value and quality, as illustrated in Figure 9. In order to precisely control the perception of the noise patterns, we perform a psychophysical evaluation of contrast sensitivity thresholds for a set of Perlin noise stimuli. We validate and extend this evaluation using an existing computational model. This allows us to predict the perception of the uncertainty noise patterns for arbitrary choices of parameters. We demonstrate and discuss the efficiency and the benefits of our method with various settings, color maps and data sets. This work has been published at APGV’2011 [21].
6.3. Modeling and Animation

Participants: Georges-Pierre Bonneau, Alexandre Derouet-Jourdan, Nicolas Holzschuch, Nassim Jibai, Cyril Soler, Joëlle Thollot.

6.3.1. Multiscale Feature-Preserving Smoothing of Tomographic Data

Participants: Nassim Jibai, Nicolas Holzschuch, Cyril Soler.

Computer tomography (CT) has wide application in medical imaging and reverse engineering. Due to the limited number of projections used in reconstructing the volume, the resulting 3D data is typically noisy. Contouring such data, for surface extraction, yields surfaces with localised artifacts of complex topology. To avoid such artifacts, we propose a method for feature-preserving smoothing of CT data, illustrated in Figure 10. The smoothing is based on anisotropic diffusion, with a diffusion tensor designed to smooth
noise up to a given scale, while preserving features. We compute these diffusion kernels from the directional histograms of gradients around each voxel, using a fast GPU implementation. This work has been published as a Siggraph’2011 Poster [26].

6.3.2. 3D Inverse Dynamic Modeling of Strands
Participants: Alexandre Derouet-Jourdan, Joëlle Thollot.

![Figure 11. Our model can physically animate the tail. The tail will retrieve its initial shape at the end of slight (possibly strong) motions.](image)

In this work, we propose a new method to automatically and consistently convert 3D splines into dynamic rods at rest under gravity, bridging the gap between the modeling of 3D strands (such as hair, plants) and their physics-based animation. An illustration is given in Figure 11. This work is done in collaboration with F. Bertails from the BIPOP team-project. It has been published in a Siggraph’2011 poster [25].

6.3.3. Lagrangian Texture Advection: Preserving both Spectrum and Velocity Field
Participants: Eric Bruneton, Nicolas Holzschuch, Fabrice Neyret.

Texturing an animated fluid is a useful way to augment the visual complexity of pictures without increasing the simulation time. But texturing flowing fluids is a complex issue, as it creates conflicting requirements: we want to keep the key texture properties (features, spectrum) while advecting the texture with the underlying flow — which distorts it. In this context we present a new, Lagrangian, method for advecting textures: the advected texture is computed only locally and follows the velocity field at each pixel (see Figure 12). The texture retains its local properties, including its Fourier spectrum, even though it is accurately advected. Due to its Lagrangian nature, our algorithm can perform on very large, potentially infinite scenes in real time. Our experiments show that it is well suited for a wide range of input textures, including, but not limited to, noise textures. This work has been published in the IEEE Transactions on Visualization and Computer Graphics (TVCG) [18].

6.3.4. Feature-Based Vector Simulation of Water Waves
Participant: Fabrice Neyret.

We have developed a method for simulating local water waves caused by obstacles in water streams for real-time graphics applications. Given a low-resolution water surface and velocity field, our method is able to decorate the input water surface with high resolution detail for the animated waves around obstacles. We construct and animate a vector representation of the waves. It is then converted to feature-aligned meshes for capturing the surfaces of the waves (see Figure 13). Results demonstrate that our method has the benefits of real-time performance and easy controllability. The method also fits well into a state-of-the-art river animation system. This work has been published in the Journal of Computer Animation and Virtual Worlds [19].
Figure 12. Left: Our method advects open-domain textures preserving both the spectrum and the motion field, in real-time. Right: Various applications in 2D and 3D, with procedural, image, bump, displacement textures.

Figure 13. Our method permits the real-time rendering of highly detailed animated features on large river scenes.
6.3.5. Volume-preserving FFD for Programmable Graphics Hardware

Participant: Georges-Pierre Bonneau.

![Figure 14. Left: FFD deformation of the armadillo mesh, without volume preservation. Right: our technique: GPU-based volume preservation of the FFD deformation.](image)

This work is the result of a collaboration with S. Hahmann from the EVASION team-project, Prof. Gershon Elber from Technion and Prof. Hans Hagen from the University of Kaiserslautern.

Free Form Deformation (FFD) is a well established technique for deforming arbitrary object shapes in space. Although more recent deformation techniques have been introduced, amongst them skeleton-based deformation and cage based deformation, the simple and versatile nature of FFD is a strong advantage, and justifies its presence in nowadays leading commercial geometric modeling and animation software systems. Since its introduction in the late 80’s, many improvements have been proposed to the FFD paradigm, including control lattices of arbitrary topology, direct shape manipulation and GPU implementation. Several authors have addressed the problem of volume preserving FFD. These previous approaches either make use of expensive non-linear optimization techniques, or resort to first order approximation suitable only for small-scale deformations. In this work we take advantage from the multi-linear nature of the volume constraint in order to derive a simple, exact and explicit solution to the problem of volume preserving FFD (see Figure 14). Two variants of the algorithm are given, without and with direct shape manipulation. Moreover, the linearity of our solution enables to implement it efficiently on GPU. The results have been published in a Visual Computer journal paper [17].
ASAP Project-Team

6. New Results

6.1. Models and abstractions for distributed systems

This section summarizes the major results obtained by the ASAP team that relate to the foundations of distributed systems.

6.1.1. The weakest failure detector to implement a register in asynchronous systems with hybrid communication

Participants: Damien Imbs, Michel Raynal.

This work introduces an asynchronous crash-prone hybrid system model. The system is hybrid in the way the processes can communicate. On the one side, a process can send messages to any other process. On another side, the processes are partitioned into clusters and each cluster has its own read/write shared memory. In addition to the model, a main contribution of the work concerns the implementation of an atomic register in this system model. More precisely, a new failure detector (denoted $M\Sigma$) is introduced and it is shown that, when considering the information on failures needed to implement a register, this failure detector is the weakest. To that end, the work presents an $M\Sigma$-based algorithm that builds a register in the considered hybrid system model and shows that it is possible to extract $M\Sigma$ from any failure detector-based algorithm that implements a register in this model. The work also (a) shows that $M\Sigma$ is strictly weaker than $\Sigma$ (which is the weakest failure detector to implement a register in a classical message-passing system) and (b) presents a necessary and sufficient condition to implement $M\Sigma$ in a hybrid communication system.

This work has been published in SSS 2011 [38].

6.1.2. The universe of symmetry breaking tasks

Participants: Damien Imbs, Michel Raynal.

Processes in a concurrent system need to coordinate using a shared memory or a message-passing subsystem in order to solve agreement tasks such as, for example, consensus or set agreement. However, coordination is often needed to “break the symmetry” of processes that are initially in the same state, for example, to get exclusive access to a shared resource, to get distinct names or to elect a leader.

This work introduces and studies the family of generalized symmetry breaking (GSB) tasks, that includes election, renaming and many other symmetry breaking tasks. Differently from agreement tasks, a GSB task is “inputless”, in the sense that processes do not propose values; the task only specifies the symmetry breaking requirement, independently of the system’s initial state (where processes differ only on their identifiers). Among various results characterizing the family of GSB tasks, it is shown that (non adaptive) perfect renaming is universal for all GSB tasks.

This work was done in collaboration with Sergio Rajsbaum from the Universidad Nacional Autonoma de Mexico and was published in SIROCCO 2011 [36].

6.1.3. Read invisibility, virtual world consistency and probabilistic permissiveness are compatible

Participants: Tyler Crain, Damien Imbs, Michel Raynal.
The aim of a Software Transactional Memory (STM) is to discharge the programmers from the management of synchronization in multiprocess programs that access concurrent objects. To that end, an STM system provides the programmer with the concept of a transaction. The job of the programmer is to design each process the application is made up of as a sequence of transactions. A transaction is a piece of code that accesses concurrent objects, but contains no explicit synchronization statement. It is the job of the underlying STM system to provide the illusion that each transaction appears as being executed atomically. Of course, for efficiency, an STM system has to allow transactions to execute concurrently. Consequently, due to the underlying STM concurrency management, a transaction commits or aborts.

This work studies the relation between two STM properties (read invisibility and permissiveness) and two consistency conditions for STM systems, namely, opacity and virtual world consistency. Both conditions ensure that any transaction (be it a committed or an aborted transaction) reads values from a consistent global state, a noteworthy property if one wants to prevent abnormal behavior from concurrent transactions that behave correctly when executed alone. A read operation issued by a transaction is invisible if it does not entail shared memory modifications. This is an important property that favors efficiency and privacy. An STM system is permissive (respectively probabilistically permissive) with respect to a consistency condition if it accepts (respectively accepts with positive probability) every history that satisfies the condition. This is a crucial property as a permissive STM system that implements opacity while ensuring read invisibility. It then shows that read invisibility, probabilistic permissiveness and virtual world consistency are compatible. To that end the work describes a new STM protocol called IR_VWC_P. This protocol presents additional noteworthy features: it uses only base read/write objects and locks which are used only at commit time; and, in favorable circumstances, the cost of a read operation is $O(1)$.

This work has been published in ICA3PP 2011 [29].

6.1.4. **Towards a universal construction for transaction-based multiprocess programs**

**Participants:** Tyler Crain, Damien Imbs, Michel Raynal.

The aim of a Software Transactional Memory (STM) system is to discharge the programmer from the explicit management of synchronization issues. The programmer’s job resides in the design of multiprocess programs in which processes are made up of transactions, each transaction being an atomic execution unit that accesses concurrent objects. The important point is that the programmer has to focus her/his efforts only on the parts of code which have to be atomic execution units without worrying on the way the corresponding synchronization has to be realized.

Non-trivial STM systems allow transactions to execute concurrently and rely on the notion of commit/abort of a transaction in order to solve their conflicts on the objects they access simultaneously. In some cases, the management of aborted transactions is left to the programmer. In other cases, the underlying system scheduler is appropriately modified or an underlying contention manager is used in order that each transaction be (“practically always” or with high probability) eventually committed.

This work paper proposed a deterministic STM system in which (1) every invocation of a transaction is executed exactly once and (2) the notion of commit/abort of a transaction remains unknown to the programmer. This system, which imposes restriction neither on the design of processes nor or their concurrency pattern, can be seen as a step towards the design of a deterministic universal construction to execute transaction-based multiprocess programs on top of a multiprocessor. Interestingly, the proposed construction is lock-free (in the sense that it uses no lock).

This work has been published in ICDCN 2012 [30].

6.1.5. **A transaction friendly binary search tree**

**Participants:** Tyler Crain, Michel Raynal.
Transactions, which provide optimistic synchronization by avoiding the use of blocking, greatly simplify multithreaded programming. In fact, the programmer has simply to encapsulate sequential operations or existing critical sections into transactions to obtain a safe concurrent program. Programmers have thus started evaluating transactional memory using data structures originally designed for pessimistic (i.e., non-optimistic) synchronization, whose prominent example is the red-black tree library developed by Oracle Labs that is part of STAMP and microbenchmark distributions. Unfortunately, existing data structures are badly suited for optimistic synchronization as they rely on strong structural invariants, like logarithmic tree depth, to bound the step complexity of pessimistically synchronized accesses. By contrast, this complexity does not apply to optimistically synchronized accesses thus making the invariants overly conservative. More dramatically, guaranteeing such invariants tends to increase the probability of aborting and restarting the same access before it completes. We introduced a concurrent binary search tree that breaks transiently its balance structural invariants for efficiency, a property we call transaction-friendly. This new tree outperforms the existing transaction-based version of the AVL and the red-black trees. Its key novelty stems from the decoupling of update operations: they are split into one transaction that modifies the abstraction state and multiple ones that restructure its tree implementation. The resulting transaction-friendly library trades aborts for few additional access steps and, in particular, it speeds up a transaction-based travel reservation application by up to 3.5X. This work was done in collaboration with Vincent Gramoli from EPFL Lausanne, and is described in [52].

6.1.6. Relations linking failure detectors associated with k-set agreement in message-passing systems

Participants: Achour Mostefaoui, Michel Raynal, Julien Stainer.

The k-set agreement problem is a coordination problem where each process is assumed to propose a value and each process that does not crash has to decide a value such that each decided value is a proposed value and at most k different values are decided. While it can always be solved in synchronous systems, k-set agreement has no solution in asynchronous send/receive message-passing systems where up to t ≥ k processes may crash.

A failure detector is a distributed oracle that provides processes with additional information related to failed processes and can consequently be used to enrich the computability power of asynchronous send/receive message-passing systems. Several failure detectors have been proposed to circumvent the impossibility of k-set agreement in pure asynchronous send/receive message-passing systems. Considering three of them (namely, the generalized quorum failure detector Σk, the generalized loneliness failure detector Λk and the generalized eventual leader failure detector Ωk) this work investigates their computability power and the relations that link them. There are three main contributions: (a) it shows that the failure detector Ωk and the eventual version of Λk have the same computational power; (b) it shows that Λk is realistic if and only if k ≥ n/2; and (c) it gives an exact characterization of the difference between Λk (that is too strong for k-set agreement) and Σk (that is too weak for k-set agreement). This work was published at SSS 2011 [45].

6.1.7. The price of anonymity: optimal consensus despite asynchrony, crash and anonymity

Participant: Michel Raynal.

This work [23], done in collaboration with François Bonnet, from JAIST, Japan, addresses the consensus problem in asynchronous systems prone to process crashes, where additionally the processes are anonymous (they cannot be distinguished one from the other: they have no name and execute the same code). To circumvent the three computational adversaries (asynchrony, failures and anonymity) each process is provided with a failure detector of a class denoted ψ, that gives it an upper bound on the number of processes that are currently alive (in a non-anonymous system, the classes ψ and P-the class of perfect failure detectors- are equivalent).

The first part presents a simple ψ-based consensus algorithm where the processes decide in 2t + 1 asynchronous rounds (where t is an upper bound on the number of faulty processes). It then shows one of its main results, namely, 2t + 1 is a lower bound for consensus in the anonymous systems equipped with ψ. The second contribution addresses early-decision. The paper presents and proves correct an early-deciding algorithm where the processes decide in \(\min(2f + 2, 2t + 1)\) asynchronous rounds (where f is the actual number
of process failures). This leads to think that anonymity doubles the cost (wrt synchronous systems) and it is conjectured that \(\min(2f + 2, 2t + 1)\) is the corresponding lower bound.

The work finally considers the \(k\)-set agreement problem in anonymous systems. It first shows that the previous \(\psi\)-based consensus algorithm solves the \(k\)-set agreement problem in \(R_t = 2 \left\lceil \frac{t}{k} \right\rceil + 1\) asynchronous rounds. Then, considering a family of failure detector classes \(\{\psi_k\}_{0 \leq k < n}\) that generalizes the class \(\psi(= \psi_0)\), the paper presents an algorithm that solves the \(k\)-set agreement in \(R_{t,k} = 2 \left\lceil \frac{1}{k^{-1}} \right\rceil + 1\) asynchronous rounds. This last formula relates the cost \((R_{t,k})\), the coordination degree of the problem \((k)\), the maximum number of failures \((t)\) and the the strength \((\ell)\) of the underlying failure detector.

6.1.8. On the road to the Weakest Failure Detector for \(k\)-Set Agreement in Message-passing Systems

Participant: Michel Raynal.

In the \(k\)-set agreement problem, each process (in a set of \(n\) processes) proposes a value and has to decide a proposed value in such a way that at most \(k\) different values are decided. While this problem can easily be solved in asynchronous systems prone to \(t\) process crashes when \(k > t\), it cannot be solved when \(k \leq t\). Since several years, the failure detector-based approach has been investigated to circumvent this impossibility. While the weakest failure detector class to solve the \(k\)-set agreement problem in read/write shared-memory systems has recently been discovered (PODC 2009), the situation is different in message-passing systems where the weakest failure detector classes are known only for the extreme cases \(k = 1\) (consensus) and \(k = n - 1\) (set agreement).

This work \([22]\), done in collaboration with François Bonnet, from JAIST, Japan, has four contributions whose aim is to help pave the way to discover the weakest failure detector class for \(k\)-set agreement in message-passing systems. These contributions are the following. (a) The first is a new failure detector class, denoted \(\Pi_k\), that is such that \(\Pi_1 = \Sigma \times \Omega\) (the weakest class for \(k = 1\)), and \(\Pi_{n-1} = \mathcal{L}\) (the weakest class for \(k = n - 1\)). (b) The second is an investigation of the structure of \(\Pi_k\) that shows that \(\Pi_k\) is the combination of two failures detector classes \(\Sigma_k\) (that is new) and \(\Omega_k\) (they generalize the previous “quorums” and “eventual leaders” failure detectors classes, respectively). (c) The third contribution concerns \(\Sigma_k\) that is shown to be necessary requirement (as far as information on failure is concerned) to solve the \(k\)-set agreement problem in message-passing systems. (d) Finally, the last contribution is a \(\Pi_{n-1}\)-based algorithm that solves the \((n - 1)\)-set agreement problem. This algorithm provides us with a new algorithmic insight on the way the \((n - 1)\)-set agreement problem can be solved in asynchronous message-passing systems. It is hoped that these contributions will help discover the weakest failure detector class for \(k\)-set agreement in message-passing systems.

6.1.9. A non-topological proof for the impossibility of \(k\)-set agreement.

Participant: Armando Castañeda.

This work was done in collaboration with Hagit Attiya, from Technion, Haifa, Israel. In the \(k\)-set agreement task each process proposes a value, and each correct process has to decide a value which was proposed, so that at most \(k\) distinct values are decided. Using topological arguments it has been proved that \(k\)-set agreement is unsolvable in the asynchronous \(wait-free\) read/write shared memory model, when \(k < n\), the number of processes.

This work \([34]\) focuses on a simple, non-topological impossibility proof of \(k\)-set agreement. The proof depends on two simple properties of the \(immediate\ snapshot\ executions\), a subset of all possible executions, and on the well known \(handshaking\ lemma\) stating that every graph has an even number of vertices with odd degree.

The paper was presented in the 13th Int’l Symposium on Stabilization, Safety, and Security of Distributed Systems (SSS’11) in Grenoble, France. The journal version of the paper was submitted to Theoretical Computer Science.
6.1.10. Enriching the reduction map of sub-consensus tasks

Participants: Armando Castañeda, Damien Imbs, Michel Raynal.

This work [51] was done in collaboration with Sergio Rajsbaum from the Universidad Nacional Autonoma de Mexico.

Understanding the relative computability power of tasks, in the presence of asynchrony and failures, is a central concern of distributed computing theory. In the wait-free case, where the system consists of \( n \) processes and any of them can fail by crashing, substantial attention has been devoted to understanding the relative power of the subconsensus family of tasks, which are too weak to solve consensus for two processes. The first major results showed that set agreement and renaming (except for some particular values of \( n \)) cannot be solved wait-free in read/write memory. Then it was proved that renaming is strictly weaker than set agreement (when \( n \) is odd).

This work considers a natural family of subconsensus tasks that includes set agreement, renaming and other generalized symmetry breaking (GSB) tasks. It extends previous results, and proves various new results about when there is a reduction and when not, among these tasks. Among other results, the work shows that there are incomparable subconsensus tasks.

6.1.11. Byzantine Consensus Decidability

Participants: Achour Mostefaoui, Michel Raynal.

Solving the consensus problem requires in one way or another that the underlying system satisfies synchrony assumptions. Considering a system of \( n \) processes where up to \( t < n/3 \) may commit Byzantine failures, we proposed in [26] a necessary and sufficient synchrony assumption to solve consensus.

Such a condition is formulated with the notions of a symmetric synchrony property and property ambiguity. A symmetric synchrony property is a set of graphs, where each graph corresponds to a set of bi-directional eventually synchronous links among correct processes. Intuitively, a property is ambiguous if it contains a graph whose connected components are such that it is impossible to distinguish a connected component that contains correct processes only from a connected component that contains faulty processes only. The paper connects then the notion of a symmetric synchrony property with the notion of eventual bi-source, and shows that the existence of a virtual \( \diamond [t + 1] \) bi-source is a necessary and sufficient condition to solve consensus in presence of up to \( t \) Byzantine processes in systems with bi-directional links and message authentication. Finding necessary and sufficient synchrony conditions when links are timely in one direction only, or when processes cannot sign messages, still remains open (and very challenging) problems.

6.1.12. Solving \( k \)-set agreement in message-passing systems

Participants: Achour Mostefaoui, Michel Raynal, Julien Stainer.

The \( k \)-set agreement problem is a coordination problem where each process is assumed to propose a value and each process that does not crash has to decide a value such that each decided value is a proposed value and at most \( k \) different values are decided. While it can always be solved in synchronous systems, \( k \)-set agreement has no solution in asynchronous send/receive message-passing systems where up to \( t \) processes may crash.

A failure detector is a distributed oracle that provides processes with additional information related to failed processes and can consequently be used to enrich the computability power of asynchronous send/receive message-passing systems. Several failure detectors have been proposed to circumvent the impossibility of \( k \)-set agreement in pure asynchronous send/receive message-passing systems. Considering three of them (namely, the generalized quorum failure detector \( \Sigma_k \), the generalized loneliness failure detector \( \mathcal{L}_k \) and the generalized eventual leader failure detector \( \Omega_k \)), we investigated their computability power and the relations that link them in [45]. It has three mains contributions: (a) it shows that the failure detector \( \Omega_k \) and the eventual version of \( \mathcal{L}_k \) have the same computational power; (b) it shows that \( \mathcal{L}_k \) is realistic if and only if \( k \geq n/2 \); and (c) it gives an exact characterization of the difference between \( \mathcal{L}_k \) (that is too strong for \( k \)-set agreement) and \( \Sigma_k \) (that is too weak for \( k \)-set agreement).
6.1.13. Efficient Implementations of Concurrent Objects

Participants: Achour Mostefaoui, Michel Raynal.

As introduced by Taubenfeld, a contention-sensitive implementation of a concurrent object is an implementation such that the overhead introduced by locking is eliminated in the common cases, i.e., when there is no contention or when the operations accessing concurrently the object are non-interfering. In [44], we present a methodological construction of a contention-sensitive implementation of a concurrent stack. In a contention-free context a push or pop operation does not rest on a lock mechanism and needs only six accesses to the shared memory. In case of concurrency a single lock is required. Moreover, the implementation is starvation-free (any operation is eventually executed). The paper, that presents the algorithms in an incremental way, visits also a family of liveness conditions and important concurrency-related concepts such as the notion of an abortable object.

6.2. Large-scale and user-centric distributed system

This section summarizes the major results obtained by the team in 2011 in the context of large-scale distributed systems and social networks. This includes the results obtained within the GOSSPLE ERC project, which encompass two types of social networks: explicit and implicit.

Explicit networks connect users based on explicit social connections. In Facebook or MySpace, users issue and accept friendship requests. In Twitter, they decide that they wish to follow the tweets of specific users. In all cases, the topology of the resulting network reflects the choices of users and often consists of links that already exist between real people. Explicit networks are therefore very useful in reinforcing and exploiting existing connections but provide little support for discovering new content.

Implicit networks complement explicit ones by providing each user with a set of anonymous acquaintances that share similar interests, that visit similar websites or that have otherwise similar profiles. Different from explicit networks, implicit ones are naturally suited to support the discovery of new content. In previous work [1], we exploited this network to improve web navigation. In the following, we consider additional applications encompassing news dissemination, online transactions, and recommendation.

6.2.1. WhatsUp: P2P news recommender

Participants: Antoine Boutet, Davide Frey, Anne-Marie Kermarrec.

The main application in the context of GOSSPLE is WhatsUp, an instant news system designed for a large-scale network with no central authority. WhatsUp builds an implicit social network based on the opinions users express about the news items they receive (like-dislike). This is achieved through an obfuscation mechanism that does not require users to ever reveal their exact profiles. WhatsUp disseminates news items through a novel heterogeneous gossip protocol that biases the choice of its targets towards those with similar interests and amplifies dissemination based on the level of interest in every news item. WhatsUp outperforms various alternatives in terms of accurate and complete delivery of relevant news items while preserving the fundamental advantages of standard gossip: namely simplicity of deployment and robustness. This work has been carried out in collaboration with Rachid Guerraoui from EPFL and was demonstrated during the different local events.

6.2.2. Personalized top-k processing

Participant: Anne-Marie Kermarrec.

Another way to improve the experience of users on the web is to personalize top-k queries. In collaboration with Xiao Bai and Vincent Leroy from Yahoo! Research in Barcelona and Rachid Guerraoui from EPFL Lausanne we, therefore, introduced P4Q, a fully decentralized gossip-based protocol to personalize query processing in social tagging systems. P4Q dynamically associates each user with social acquaintances sharing similar tagging behaviors. Queries are gossiped among such acquaintances, computed on the fly in a collaborative, yet partitioned manner, and results are iteratively refined and returned to the querier. Analytical and experimental evaluations convey the scalability of P4Q for top-k query processing, as well its inherent ability to cope with users updating profiles and departing. The work appeared in the ACM transactions of database systems [12].
6.2.3. Social Market
Participants: Davide Frey, Arnaud Jegou, Anne-Marie Kermarrec.

The ability to identify people that share one’s own interests is one of the most interesting promises of the Web 2.0 driving user-centric applications such as recommendation systems or collaborative marketplaces. To be truly useful, however, information about other users also needs to be associated with some notion of trust. Consider a user wishing to sell a concert ticket. Not only must she find someone who is interested in the concert, but she must also make sure she can trust this person to pay for it. Social Market (SM) solve this problem by allowing users to identify and build connections to other users that can provide interesting goods or information and that are also reachable through a trusted path on an explicit social network like Facebook. This convergence of implicit and explicit networks yields TAPS, a novel gossip protocol that can be applied in applications devoted to commercial transactions, or to add robustness to standard gossip applications like dissemination or recommendation systems.

This work has been published at SSS 2011 [33], and an extended version bringing better performances and strong privacy guarantees have recently been submitted for publication.

6.2.4. Member classification and party characteristics in Twitter
Participant: Antoine Boutet.

In modern politics, parties and individual candidates must have an online presence and usually have dedicated social media coordinators. In this context, real time member classification and party characterization, taking into account the dynamic nature of social media, are essential to highlight the main differences between parties and to monitor their activities, influences, structures, contents and mood. This work [53] was been done in collaboration with E. Yoneki from Computer Lab, Cambridge, UK.

6.2.5. Graph Drawing and Visual Recommendations
Participants: Anne-Marie Kermarrec, Afshin Moin.

An important aspect of social network is their graph structure. In a collaboration with Vincent Leroy (Yahoo! Research) and Gilles Tredan (TU Berlin) [41], we started from this structure to propose a decentralized gossip-based algorithm called SoCS (Social Coordinate Systems). SoCS achieves efficient distributed social graph embedding using a force-based graph embedding technique to extract communities from a graph. SoCS (i) scales to large dynamic graph, aggregating the computing power of individual nodes and, (ii) avoids a central entity controlling users sensitive data such as relations and preferences. We evaluated SoCS using two different force-based models and compare them in the context of a generated Kleinberg small-world topology. More specifically, we showed that the SoCS graph embedding enables to clearly distinguish between short and long-range links. We also evaluate SoCS against a real DBLP data set, showing that removed links are correctly predicted.

Graph structures are also at the basis of our work on energy/force-based models for graph visualization. We applied visualization both to social network and in the context of recommendation systems. In particular we are working on an SVD-like algorithm for drawing precise 2-dimensional visual recommendations based on Principal Component Analysis (PCA) and Curvilinear Component Analysis (CCA).

6.2.6. Private Similarity Computation in Distributed Systems: from Cryptography to Differential Privacy
Participants: Mohammad Alaggan, Anne-Marie Kermarrec.

The use of personal data in the context of social networks raises important concerns about privacy. In a collaboration [24] with Sébastien Gambs from the CIDre team, we addressed the problem of computing the similarity between two users (a key operation in an implicit social network [1]) while preserving their privacy in a fully decentralized system and for the passive adversary model. First, we introduced a two-party protocol for privately computing a threshold version of the similarity and applied it to well-known similarity measures such as the scalar product and the cosine similarity. The output of this protocol is only one bit
of information telling whether or not two users are similar beyond a predetermined threshold. Afterwards, we explored the computation of the exact and threshold similarity within the context of differential privacy. Differential privacy is a recent notion developed within the field of private data analysis guaranteeing that an adversary that observes the output of the differentially private mechanism, will only gain a negligible advantage (up to a privacy parameter) from the presence (or absence) of a particular item in the profile of a user. This provides a strong privacy guarantee that holds independently of the auxiliary knowledge that the adversary might have. More specifically, we designed several differentially private variants of the exact and threshold protocols that rely on the addition of random noise tailored to the sensitivity of the considered similarity measure. We also analyzed their complexity as well as their impact on the utility of the resulting similarity measure.

6.2.7. Constellation: Programming decentralized social networks

Participants: François Taiani, Anne-Marie Kermarrec.

As they continue to grow, social and collaborative applications (e.g. twitter, Facebook, digg) are increasingly calling for disruptive distributed solutions than can cater for the millions of users these applications serve daily, in hundreds of countries, over a wide variety of devices. To address these challenges, fully decentralized versions of social and collaborative applications are progressively emerging that seek to provide naturally scalable solutions to deliver their services. Gossip protocols in particular appear as a natural solution to implement these decentralized versions, as they intrinsically tend to be highly resilient, efficient, and scalable.

Social applications based on gossip have however been limited so far to relatively homogeneous systems: They typically rely on one similarity measure to self-organize large amount of distributed users in implicit communities, and thus offer powerful means to search, mine, and serve personalized data in a distributed manner.

We posit in this work [54] that we now need to move to more complex gossip-based social applications that can cater for different types of data and similarity, organized in multiple levels of abstraction. Exploring, designing, and evaluating such novel approaches is unfortunately time-consuming and error-prone. To help in this task, we have started to design a new programming language, Constellation, that seeks to simplify the realization and experimentation with social gossip-based applications. Constellation is based on two central observations: (i) future decentralized social applications will need to handle heterogeneous forms of data and self-organization, and (ii) to offer more powerful services, these applications will need to move beyond physical nodes to encompass richer data structures organized in virtualized levels of abstractions.

6.2.8. Leveraging content interconnections for efficient data storage.

Participants: Anne-Marie Kermarrec, Konstantinos Kloudas, François Taiani.

Traffic generated by User Generated Content (UGC) sharing sites, such as YOUTUBE, accounts for a substantial fraction of today’s global Internet load. This success has however brought a number of key technical challenges, crucial for system sustainability and user experience. One of them is the need to place content close to consumers, so that user perceived latency is reduced and bandwidth utilization is minimized. In a joint work with Kevin Huguenin, we try to tackle this problem by leveraging the fact that content hosted by these sites is interconnected, forming a content graph that as shown by former works, has an important impact on a file’s view pattern. In our work titled “Recommended nearby in UGC delivery networks: leveraging geographical and content locality”, we focused on YOUTUBE and we studied how two types of locality previously analyzed in isolation in UGC systems, namely content locality (a.k.a graph locality, induced by the related video feature) and geographic locality, are in fact correlated. Leveraging the above finding, we proposed a novel algorithm for replica placement that tries to predict where future views for a video will come from based on the video’s related videos and places its replicas accordingly. This work has been submitted for publication.

6.2.9. Transparent Componentization: High-level (Re)configurable Programming for Evolving Distributed Systems

Participants: François Taiani, Marin Bertier, Anne-Marie Kermarrec.
This work was done in collaboration Component frameworks and high-level distributed languages have been widely used to develop distributed systems, and provide complementary advantages: Whereas component frameworks foster composability, reusability, and (re)configurability; distributed languages focus on behavior, simplicity and programmability. We argue that both types of approach should be brought together to help develop complex adaptive systems, and we propose an approach to combines both technologies without compromising on any of their benefits. Our approach, termed Transparent Componentization [43], automatically maps a high-level distributed specification onto a underlying component framework. It thus allows developers to focus on the programmatic description of a distributed system’s behavior, while retaining the benefits of a component architecture. As a proof of concept, we present WhispersKit, a programming environment for gossip-based distributed systems. Our evaluation shows that WhispersKit successfully retains the simplicity and understandability of high-level distributed language while providing efficient and transparent reconfigurability thanks to its component underpinnings.

### 6.2.10. Efficient peer-to-peer backup services through buffering at the edge
**Participants:** Anne-Marie Kermarrec, Alexandre Van Kempen.

The availability of end devices of peer-to-peer storage and backup systems has been shown critical for usability and for system reliability in practice. This has led to the adoption of hybrid architectures composed of both peers and servers. Such architectures mask the instability of peers thus approaching the performances of client-server systems while providing scalability at a low cost. In this work [31] - done in collaboration with Erwan Le Merrer, Serge Defrance, Nicolas Le Scouarne and Gilles Straub from Technicolor, Rennes, France - we advocate the replacement of such servers by a cloud of residential gateways, as they are already present in users’ homes, thus pushing the required stable components at the edge of the network. In our gateway-assisted system, gateways act as buffers between peers, compensating for their intrinsic instability. This enables to offload backup tasks quickly from the user’s machine to the gateway, while significantly lowering the retrieval time of backed up data. We evaluate our proposal using real world traces including existing traces from Skype and Jabber as well as a trace of residential gateways for availability, and a residential broadband trace for bandwidth. Results show that the time required to backup data in the network is comparable to a server-assisted approach, while substantially improving the time to restore data, which drops from a few days to a few hours. As gateways are becoming increasingly powerful in order to enable new services, we expect such a proposal to be leveraged on a short term basis.

### 6.2.11. Commutative Replicated Data Type for Semantic Stores
**Participant:** Stéphane Weiss.

This work has been done in collaboration with Khaled Aslan (Université de Nantes - Lina), Pascal Molli (Université de Nantes - Lina) and Hala Skaf-Molli (Université de Nantes - Lina).

Web 2.0 tools are currently evolving to embrace semantic web technologies. Blogs, CMS, Wikis, social networks and real-time notifications, integrate ways to provide semantic annotations and therefore contribute to the linked data and more generally to the semantic web vision. This evolution generates a lot of semantic datasets of different qualities, different trust levels and partially replicated. This raises the issue of managing the consistency among these replicas. This issue is challenging because semantic data-spaces can be very large, they can be managed by autonomous participants and the number of replicas is unknown. A new class of algorithms called Commutative Replicated Data Type are emerging for ensuring eventual consistency of highly dynamic content on P2P networks. We define C-Set [25] a CRDT specifically designed to be integrated in Triple-stores. C-Set allows efficient P2P synchronization of an arbitrary number of autonomous semantic stores.

### 6.2.12. Building large scale platform for chemical program
**Participants:** Marin Bertier, Achour Mostefaoui.

This work [28] was done in collaboration with the Myriads project team.
Chemical programming is a promising paradigm to design autonomic systems. Within such a paradigm, computations can be seen as chemical reactions controlled by a set of chemical rules. In other words, data are molecules of a chemical solutions, reacting together to produce new data. Reactions take place in an implicitly parallel, and autonomic fashion.

Our objective was to design a distributed chemical platform bringing such concepts. This platform should be adapted to large scale distributed system to benefit at his best the inherent distribution of chemical program.
5. New Results

5.1. Medical Image Analysis

5.1.1. Spatial Decision Forests for MS Lesion Segmentation in Multi-Channel MR Images

**Participants:** Ezequiel Geremia, Nicholas Ayache, Olivier Clatz, Antonio Criminisi [MSR], Ender Konukoglu [MSR], Bjoern Menze [MIT].

- A new approach for MS lesions segmentation was proposed [33].
- Random forest for automatic segmentation of MS lesions in 3D MR images.
- Features: multi-channel MR intensities, priors, long-range spatial context, symmetry.
- Quantitative evaluation shows significant improvement over the MICCAI Grand Challenge 2008.
- The automatically learned decision sequence mimics the state-of-the-art pipeline.
- Independent validation carried out by the MICCAI Challenge website 2008.
- Exhaustive analysis of the discriminative power of channels and features.
- Analysis of the influence of random forest’s meta-parameters on the classification performance.

5.1.2. Left Ventricle Segmentation from Cardiac 4D Cine MRI Sequences

**Participants:** Jan Margeta [Correspondant], Ezequiel Geremia, Nicholas Ayache, Antonio Criminisi [MSR].

*This work was performed in collaboration with Microsoft Research and was partly supported through its PhD Scholarship Programme.*

- We extend the previous work for multiple sclerosis lesion segmentation of Geremia et al. [33] for spatio-temporal cardiac images.
- A fully automatic two layer left ventricle segmentation algorithm from 4D cardiac cine MRI sequences (See Fig. 2) was proposed for MICCAI STACOM LV segmentation challenge [63] using a random forest classification algorithm.
- Spatio-temporal features are used in the random forest framework to learn the segmentation task without explicitly defining the segmentation rules.
- Machine learning based MRI intensity standardization and pose normalization preprocessing pipeline was proposed to deal with diverse cardiac MRI datasets.

5.1.3. Design and use of anatomical atlases for automatic segmentation: application to radiotherapy of the head and neck region

**Participants:** Liliane Ramus [Correspondant], Grégoire Malandain, Vincent Grégoire [UCL], Juliette Thariat [CAL].

*This work is done in collaboration with DOSIsoft S.A., Centre Antoine Lacassagne (CAL) and Université Catholique de Louvain.*
Figure 1. Segmenting Case CHB05 from the public MSGC dataset. From left to right: preprocessed T1-weighted ($I_T1$), T2-weighted ($I_T2$) and FLAIR MR images ($I_{FLAIR}$) overlayed with the associated ground truth $GT$, the posterior map $Posterior = (P_{lesion})_k$ displayed using an inverted grey scale and the FLAIR sequence overlayed with the segmentation ($Seg = (Posterior \geq \tau_{posterior})$ with $\tau_{posterior} = 0.5$). Segmentation results show that most of lesions are detected. Although some lesions are not detected, e.g. peri-ventricular lesion in slice 38, they appear enhanced in the posterior map. Moreover the segmentations of slices 38 and 42 show peri-ventricular regions, visually very similar to MS lesions, but not delineated in the ground truth.
Figure 2. Two classification layers are used for left ventricle segmentation with random forests. (1) first layer posterior probability is used as a weight map for context aware MRI intensity standardization and cardiac pose normalization, (2) second layer is then used for a more confident left ventricle segmentation, (3) second level posterior probability isocontour overlay, (4) volumetric visualisation of the obtained segmentation.

In the context of radiotherapy of the head and neck, we propose different strategies to design anatomical atlases and we compare their performances for automatic segmentation [28]:

- We investigate average atlas construction, atlas stratification and patient-specific strategies based on the selection and fusion of the most appropriate atlases for each patient. We compared global, regional and local selection and fusion of the atlases.
- We show that the proposed patient-specific strategies enable to significantly improve the quality of the automatic segmentation in comparison with average atlas strategies. Visual results are presented on figure 3.
- We evaluated the proposed algorithms in two different contexts: segmentation of the lymph node levels and the organs at risk for radiotherapy planning, and segmentation of the teeth for post-irradiation dental care management. Automatic segmentations of the teeth are shown on figure 4.

5.2. Biological Image Analysis

5.2.1. Pre-clinical molecular imaging: reconstruction of tumors in rodents with SPECT imaging

Participants: Marine Breuilly [Correspondant], Grégoire Malandain, Nicholas Ayache, Jacques Darcourt [CAL], Philippe Franken [CAL], Thierry Pourcher [CEA].

This work is jointly conducted with the Transporter in Imagery and Oncologic Radiotherapy team (TIRO, CEA-CAL-UNSA) located in Nice.
Figure 3. Atlas-based segmentation of the lymph node level II using the average atlas (blue contours on left figure) and using the atlas that is locally adapted to the patient’s anatomy (yellow contours on right figure), compared with the manual contours (red contours on both figures).

Figure 4. Automatic segmentation of the teeth using a multi-atlas framework (in green) in comparison with the manual segmentation (in blue). Both segmentations are represented on the upper jaw.
The coupled CT and SPECT device allows to image both the anatomy (with the CT) and physiology information targeted by a dedicated radio-pharmaceutical tracer (here the tumors, with the SPECT). However, tumor quantification is impaired by the respiratory motion that induces an artificial enlargement of the moving structures. We propose then to select all the motion-less phases from a 4D SPECT images to reconstruct a motion-free 3D image. In addition, we also propose to correct for the heterogeneity of the respiratory cycles by re-tagging the SPECT raw data.

The resulting 3D motionless gated image shows improvement of volume accuracy compared to the non gated SPECT image; and noise reduction compared to the 4D SPECT image (see Figure 5).

5.3. Computational Anatomy

5.3.1. The Kernel Bundle framework: Sparse Multiscale Diffeomorphic Deformations

**Participants:** Stefan Sommer [DIKU], Mads Nielsen [DIKU], François Lauze [DIKU], Xavier Pennec [Correspondant].

*This work is performed in collaboration between DIKU (University of Copenhagen) and Asclepios (Inria). It was initiated during a 5 month visit of Stefan Sommer in 2011.*

In the analysis and modeling of anatomical deformations, we expect deformations to have both large and small scale components. However, we expect these large and small scale deformation to occur at different places. Thus, one would like to represent anatomical deformations with a small number of deformation atoms are different scales that are sparsely distributed across space and scale.

- In [71], we propose a multi-scale kernel bundle framework (LDDKBMM) that extends the LDDMM framework by incorporating multiple kernels at multiple scales in the registration. Experiments show that the method automatically adapts to the right scales, and it therefore removes the need for classical scale selection methods.
- In [72], we derive the Kernel Bundle EPDiff evolution equations, which provide optimal warps in this new framework.
5.3.2. Longitudinal modeling of the structural changes of the brain in Alzheimer’s disease.
Participants: Marco Lorenzi [Correspondant], Xavier Pennec, Giovanni Frisoni [IRCCS Fatebenefratelli Brescia, Italy], Nicholas Ayache.

This work is done in collaboration with LENITEM, IRCCS San Giovanni di Dio Fatebenefratelli, Brescia, Italy.

This work addresses the analysis and the quantification of the longitudinal structural changes of the brain affected by Alzheimer’s disease (AD). We propose a framework based on the non-rigid registration of brain MRIs using stationary velocity fields. In 2011, the main scientific developments were:

- Unbiased detection of the structural changes in the brain [60]. The method robustifies the Demons diffeomorphic registration by estimating and removing the multiplicative and additive intensity biases affecting the images.
- Definition of a population-based atlas for the longitudinal brain structural changes. In this work we proposed the Schild’s Ladder as a general method for parallel transporting the subject-specific longitudinal deformation trajectories in a reference space [61]. The work was awarded with the runner-up prize at the “Information Processing in Medical Imaging (IPMI)” conference in Irsee, Germany. Other transport methods from the Lie group theory have been successively proposed and investigated [62].
- Group-wise statistical analysis of the brain longitudinal changes in multiple time points [60]. The framework has been applied for the analysis of the longitudinal brain changes in healthy subjects at risk of AD, and the results showed an accelerated progression of atrophy for the subjects positive to the marker of Alzheimer Aβ42 (see Figure 6).

Finally, the above framework has been promoted to the neuroscience community as diagnostic tool and support for clinical trials [75].

5.3.3. Statistical Analysis of White Matter Fiber Bundles
Participants: Stanley Durrleman [Correspondant], Pierre Fillard [Parietal, INRIA Saclay], Xavier Pennec, Alain Trouvé [CMLA, ENS Cachan], Nicholas Ayache.

This work is an application of the generic morphometric method developed in 2009 to the statistical analysis of the shape and texture of white matter fiber bundles extracted from Diffusion Tensor Images (DTI).

- Registration, Atlas Estimation and Variability Analysis of White Matter Fiber Bundles Modeled as Currents [32].

5.3.4. Comparison of endocranial ontogenies in chimpanzees and bonobos
Participants: Stanley Durrleman [Correspondant], Xavier Pennec, Alain Trouvé [CMLA, ENS Cachan], Nicholas Ayache, José Braga [AMIS, Univ. Toulouse 3].

This work has been performed in the context of the INRIA collaborative project ARC 3D-Morphine (PI: Sylvain Prima, IRISA) and a follow-up collaboration with José Braga at Université Paul Sabatier, Toulouse.

This work quantifies ontogenetic differences between bonobo and chimpanzee endocrania, using dental development as a timeline. Synthetic endocranial trajectories are estimated from time series cross-sectional data. Then, differences in morphology and in rate of shape changes is quantified using the spatiotemporal registration introduced in 2009.

- Comparison of the endocranial ontogenies between chimpanzees and bonobos via temporal regression and spatiotemporal registration.
Figure 6. Top. Average longitudinal brain atrophy for the healthy subjects at risk for Alzheimer’s disease (Aβ42 positive). Bottom. Annual percentage differential evolution modelled for the Aβ42 positive group with respect to the healthy aging. The analysis shows an increased ventricular expansion and the matter loss in the cortex and in the temporal areas.
Figure 7. The proposed method estimates a variability model from the white matter fiber bundles extracted from six subjects (a-original data, b same data approximated at the current resolution). The model allows us to synthesize artificial bundles that reproduce the variability in shape and in fiber density estimated from the original data (c).

Image taken from [32]

Figure 8. Typical endocranial trajectory of bonobos (top) and chimpanzees (bottom) estimated from time series cross-sectional surface data (59 chimpanzees and 60 bonobos)
Figure 9. Graph of time-wrap (magenta curve) putting into correspondence the developmental stages of the bonobos to that of the chimpanzees. The function measures the differences in rate of shape changes over time between the endocranial trajectories estimated in Fig. 8. This shows that the bonobos endocranial ontogeny is retarded by a factor $0.25$ compared to that of the chimpanzees.

5.3.5. Statistical Modelling of Cardiac Growth and Deformation from Medical Images

Participants: Kristin McLeod [Correspondant], Tommaso Mansi, Adityo Prakosa, Maxime Sermesant, Xavier Pennec.

Parts of this work were performed within the framework of the EU project Care4me ITEA2, and the INRIA ARC Sirap, in collaboration with St Thomas Hospital, King’s College London, the REO team from INRIA Rocquencourt and Necker Paediatric Hospital in Paris.

This work builds on the statistical analysis framework for surfaces developed by Durrleman and Mansi in 2009.

- The iLogDemons motion tracking algorithm of Mansi et al [37] was applied to a data-set of 15 subjects and 1 phantom each with a cine-MR, tagged-MR and echocardiography sequence as a part of the STACOM workshop challenge at MICCAI 2011 [64]. The paper received the Best Paper Award for the Motion Challenge.
- The work of Mansi et al for a statistical model of cardiac growth in the right ventricle [38] was extended to the left ventricle to obtain a bi-ventricular cardiac growth model for patients with repaired tetralogy of Fallot (see Fig. 10).
- The preliminary analysis of a statistical model for reduced blood flow simulations in the pulmonary artery proposed in 2010 is currently being extended to a journal version to further analyse the method on a larger data-set.

5.3.6. Statistical Modeling of Shapes Using Trees of Locally Affine Transformations

Participants: Christof Seiler [Correspondant], Xavier Pennec, Mauricio Reyes [Institute for Surgical Technology and Biomechanics, University of Bern, Switzerland].
Figure 10. Mean growth model computed from a population of 13 repaired tetralogy of Fallot patients. Both ventricles grow as body surface area (used as an index of growth) increases.

This work is performed in the context of the joint PhD of Christof Seiler at the Institute for Surgical Technology and Biomechanics, University of Bern, Switzerland and Asclepios INRIA.

The goal of this work is to analyze anatomical shapes through deformations defined with few but important and intelligible parameters. Advances towards this goal were the following in 2011.

- Fusion of the Log-demons registration and the Log-Euclidean polyaffine framework. The results of the new registration method applied to femur CT’s was presented at SPIE [69].
- Decomposition of diffeomorphic deformations into a tree of locally affine transformations applied to mandible CT’s. This work won the young scientist award at MICCAI 2011 in Toronto [68].

5.3.7. Atlas of Cardiac Fiber Architecture from DT-MRI

Participants: Hervé Lombaert, Hervé Delingette [Correspondant], Nicholas Ayache, Jean-Marc Peyrat, Pierre Croisille.

This work is a collaboration between Creatis, Lyon and INRIA Sophia Antipolis, including members of Ecole Polytechnique of Montreal. Financial support is partly from the National Science and Engineering Research Council of Canada, and the Michael Smith Foreign Study Program.

The variability of the cardiac fiber architecture has been investigated in a human population. An automatic method has been developped to construct an atlas of DTMRI images. A statistical analysis has been carried on using the Log-Euclidean metric.

- An automatic method has been developped to construct an atlas of DTMRI images. The first human atlas of DTMRI has been build [56]. This work received the Best Paper Award at the FIMH 2011 conference in New York City.
- Results have also been published in [59] where the variability of the cardiac architecture is measured using the Log-Euclidean metric.
The variability of the cardiac laminar sheets in human DTMRI has been studied [58].

Differences in a population of normal and abnormal hearts have been investigated [57].

5.4. Computational Physiology

5.4.1. Tumor Growth Modeling

Participants: Erin Stretton [Correspondant], Nicholas Ayache, Hervé Delingette, Bjoern Menze, Ender Konukoglu, Ezequiel Geremia, Emmanuel Mandonnet.

This work was funded by Care4me.

- Performing a sensitivity analysis of long time series of multi-modal data.
- Improving our current models and their inputs, including creating a white matter and brain mask template with the help of a neurosurgeon and integrating the Powell bound constrained optimization into the minimization routine.
- Performed comparison of using a patient DTI, an atlas DTI or no DTI at all showing the difference in accuracies in the simulation results since the patient DTI is not always available in a clinical setting or is of poor quality. We found that using an atlas DTI produced only slightly less accurate results than using a patient DTI, where as using no DTI at all did not produce accurate results.

5.4.2. Synthetic Echocardiographic Image Sequences for Cardiac Inverse Electro-Kinematic Learning

Participants: Adityo Prakosa [Correspondant], Maxime Sermesant, Hervé Delingette, Eric Saloux [CHU Caen], Pascal Allain [Philips Healthcare], Pascal Cathier [Philips Healthcare], Patrick Etyngier [Philips Healthcare], Nicolas Villain [Philips Healthcare], Nicholas Ayache.
Figure 12. Tracked fibers from the human atlas of DTMRI of the myocardium.
This work is done in collaboration with Medisys, Philips Healthcare Suresnes, France, and Cardiology Department of CHU Caen, France.

- A database of 120 synthetic 3D echocardiography (US) sequences is created based on a cardiac electromechanical model (see Figure 13).
- Kinematic descriptors are extracted from the displacement field estimated from the synthetic 3D US sequence using the iLogDemons non-rigid registration method [37].
- Cardiac inverse electro-kinematic learning is done by using the database of synthetic 3D US sequences in order to estimate the cardiac depolarization times for the given kinematic descriptors [67]. First evaluation on two clinical sequences from patients with Left Bundle Branch Block shows encouraging results.

5.4.3. Prediction of patient-specific Ventricular Tachycardia for radio-frequency ablation therapy planning

Participants: Jatin Relan [Correspondant], Maxime Sermesant, Hervé Delingette, Nicholas Ayache.

This work is funded by the FP7 European Project euHeart.

In this work, we build a patient-specific cardiac electrophysiology (EP) model derived from hybrid XMR imaging and non-contact electro-anatomical mapping procedure on a patient with heart failure. The model is then used to predict patient-specific arrhythmias, such as induced ischemic Ventricular Tachycardia (VT) (Fig. 14) and leads in generation and evaluation of patient-specific VT circuits, with critical exit points for Radio Frequency (RF) ablation. These predictions are now validated with some clinical cases, with electrophysiology mapping of induced VT in patients undergoing the clinical VT-Stim procedures (Fig. 14).

5.4.4. Real-time simulation of catheter ablation in the context of cardiac arrhythmia

Participants: Hugo Talbot [Correspondant], Federico Spadoni, Maxime Sermesant, Hervé Delingette, Stephane Cotin.
Figure 14. (a & b) Analysis of electroanatomical mapping data, to personalise the depolarisation and repolarisation wavefront dynamics. (c) Anatomical data personalisation along with ischemic regions (red). (d) A VT inducibility map showing regions with high probability of inducing VT with a VT-Stim procedure. (e) Critical exit point map showing the most eligible regions for RF ablation success. (f & g) An example of one of the various induced VT circuits, with VT-Stim model prediction. (h & i) Induced VT circuit in a clinical case (red = exit point).

This work is performed in the context of the euHeart project and the PhD of Hugo Talbot in collaboration with the Shacra (INRIA, Lille Nord Europe) team.

- This work aims at simulating in real-time the endovascular procedure of radiofrequency ablation of the left ventricle for patient suffering from Ventricular Tachycardia.
- Fast simulation of electrophysiology has been reached with a Eikonal model[40].
- Use the SOFA platform for simulating endovascular navigation and cardiac electrophysiology.

5.4.5. Personalized model of the heart for cardiac therapy planning

Participants: Stéphanie Marchesseau [Correspondant], Ken C.L. Wong, Hervé Delingette, Maxime Serme-sant, Nicholas Ayache.

This work has been performed in the context of the euHeart european project.

- We improved the existing electromechanical model of the heart (see Fig 16 ) to include mechanical non linearity, viscosity and strain rate dependent contractility. It was implemented in SOFA with a new four valves model to deal with the cardiac phases and enforce isovolumetric constraint.
- We have obtained first personalization of cardiac mechanics from 3 cine-MRI cases using a variational approach (adjoint method)[54].
Figure 15. (Left) Simulation of catheterization with a force-feedback device; Simulation of cardiac electrophysiology.

Figure 16. (Left) Electromechanical model of the heart that is coupled with medical images; (Right) Pressures and volumes curves of the left ventricle resulting from the simulation of one cardiac cycle.
ASCOLA Project-Team

6. New Results

6.1. Aspects

Participants: Rémi Douence, Abdelhakim Hannousse, Ismael Mejía, Jacques Noyé, Angel Núñez, Nicolas Tabareau, Mario Südholt.

We have provided results on three subject matters in the domain of aspect-oriented software development: the foundations of aspects, aspect languages and their applications, as well as the use of aspects for the manipulation of distributed systems.

As a side note on the form of this document, the reader should be aware that much of our work reported in this section is not exclusive to AOSD but also contributes to software composition issues in a larger sense. This applies, in particular, to the results cited in the subsections on aspect languages and distributed aspects.

6.1.1. Foundations of Aspects

In the domain of foundations of AOSD, we have mainly provided new results on the preservation of formal correctness properties in the presence of aspects and how AOP can be modeled using category theory.

- **Property preservation in the presence of aspects.** In general aspects can arbitrarily change the semantics of the base program. We have identified categories of aspects that preserve class of properties of the base programs [17]. This approach makes it possible to prove once and for all that a category of aspects preserve a class of properties. The categories are defined with respect to the semantics of the woven program as well as with restricted aspect languages. In this latter case, languages are defined by grammars hence checking for property preservation boils down to a syntactic check for aspects. Classes of properties are defined using a subset of temporal logic both for sequential and concurrent programs. Our framework is abstract in that it does not depend on the actual programming language but only on conditions on its small step semantics.

- **AOP and category theory.** Aspect-Oriented Programming (AOP) started ten years ago with the remark that modularization of so-called crosscutting functionalities is a fundamental problem for the engineering of large-scale applications. Originating at Xerox PARC, this observation has sparked the development of a new style of programming that is gradually gaining traction. However, AOP lacks theoretical foundations to clarify new ideas showing up in its wake. We have proposed to put a bridge between AOP and the notion of 2-category to enhance the conceptual understanding of AOP [36], [46]. Starting from the connection between the \(\lambda\)-calculus and the theory of categories, we have provided an internal language for 2-categories and shown how it can be used to define the first categorical semantics for a realistic functional AOP language, called MinAML. We have later taken advantage of this new categorical framework to introduce the notion of computational 2-monads for AOP [37]. We have illustrated their conceptual power by defining a 2-monad for Éric Tanter’s execution levels—which constitutes the first algebraic semantics for execution levels—and then introducing the first exception monad transformer specific to AOP that gives rise to a non-flat semantics for exceptions by taking levels into account.

- **Membranes for AOP.** AOP aims to enhance modularity and reusability in software systems offering an abstraction mechanism to deal with crosscutting concerns. However, in most aspect-oriented languages aspects have a global view of computation that actually introduces a strong coupling between advised code and aspect code, hampering modularity. Proposals that address this problem can be classified in two categories: the first one focuses on controlling aspect scoping, i.e. the visibility of join points to aspects, while the second one focuses on protecting software units from aspects. As a new approach, we have proposed programmable membranes (inspired by the work of Boudol for distributed processes) to control aspect influence over software systems as a uniform framework that unifies and extends previous approaches [49].
• **Aspects and invertible program restructurations.** When one chooses a main axis of structural decomposition of a problem, the other axes become secondary. This is known as the tyranny of the dominant decomposition and this hinders program maintenance of secondary concerns. We propose to use automatic program transformations built on top of refactorers in order to solve this tyranny issue [47]. This offers a new approach to the expression problem by always providing the right view to the programmers.

6.1.2. Aspect Languages

This year we have provided major results on the integration of programming features for objects, events and aspects, and aspect execution infrastructures. Furthermore, we have investigated the application of aspect languages to the Java security model, component-based software development and software product lines.

• **Integrating OOP, AOP and EBP:** Object-Oriented Programming (OOP) has become the de facto programming paradigm. Event-Based Programming (EBP) and Aspect-Oriented Programming (AOP) complement OOP, covering some of its deficiencies when building complex software. Today’s applications combine the three paradigms. However, OOP, EBP and AOP have not yet been properly integrated. Their underlying concepts are in general provided as distinct language constructs, whereas they are not completely orthogonal. This lack of integration and orthogonality complicates the development of software as it reduces its understandability, its composability and increases the required glue code. [16] proposes an integration of OOP, EBP and AOP leading to a simple and regular programming model. This model integrates the notions of class and aspect, the notions of event and join point, and the notions of piece of advice, method and event handler. It reduces the number of language constructs while keeping expressiveness and offering additional programming options. ECaesarJ had previously been developed based on these ideas. [16] introduces a simpler variant of it, EJava, a plain extension of Java. [24] shows that these ideas can also be easily applied to Scala, leading to EScala, and focuses on the idea that the declarative events provided by the model can be seen as object-oriented events, which, unlike global typed events, obey to the basic OO principles (OO modular reasoning, encapsulation and late-binding). An efficient implementation of EScala is described, based on the idea that an event should not be produced in the absence of at least a consumer. This is equivalent to what could be programmed by hand using variants of the observer pattern, except that all the necessary scaffolding is provided by the language compiler and runtime rather than by the programmer.

• **Prototyping and composing Aspect Languages:** [11] presents CALI (Common Aspect Languages Interpreter), a framework for rapid prototyping and composition of aspect languages based on interpreters. In practice the common interpreter is actually a thin interpretative layer built on top of Java and implemented as an AspectJ aspect. This interpreter implements common aspect mechanisms and leaves holes to be defined when developing concrete languages. The approach has been validated by implementing prototypes of significant subsets of well-known general-purpose and domain-specific aspect languages (AspectJ, EAOP, COOL and a couple of other small domain-specific aspect languages) and exploring variants of AspectJ. Languages implemented with CALI, for instance AspectJ and COOL, can then be easily composed.

• **Application to security:** It is inevitable that some concerns crosscut a sizeable application, resulting in code scattering and tangling. This issue is particularly severe for security-related concerns: it is difficult to be confident about the security of an application when the implementation of its security-related concerns is scattered all over the code and tangled with other concerns, making global reasoning about security precarious. In [21], we consider the case of access control in Java, which turns out to be a crosscutting concern with a non-modular implementation based on runtime stack inspection. We describe the process of modularizing access control in Java by means of AOP. We first show a solution based on AspectJ that must rely on a separate automata infrastructure. We then put forward a novel solution via dynamic deployment of aspects and scoping strategies. Both solutions, apart from providing a modular specification of access control, make it possible to easily express other useful policies such as the Chinese wall policy. However, relying on expressive scope
control results in a compact implementation, which, at the same time, permits the straightforward expression of even more interesting policies.

- **Aspects and software components**: The relationship of aspects and components, as well as their integration as part of real-world infrastructures and applications is still subject to many open issues. We have studied, in particular, how crosscutting concerns naturally appear when several architectural views must be considered at the same time. In this context, we have proposed a domain-specific language to specify these architectures. We have proposed an implementation of composable controllers in Fractal as well as composition operators that makes it possible to solve aspects interferences [25]. We have also shown how to formally model the implementation in Uppaal in order to statically check aspects interference [26]. This work has principally been undertaken in the context of the PhD thesis of Abdelhakim Hannouse [12] that has been defended in Sep. 2011. Another fundamental issue that relates components and aspects is the question whether behavioral protocols can be used to concisely define crosscutting concerns of component-based systems. Furthermore, the protocols should then be instrumental to enable (automatic) reasoning about composition properties of component systems. As part of her PhD thesis (defended in Oct. 2011) [14], Dong Ha Nguyen has defined a notion of aspects that allow crosscutting concerns to be expressed in terms of a class of non-regular behavioral protocols, so-called visibly-pushdown languages. She has developed, most notably, a constructive way of building correct component-based systems that respect such aspect-modified behavioral protocols. Furthermore, she has shown this year how composition properties can generally be verified using model checking techniques.

- **Aspects and software product lines**: In [41], we take a closer look at the difficulties of feature-oriented modularisation of product lines and demonstrate, using a case study in the domain of home automation, how a better modularisation can be achieved with the ECaesarJ programming language, through a type-safe and stable decomposition of a broad spectrum of software abstractions: classes, methods, events, and state machines, based on late binding and mixin composition. A nice property of this modularisation is that it directly captures, at the implementation level, the high-level decomposition in features, without requiring the user to resort on complex transformation technology (the technology is embedded in the compiler).

Furthermore, ASCOLA members have co-edited and contributed to a comprehensive book on aspects, model-driven engineering and product lines [42] (see Sec. 6.2 for details).

### 6.1.3. Aspects for Distributed Systems

In the field of aspects for distributed systems, we have mainly extended the AWED model for distributed aspects (see Sec. 5.1) in order to define and implement a gray-box distributed composition model. We have also worked on a notion of distributed crosscuts that enable causality relationships to be captured using logical clocks.

- **Gray-box distributed composition**: Existing composition and coordination techniques for distributed applications typically support only interface-level (black-box) composition or arbitrary access to the implementation (gray-box or white-box composition). In [20], we have presented a structured approach to the composition of complex distributed software systems that require invasive modifications. Concretely, we have provided three contributions:
  - We have introduced a small kernel composition language for structured gray-box composition using invasive distributed patterns.
  - We have motivated that gray-box composition approaches should be defined and evaluated in terms of the flexibility and control they provide; a notion of degrees of invasiveness has been introduced to help assess this trade-off.
  - We have applied and evaluated it in the context of several studies involving two real-world software systems: benchmarking of grid algorithms with NASGrid and transactional replication with JBoss Cache. As a main result, we have shown that gray-box composition using
invasive distributed patterns allows the declarative and modular definition of evolutions of real-world applications that need moderate to high degrees of invasive modifications.

We have then provided a first framework-based implementation based on our AWED tool and applied it to evolution tasks in OpenMRS, a health information system [31]. The composition framework supports the definition of expressive pattern-based invasive compositions based on the skeleton paradigm for distributed patterns. Concretely, we have shown that the composition framework enables the concise definition of an evolution scenario of OpenMRS that supports the consolidation of patient data from different distributed instances.

Finally, we have studied a model that integrates distributed aspects and actors and thus improves on the robustness properties of existing models for distributed aspects [32].

- **Causal aspects for distributed applications.** In [45], we have applied logical clocks à la Lamport in order to define causality between distributed join points. This enables us to declaratively define pointcuts in a distributed context such as web-based applications in JavaScript. The definition of advice can then be simplified, because they are executed only when necessary and do not have to maintain and check crosscutting information.

### 6.2. Software Composition

**Participants:** Jean-Claude Royer, Hervé Grall, Christine Louberry, Mario Südholt.

ASCOLA’s work on software composition addresses the foundations of software composition methods, the definition and implementation of concrete composition techniques and their application to different functionalities and application domains. This year we have contributed to the questions of how to identify components in legacy software, how to effectively deploy and reconfigure component-based software in pervasive environments, and how to apply software composition techniques to Cloud security as well as software product lines.

- **Component identification.** The communication integrity property is one of the major principles to implement software architectures, however, there is a lack of tooling for assessing the quality of components codes. To cope with this issue, we defined, in [23], a Java component model and a tool for identifying component types based on the communication integrity property. We apply it to several case studies and compare the result with the SOMOX component recovery tool.

- **QoS-driven deployment and reconfiguration of pervasive applications.** [28] presents the Kalimucho platform, a platform for the dynamic reconfiguration of applications on mobiles and constraints devices. First this article focuses on the heuristics implemented by Kalimucho. They support finding a configuration and a deployment matching two criteria: utility and durability. Moreover, we present a case study to experiment the approach of Kalimucho. It confirms that Kalimucho provides a satisfactory execution time for mobile devices.

A second result we have contributed in this context is a two-dimensional QoS model for Kalimucho that supports the QoS-driven deployment of mobile applications [29]. After presenting the definitions of the context and the quality of service considered in this work, this article describes the QoS model and the process allowing finding the best configuration and deployment. Finally, we present several results concerning the execution time of the deployment process of Kalimucho with different devices.

- **Securing the Cloud: cross domain and multi-level concerns.** The evolution of new deployment architectures, as illustrated by the move towards mobile platforms and the Internet Of Services, and the introduction of new security regulations (imposed by national and international regulatory bodies, such as SOX4 or BASEL5) are important constraints in the design and development of service composition. In such a context, it is not sufficient to apply the corresponding adaptations only at the service orchestration or at the choreography level; there is also the need for controlling the impact of new security requirements on several architectural layers. In [35] we have presented a new service model that supports the clean modularization of such crosscutting security concerns.
• **Software composition and product lines.** As part of the AMPLE project (see [http://www.ample-project.net](http://www.ample-project.net)) we have co-edited a book [42] covering the main scientific solutions and techniques on new methods and techniques for software product lines that have been developed in the project. This project aims at improving traditional software product lines engineering using advanced software engineering namely model-driven and aspect-oriented engineering approaches. Software composition takes an important part in this book and it appears in several chapters with models, events, aspects and components.

Chapter [43] provides an overview of software product lines, model-driven engineering and aspect-oriented software development. The challenges to address and the expected benefits are drawn, this is concluded by an overview of the AMPLE approach and its tool chain.

Chapter [40] reviews the specificities of traceability in a product line context starting by identifying the challenges of maintaining traceability for traditional system development and for software product lines. This work defines the concepts that should guide the adoption of a traceability environment for product lines and illustrates these specifications with a concrete example of a traceability repository. It also provides examples of scenarios that use this traceability environment to solve concrete problems.

### 6.3. Cloud Computing, Virtualization and Data Centers

**Participants:** Frederico Alvares, Gustavo Bervian Brand, Thomas Chavrier, Fabien Hermenier, Adrien Lèbre, Thomas Ledoux, Guillaume Le Louët, Jean-Marc Menaud, Hien Nguyen Van, Rémy Pottier, Flavien Quesnel.

In the context of Cloud computing ASCOLA members have principally worked this year on capacity planning solutions for large scale distributed system. Capacity planning is the process of planning, analyzing, sizing, managing and optimizing capacity to satisfy demand in a timely manner and at a reasonable cost.

Applied to distributed systems like the Cloud, a capacity planning solution must mainly provide necessary resources for the proper execution of applications and respect service-level agreements in a large distributed environment.

The main challenges in this context are: scalability, fault tolerance and reactivity of the solution in a large-scale distributed system; analyzing, sizing, and optimizing resources to minimize the cost (energy, human, hardware etc.); and profiling, adapting application to ensure the quality of service (throughput, response time, availability etc.).

Our solutions are mainly based on virtualized infrastructures. Our main results concern the management and the execution of applications by leveraging virtualization capabilities on cloud infrastructures and the investigation of solutions that aim at optimizing the trade-off between performance and energy costs of both applications and Cloud resources.

#### 6.3.1. Virtualization and Job Management

This year, in cooperation with the Myriads project-team from INRIA Rennes-Bretagne Atlantique, we have continued to address resource-management issues concerning the federation of very large scale platforms. We have completed our approach aiming at the automatic adaptation of both hardware and software resources to the needs of the applications through a unique method. For each application, scientists describe the requirements in terms of both hardware and software expectations through the definition of a Virtual Platform (VP) and a Virtual System Environment (VSE) [18].

In addition, we started to address the design and the implementation of a fully distributed cloud OS. Designing and implementing such models is a tedious and complex task. However, as well as research studies on OSes and hypervisors are complementary at the node level, we showed that virtualization frameworks can benefit from lessons learned from distributed operating system proposals [34]. Leveraging this preliminary result, we designed and developed a first proof-of-concept of a fully distributed scheduler [33]. This system makes it possible to schedule VMs cooperatively and dynamically in large scale distributed systems. Preliminary results showed that our scheduler was more reactive. This building block is a first element of a more complete...
cloud OS, entitled DISCOVERY (DIStributed and COoperative mechanisms to manage Virtual EnviRonments autonomaLLY) [30]. The ultimate goal of this system is to overcome the main limitations of the traditional server-centric solutions. The system, currently under development, relies on a peer-to-peer model where each agent can efficiently deploy, dynamically schedule and periodically checkpoint the virtual environments s/he manage.

We have contributed new results on the Entropy software and extended our solution VM that features dynamic consolidation. In [44] and [38] we extended our dynamic consolidation manager to take into account not only resource constraints but also the placement constraints of highly available (HA) applications. In fact, most previous dynamic consolidation systems optimize the placement of the VMs according to their resource usage but do not consider the application placement constraints that are required to achieve both high availability and scalability. Our approach provides efficient dynamic consolidation while guaranteeing to the application administrator that placement requirements will be satisfied and relieving the data center administrator of the burden of considering the constraints of the applications when performing maintenance.

In the same domain, Jean-Marc Menaud has defended his habilitation (HdR - Habilitation à diriger des recherches) [13] on Jun. 22, 2011. One part of this HDR focuses on dynamic adaptation strategies for cluster administration. We have proposed a dedicated language for virtual machines management and one particular feature of our solution is to use a constraint solver to provide an appropriate placement. Based on these results, our recent contributions address the problem of data center energy consumption.

Moreover, we have continued to analyze how energy concerns can be addressed in large scale distributed infrastructures.

### 6.3.2. Optimization of Energy Consumption in Data Centers

As a direct consequence of the increasing popularity of Cloud Computing solutions, data centers are growing at a fast rate and hence have to face difficult energy consumption issue. Available solutions rely on Cloud Computing models and virtualization techniques to scale up/down applications based on their performance metrics. Although those proposals can reduce the energy footprint of applications and, by transitivity, of cloud infrastructures, they do not consider the internal characteristics of applications to finely define a trade-off between QoS properties of applications and their energy footprint. In [22], we propose a self-adaptation approach that considers both application internals and system properties to reduce the energy footprint in cloud infrastructures. Each application and the infrastructure are equipped with their own control loop, which allows them to autonomously optimize their executions. Simulations show that the approach may lead to appreciable energy savings without interfering on application provider revenues.

### 6.3.3. Cloud Computing and SLA Management

Cloud computing is a paradigm for enabling remote, on-demand access to a set of configurable computing resources as a service. The pay-per-use model enables service providers to offer their services to customers at different Quality-of-Service (QoS) levels. These QoS parameters are used to compose service-level agreements (SLAs) between a service provider and a service consumer. A main challenge for a service provider is to manage SLAs for its service consumers, i.e., automatically determine the appropriate resources required from the lower layer in order to respect the QoS requirements of the consumers. In [27], we have proposed an optimization framework driven by consumer preferences to address the SLA dependencies problem across the different cloud layers as well as the need of flexibility and dynamicity required by the domain of Cloud computing. Our approach aims at selecting the optimal vertical business process designed using cross-layer cloud services and enforcing SLA dependencies between layers. Experimental results demonstrate the flexibility and effectiveness of our approach.

### 6.4. Foundations of program semantics

**Participants:** Nicolas Tabareau, Guilhem Jaber.

ASCOLA team members have contributed several results to the foundations of program semantics.
6.4.1. Program Equivalences

Reasoning about program equivalence is a major problem in semantics. This very old topic has many applications, e.g., program verification, compiler correctness or representation independence. It has been understood since the late 1960s that tools and structures arising in mathematical logic and proof theory can usefully be applied to the development of reasoning principles for program equivalence. In recent years, based on the seminal work of Pitts and Stark, the notion of logical relation appeared to be very fruitful for proving the equivalence of programs in the presence of features like general recursive types, general (higher-order) mutable references, and first-class continuations. We have studied the notion of logical relations for proving program equivalences of low level machine codes [39].

We have also developed a forcing theory inspired by Cohen’s forcing to increase the power of a semantics model just as the latter makes it possible to enrich a set theoretical universe. In this way, we can define a new generation of logical relations—that can be introduced modularly using forcing theory—to be used for proving program equivalence for low level languages, concurrent languages or domain specific languages. [48]
5. New Results

5.1. Reactive trajectories for molecular dynamics

Participants: Frédéric Cérou, Arnaud Guyader, Florent Malrieu.

See 3.3 and 4.2.

This is a collaboration with Tony Lelièvre (CERMICS, Ecole des Ponts ParisTech).

Consider a one-dimensional Brownian motion in a double well potential. It is known that, as its variance goes to zero, the Brownian particle has to wait for a longer and longer time to jump from a well to the other. This metastable behavior is described by the Freidlin–Wentzell theory. We are investigating the length of the paths between the last passage time in the bottom of a well and the hitting time of the other one (reactive trajectory). In the case of an Ornstein–Uhlenbeck process between the wells, we obtained the remarkable result that the time length of the reactive trajectories converges in distribution when the noise intensity goes to zero, to a Gumbel random variable shifted by a deterministic term growing like minus the logarithm of the noise intensity. Our numerical simulations are also in good accordance with this theoretical result. We are also very close to extend this result to more general one-dimensional diffusion processes.

5.2. Learning the optimal importance distribution

Participants: François Le Gland, Rudy Pastel.

See 3.3 and 4.2.

This is a collaboration with Jérôme Morio (ONERA Palaiseau).

As explained in 3.3, multilevel splitting ideas can be useful even to solve some static problems, such as evaluating the (small) probability that a random variable exceeds some (extreme) threshold. Incidentally, it can also be noticed that a population of particles is available at each stage of the algorithm, which is distributed according to the original distribution conditioned on exceeding the current level. Furthermore, this conditional distribution is known to be precisely the optimal importance distribution for evaluating the probability of exceeding the current level. In other words, the optimal importance distribution is learned automatically by the algorithm, as a by-product, and therefore can be used to produce an importance sampling estimate with very low variance. Building on this idea, several other iterative methods have been studied, that learn the optimal importance distribution at each stage of the algorithm, such as nonparametric adaptive importance sampling (NAIS) [69], or the cross-entropy (CE) method [65], [33]. These methods have been applied to a practical example from the aerospace industry, the evaluation of collision probabilities between two satellites, or between a satellite and space debris.

5.3. Impact of dimension in particle filtering and the Laplace method

Participants: François Le Gland, Paul Bui-Quang.

See 3.1.

This is a collaboration with Christian Musso (ONERA Palaiseau).
Particle filtering is a widely used Monte Carlo method to approximate the posterior probability distribution in non-linear filtering, with an error scaling as $1/\sqrt{N}$ in terms of the sample size $N$, but otherwise independently of the underlying state dimension. However, it has been observed for a long time in practice that particle filtering can be quite inefficient when the dimension of the system is high. In a simple static linear Gaussian model, it has been possible indeed to check that the error on the estimation of the predicted likelihood, a quantitative indicator of the consistency between the prior distribution and the likelihood function, increases exponentially with the dimension \[30\]. This preliminary result has been extended to a non-linear / non-Gaussian model, using the Laplace method \[23\]. The Laplace method, which approximates multidimensional integrals accurately, has also been used to compute the asymptotic variance of the importance weights, as the sample size $N$ goes to infinity, and to analyze its dependence on the dimension.

5.4. Stochastic wind-wave modelling

**Participant:** Valérie Monbet.

This is a collaboration with Pierre Ailliot (UBO) and Christophe Maisondieu (IFREMER).

Directional wave spectra generally exhibit several peaks due to the coexistence of wind sea generated by local wind conditions and swells originating from distant weather systems. This paper proposes a new algorithm for partitioning such spectra and retrieving the various systems which compose a complex sea-state. It is based on a sequential Monte-Carlo algorithm which allows to follow the time evolution of the various systems. The main particularity of the algorithm is that the dimension of the hidden state can change from time to time and a model selection step is included. The proposed methodology is validated on both synthetic and real spectra and the results are compared with a method commonly used in the literature.

5.5. Sequential data assimilation: ensemble Kalman filter vs. particle filter

**Participants:** François Le Gland, Valérie Monbet.

*See 6.4.*

Surprisingly, very little was known about the asymptotic behaviour of the ensemble Kalman filter \[38\], \[39\], \[40\], whereas on the other hand, the asymptotic behaviour of many different classes of particle filters is well understood, as the number of particles goes to infinity. Interpreting the ensemble elements as a population of particles with mean-field interactions, and not only as an instrumental device producing an estimation of the hidden state as the ensemble mean value, it has been possible to prove the convergence of the ensemble Kalman filter, with a rate of order $1/\sqrt{N}$, as the number $N$ of ensemble elements increases to infinity \[25\]. In addition, the limit of the empirical distribution of the ensemble elements has been exhibited, which differs from the usual Bayesian filter. The next step has been to prove (by induction) the asymptotic normality of the estimation error, i.e. to prove a central limit theorem for the ensemble Kalman filter.
ATEAMS Project-Team

6. New Results

6.1. Ambiguity Detection in Context-free Grammars

The work on static detection of ambiguity in context-free grammars continued in 2011. Bas Basten has worked on scaling previous results to so-called character level grammars. This includes the application of declarative disambiguation filters that increase the efficiency as well as the accuracy of the analysis [14].

6.2. Automated Diagnostics for Ambiguity in Context-free Grammars

When an ambiguity is found this is reported by a complex trace (usually a set of parse trees). It is difficult for a human to spot the cause of the ambiguity and devise a fitting solution. The Dr Ambiguity algorithm is an expert tool, by Bas Basten and Jurgen Vinju, that compares different parse trees for the same sentence on essential attributes that can be distinguished by declarative disambiguation methods [15].

6.3. A general library for software visualization

The Rascal standard library was extended with a very flexible component for the rapid construction of new/experimental (inter-active) visualizations. The current library is fully working and forms the inspiration for a possible domain-specific extension of the Rascal meta programming language to be integrated at a later stage [23]. This is work by Paul Klint and Atze van der Ploeg.

6.4. Comparing Design Patterns - the case of Visitor versus Interpreter

In this research application of Rascal, Mark Hills, Tijs van der Storm, Paul Klint and Jurgen Vinju focused on analyzing the emergent differences in quality when choosing between two different source code design patterns. We constructed a refactoring tool that translates instances of the Visitor design pattern to the Interpreter design pattern in a semi-automated fashion. This then allowed us to study two versions of an otherwise equivalent system in terms of efficiency and maintainability [24].

6.5. Entry in the language workbench competition

Tijs van der Storm and Jurgen Vinju participated on the Language Workbench Competition 2011 (LWC’11), showcasing the DSL construction and capabilities of Rascal. The objective was the development of a number of DSLs for entity-relation modeling. The modular implementation of these languages was documented in a technical report [35]. The DSL implementation featured modular context-free grammars for parsing, modular type checkers, modular code generators and full-fledged IDEs (syntax highlighting, outlining, error marking, etc.). The complete implementation only takes around 700 lines of Rascal code.

6.6. A compiler for OBERON-0

Tijs van der Storm led the participation of ATEAMS in the LDTA Tool Challenge 2011. This was a collaborative effort together with Atze van der Ploeg, Mark Hills, Bas Basten, Paul Klint, Bert Lisser, Jeroen van den Bos, Jurgen Vinju and Arnold Lankamp. The objective of the challenge was to implement all aspects of a simple, imperative language called Oberon-0. The components that had to be implemented included: parsing, pretty printing, name analysis, type checking, and compilation to C. Additionally, the components should be developed in a modular fashion according to four language levels: each language level added more language features and required the modular extension of the components. Although not required for the challenge, we also developed a compiler targeting Java, a compiler targeting JVM byte code, a control-flow graph visualizer, and IDE support. The implementation required only around 4200 lines of Rascal code. The result was presented at the international workshop on Language Descriptions Tools and Applications.
6.7. Generalized Grammar Recovery

Vadim Zaytsev managed to generalize the algorithm for recovering context-free grammars from legacy language documentation. This facilitates the recovery of a lot more grammars to be used in the study of grammarware and software language engineering.

6.8. Comparing Context-free Grammars through test data

Equivalence of the languages generated by two different context-free grammars is undecidable, yet language equivalence is one of the most important quality aspects of context-free grammars for programming languages. Vadim Zaytsev introduced and experimentally validated a method based on differential analysis: generating sentences from both grammars and cross-testing them.
6. New Results

6.1. Computational Diffusion MRI

This sub-theme is dedicated to describe our various contributions performed within the framework of Computational Diffusion MRI. In 6.1.1, we start by presenting our contributions to improving dMRI signal and optimize dMRI acquisition schemes. Then, we present our modeling contributions related to the problem of reconstructing and characterizing important Diffusion MRI features such as the Orientation Distribution Function (ODF) and the Ensemble Average Propagator (EAP) in 6.1.2, including contributions of the compressed sensing theory to dMRI and contributions to online motion detection. Finally, we end up, in 6.1.3, with some general applications such as tractography, clustering and microstructures recovery with pore size distribution estimation.

6.1.1. Improving dMRI Signal and Acquisitions

6.1.1.1. Optimal Design of Multiple Q-shells experiments for Diffusion MRI

Participants: Rachid Deriche, Emmanuel Caruyer, Iman Aganj [Department of Electrical and Computer Engineering, University of Minnesota], Christophe Lenglet [Department of Electrical and Computer Engineering, University of Minnesota], Guillermo Sapiro [Department of Electrical and Computer Engineering, University of Minnesota], Jian Cheng [ATHENA and LIAMA, China], Jiang Tianzi [LIAMA, China].

This work was partly supported by the CD-MRI Associate Team.

Recent advances in diffusion MRI make use of the diffusion signal sampled on the whole Q-space, rather than on a single sphere. While much effort has been done to design uniform sampling schemes for single shell experiment, it is yet not clear how to build a strategy to sample the diffusion signal in the whole Fourier domain. In this work, we proposed a method to generate acquisition schemes for multiple Q-shells experiment in diffusion MRI. The acquisition protocols we designed are incremental, which means they remain approximately optimal when truncated before the acquisition is complete. Our method is fast, incremental, and we can generate diffusion gradients schemes for any number of acquisitions, any number of shells, and any number of points per shell. The samples arranged on different shells do not share the same directions. The method has been tested for Spherical Polar Fourier reconstruction of the diffusion signal, and is based on Monte-Carlo simulations. Several preferred acquisition parameters are identified.

This work has been published in [20].

6.1.1.2. Incremental gradient table for multiple Q-shells diffusion MRI

Participants: Rachid Deriche, Emmanuel Caruyer, Iman Aganj [Department of Electrical and Computer Engineering, University of Minnesota], Christophe Lenglet [Department of Electrical and Computer Engineering, University of Minnesota], Guillermo Sapiro [Department of Electrical and Computer Engineering, University of Minnesota].

This work was partly supported by the CD-MRI Associate Team.

Most studies on sampling optimality for diffusion MRI deal with single Q-shell acquisition. For single Q-shell acquisition, incremental gradient table has proved useful in clinical setup, where the subject is likely to move, or for online reconstruction. In this work, we proposed a generalization of the electrostatic repulsion to generate gradient tables for multiple Q-shells acquisitions, designed for incremental reconstruction or processing of data prematurely aborted.

This work has been published in [21].

6.1.1.3. Impact of radial and angular sampling on multiple shells acquisition in diffusion MRI

Participants: Rachid Deriche, Sylvain Merlet, Emmanuel Caruyer.
In this work, we evaluated the impact of radial and angular sampling on multiple shells (MS) acquisition in diffusion MRI. The validation of our results is based on a new and efficient method to accurately reconstruct the Ensemble Average Propagator (EAP) in terms of the Spherical Polar Fourier (SPF) basis from very few diffusion weighted magnetic resonance images (DW-MRI). This approach nicely exploited the duality between SPF and a closely related basis in which one can respectively represent the EAP and the diffusion signal using the same coefficients. We efficiently combined this relation to the recent acquisition and reconstruction technique called Compressed Sensing (CS). Based on results of multi-tensors models reconstruction, we showed how to construct a robust acquisition scheme for both neural fibre orientation detection and attenuation signal/EAP reconstruction.

This work has been published in [32].

### 6.1.1.4. Simultaneous Smoothing and Estimation of DTI via Robust Variational Non-local Means

**Participants:** Rachid Deriche, Meizhu Liu [Department of CISE, University of Florida, Gainesville, USA], Baba Vemuri [Department of CISE, University of Florida, Gainesville, USA].

Regularized diffusion tensor estimation is an essential step in DTI analysis. There are many methods proposed in literature for this task but most of them are neither statistically robust nor feature preserving denoising techniques that can simultaneously estimate symmetric positive definite (SPD) diffusion tensors from diffusion MRI. One of the most popular techniques in recent times for feature preserving scalar-valued image denoising is the non-local means filtering method that has recently been generalized to the case of diffusion MRI denoising. However, these techniques denoise the multi-gradient volumes first and then estimate the tensors rather than achieving it simultaneously in a unified approach. Moreover, some of them do not guarantee the positive definiteness of the estimated diffusion tensors. In this work, we proposed a novel and robust variational framework for the simultaneous smoothing and estimation of diffusion tensors from diffusion MRI. Our variational principle makes use of a recently introduced total Kullback-Leibler (tKL) divergence, which is a statistically robust similarity measure between diffusion tensors, weighted by a non-local factor adapted from the traditional non-local means filters. For the data fidelity, we use the nonlinear least-squares term derived from the Stejskal-Tanner model. We have performed experimental results depicting the positive performance of our method in comparison to competing methods on synthetic and real data examples.

This work has been published in [31].

### 6.1.1.5. Anisotropic LMMSE denoising of MRI based on statistical tissue models

**Participants:** Rachid Deriche, Gonzalo Vegas-Sánchez-Ferrero [Universidad de Valladolid, Spain], Santiago Aja Fernández [Universidad de Valladolid, Spain].

Linear Minimum Mean Squared Error Estimation (LMMSE) is a simple, yet powerful denoising technique within MRI. It is based on the computation of the mean and variance of the data being filtered according to a noise model assumed, which is usually accomplished by calculating local moments over squared neighborhoods. When these neighborhoods are centered in pixels corresponding to image contours, the estimation is not accurate due to the presence of two or more tissues with different statistical properties. In this work, we overcome this limitation by introducing an anisotropic LMMSE scheme: the grey levels of each tissue in the MRI volume are modeled as a Gamma-mixture, such that we can discriminate between the different matters to construct anisotropic neighborhoods containing only one kind of tissue. The potential of the Gamma distribution relies on its ability to fit both the Rician distribution traditionally used to model the noise in MRI and the non-central Chi noise found in modern parallel MRI systems.

This work is currently under submission.

### 6.1.2. Modeling in Diffusion MRI

#### 6.1.2.1. Multiple q-Shell Diffusion Propagator Imaging

**Participants:** Rachid Deriche, Maxime Descoteaux [Sherbrooke University, Quebec], Denis Le Bihan [NeuroSpin, IFR 49 CEA Saclay], Jean-François Mangin [NeuroSpin, IFR 49 CEA Saclay], Cyril Poupon [NeuroSpin, IFR 49 CEA Saclay].
This work was partly supported by the Association France Parkinson and the ANR NucleiPark project.

Many recent high angular resolution diffusion imaging (HARDI) reconstruction techniques have been introduced to infer an orientation distribution function (ODF) of the underlying tissue structure. These methods are more often based on a single-shell (one b-value) acquisition and can only recover angular structure information contained in the ensemble average propagator (EAP) describing the three-dimensional (3D) average diffusion process of water molecules. The EAP can thus provide richer information about complex tissue microstructure properties than the ODF by also considering the radial part of the diffusion signal. In this work, we presented a novel technique for analytical EAP reconstruction from multiple q-shell acquisitions. The solution is based on a Laplace equation by part estimation between the diffusion signal for each shell acquisition. This simplifies greatly the Fourier integral relating diffusion signal and EAP, which leads to an analytical, linear and compact EAP reconstruction. An important part of this work is dedicated to validate the diffusion signal estimation and EAP reconstruction on real datasets from ex vivo phantoms. We also illustrated multiple q-shell diffusion propagator imaging (mq-DPI) on a real in vivo human brain and performed a qualitative comparison against state-of-the-art diffusion spectrum imaging (DSI) on the same subject. mq-DPI is shown to reconstruct robust EAP from only several different b-value shells and less diffusion measurements than DSI. This opens interesting perspectives for new q-space sampling schemes and tissue microstructure investigation.

This work has been published in [13].

6.1.2.2. A Riemannian Framework for Ensemble Average Propagator Computing

Participants: Rachid Deriche, Jian Cheng [ATHENA and LIAMA, China], Aurobrata Ghosh, Jiang Tianzi [LIAMA, China].

This work was partly supported by the Association France Parkinson and the ANR NucleiPark project.

In Diffusion Tensor Imaging (DTI), Riemannian framework (RF) has been proposed for processing tensors, which is based on Information Geometry theory. Many papers have shown that RF is useful in tensor estimation, interpolation, smoothing, regularization, segmentation and so on. Recently RF also has been proposed for Orientation Distribution Function (ODF) computing and it is applicable to any Probability Density Function (PDF) based on any orthonormal basis representation. Spherical Polar Fourier Imaging (SPFI) was proposed recently to fast and robustly estimate the ODF and Ensemble Average Propagator (EAP) from arbitrary sampled DWI signals. In this work, we proposed the RF for EAPs and implemented it via SPFI. We proved that the RF for EAPs is diffeomorphism invariant, which is the natural extension of affine invariant RF for tensors. It could avoid the so-called swelling effect for interpolating EAPs, just like the RF for tensors. We also proposed the Log-Euclidean framework (LEF), Affine-Euclidean framework (AEF), for fast processing EAPs, and Geometric Anisotropy (GA) for measuring the anisotropy of EAPs, which are all the extensions of previous concepts in RM for tensors respectively.

This work has been published in [22].

6.1.2.3. Diffeomorphism Invariant Riemannian Framework for Ensemble Average Propagator Computing

Participants: Rachid Deriche, Jian Cheng [ATHENA and LIAMA, China], Aurobrata Ghosh, Jiang Tianzi [LIAMA, China].

This work was partly supported by the Association France Parkinson and the ANR NucleiPark project.

In Diffusion Tensor Imaging (DTI), Riemannian framework based on Information Geometry theory has been proposed for processing tensors on estimation, interpolation, smoothing, regularization, segmentation, statistical test and so on. Recently Riemannian framework has been generalized to Orientation Distribution Function (ODF) and it is applicable to any Probability Density Function (PDF) under orthonormal basis representation. Spherical Polar Fourier Imaging (SPFI) was proposed for ODF and Ensemble Average Propagator (EAP) estimation from arbitrary sampled signals without any assumption. Tensors only can represent Gaussian EAP and ODF is the radial integration of EAP, while EAP has full information for diffusion process. To our knowledge, so far there is no work on how to process EAP data. In this work, we presented a Riemannian framework as a mathematical tool for such task. We proposed a state-of-the-art Riemannian framework for EAPs by representing the square root of EAP, called wavefunction based
on quantum mechanics, with the Fourier dual Spherical Polar Fourier (dSPF) basis. In this framework, the exponential map, logarithmic map and geodesic have closed forms, and weighted Riemannian mean and median uniquely exist. We analyzed theoretically the similarities and differences between Riemannian frameworks for EAPs and for ODFs and tensors. The Riemannian metric for EAPs is diffeomorphism invariant, which is the natural extension of the affine-invariant metric for tensors. We proposed Log-Euclidean framework to fast process EAPs, and Geodesic Anisotropy (GA) to measure the anisotropy of EAPs. With this framework, many important data processing operations, such as interpolation, smoothing, atlas estimation, Principal Geodesic Analysis (PGA), can be performed on EAP data. The proposed Riemannian framework was validated in synthetic data for interpolation, smoothing, PGA and in real data for GA and atlas estimation. Riemannian median is much robust for atlas estimation.

This work has been published in [23].

6.1.2.4. Theoretical Analysis and Practical Insights on EAP Estimation via a Unified HARDI Framework

Participants: Rachid Deriche, Jian Cheng [ATHENA and LIAMA, China], Jiang Tianzi [LIAMA, China].

This work was partly supported by the Association France Parkinson and the ANR NucleiPark project.

Since Diffusion Tensor Imaging (DTI) cannot describe complex non-Gaussian diffusion process, many techniques, called as single shell High Angular Resolution Diffusion Imaging (sHARDI) methods, reconstruct the Ensemble Average Propagator (EAP) or its feature Orientation Distribution Function (ODF) from diffusion weighted signals only in single shell. Q-Ball Imaging (QBI) and Diffusion Orientation Transform (DOT) are two famous sHARDI methods. However, these sHARDI methods have some intrinsic modeling errors or need some unreal assumptions. Moreover they are hard to deal with signals from different q-shells. Most recently several novel multiple shell HARDI (mHARDI) methods, including Diffusion Propagator Imaging (DPI), Spherical Polar Fourier Imaging (SPFI) and Simple Harmonic Oscillator based Reconstruction and Estimation (SHORE), were proposed to analytically estimate EAP or ODF from multiple shell (or arbitrarily sampled) signals. These three methods all represent diffusion signal with some basis functions in spherical coordinate and use plane wave formula to analytically solve the Fourier transform. To our knowledge, there is no theoretical analysis and practical comparison among these sHARDI and mHARDI methods. In this work, we proposed a unified computational framework, named Analytical Fourier Transform in Spherical Coordinate (AFT-SC), to perform such theoretical analysis and practical comparison among all these five state-of-the-art diffusion MRI methods. We compared these five methods in both theoretical and experimental aspects. With respect to the theoretical aspect, some criteria are proposed for evaluation and some differences together with some similarities among the methods are highlighted. Regarding the experimental aspect, all the methods were compared in synthetic, phantom and real data. The shortcomings and advantages of each method were highlighted from which SPFI appears to be among the best because it uses an orthonormal basis that completely separates the spherical and radial information.

This work has been published in [24].

6.1.2.5. Compressive Sensing Ensemble Average Propagator Estimation via L1 Spherical Polar Fourier Imaging

Participants: Rachid Deriche, Sylvain Merlet, Emmanuel Caruyer, Jian Cheng [ATHENA and LIAMA, China], Jiang Tianzi [LIAMA, China].

In diffusion MRI (dMRI) domain, many High Angular Resolution Diffusion Imaging (HARDI) methods were proposed to estimate Ensemble Average Propagator (EAP) and Orientation Distribution Function (ODF). They normally need many samples, which limits their applications. Some Compressive Sensing (CS) based methods were proposed to estimate ODF in Q-Ball Imaging (QBI) from limited samples. However EAP estimation is much more difficult than ODF in QBI. Recently Spherical Polar Fourier Imaging (SPFI) was proposed to represent diffusion signal using Spherical Polar Fourier (SPF) basis without specific assumption on diffusion signals and analytically obtain EAP and ODF via the Fourier dual SPF (dSPF) basis from arbitrarily sampled signal. Normally the coefficients of SPF basis are estimated via Least Square with weighted L2 norm regularization (L2-SPFI). However, L2-SPFI needs a truncated basis to avoid overfitting, which brings some estimation errors. By considering the Fourier relationship between EAP and signal and the Fourier basis pair provided in SPFI, we proposed a novel EAP estimation method, named L1-SPFI, to estimate...
EAP from limited samples using CS technique, and favorably compared it to the classical L2-SPFI method. L1-SPFI estimates the coefficients in SPFI using least square with weighted L1 norm regularization. The weights are designed to enhance the sparsity. L1-SPFI significantly accelerates the ordinary CS based Fourier reconstruction method. This is performed by using SPF basis pair in CS estimation process which avoids the numerical Fourier transform in each iteration step. By considering high order basis in L1 optimization, L1-SPFI improves EAP reconstruction especially for the angular resolution. The proposed L1-SPFI was validated by synthetic, phantom and real data. The CS EAP and ODF estimations are discussed in detail and we showed that recovering the angular information from CS EAP requires much less samples than exact CS EAP reconstruction. Various experiments on synthetic, phantom and real data validate the fact that SPF basis can sparsely represent DW-MRI signals and L1-SPFI largely improves the CS EAP reconstruction especially the angular resolution.

This work has been published in [25], [26].

6.1.2.6. Spherical Polar Fourier EAP and ODF Reconstruction via Compressed Sensing in Diffusion MRI

**Participants:** Rachid Deriche, Sylvain Merlet, Aurobrata Ghosh, Jian Cheng [ATHENA and LIAMA, China].

In diffusion magnetic resonance imaging (dMRI), the Ensemble Average Propagator (EAP), also known as the propagator, describes completely the water molecule diffusion in the brain white matter without any prior knowledge about the tissue shape. In this work, we described a new and efficient method to accurately reconstruct the EAP in terms of the Spherical Polar Fourier (SPF) basis from very few diffusion weighted magnetic resonance images (DW-MRI). This approach exploits the duality between SPF and a closely related basis in which one can respectively represent the EAP and the diffusion signal using the same coefficients, and efficiently combines it to the recent acquisition and reconstruction technique called Compressed Sensing. Our work provides an efficient analytical solution to estimate, from few measurements, the diffusion propagator at any radius. We also provide a new analytical solution to extract an important feature characterising the tissue microstructure: the Orientation Distribution Function (ODF). We illustrate and prove the effectiveness of our method in reconstructing the propagator and the ODF on both noisy multiple q-shell synthetic and phantom data.

This work has been published in [33].

6.1.2.7. On Line Reconstruction and Motion Detection in HARDI

**Participants:** Rachid Deriche, Emmanuel Caruyer, Iman Aganj [Department of Electrical and Computer Engineering, University of Minnesota], Christophe Lenglet [Department of Electrical and Computer Engineering, University of Minnesota], Guillermo Sapiro [Department of Electrical and Computer Engineering, University of Minnesota].

This work was partly supported by the CD-MRI Associate Team.

With acquisition protocols such as high angular resolution diffusion imaging, head motion can become an issue. Although the misalignment between diffusion-weighted images (DWIs) can be corrected in a post-processing step, this might increase partial volume effects, because of the relatively low spatial resolution of DWIs and interpolation in the registration procedure. If able to detect motion online, the scanner technician could be issued a warning and make a decision accordingly. Orientation distribution functions (ODF) can be reconstructed online using a Kalman filter (KF). In this work, we presented three contributions related to the problem of online ODF reconstruction and motion detection in HARDI. First, we developed a proper error propagation accounting for the non-linear transform on the diffusion signal. Next, we developed two motion detection algorithms, based on the monitoring of residuals, and compared them using synthetic data.

This work has been published in [18].
The orientation distribution function (ODF) can be reconstructed online incrementally from diffusion-weighted MRI with a Kalman filtering framework. This online reconstruction can provide real-time feedback to the practitioner, especially appreciated for long acquisition protocols typical in Q-ball imaging. On top of the Kalman filter, we proposed a method to evaluate online the reconstruction accuracy of the estimated ODF in constant solid angle. In addition, monitoring the residuals of the Kalman filter, we designed, based on statistical tests, two algorithms for online detection of subject motion. The proposed techniques, tested on real and synthetic data under various experimental conditions, can detect rotation by angle less than 3°.

This work has been published in [19].

6.1.3. From DW-MRI to Fiber Pathways and Microstructures Recovery

6.1.3.1. A Polynomial Approach for Maxima Extraction and Its Application to Tractography in HARDI

Participants: Rachid Deriche, Aurobrata Ghosh, Demian Wassermann [Harvard Medical School].

A number of non-parametrically represented High Angular Resolution Diffusion Imaging (HARDI) spherical diffusion functions have been proposed to infer more and more accurately the heterogeneous and complex tissue microarchitecture of the cerebral white-matter. These spherical functions overcome the limitation of Diffusion Tensor Imaging (DTI) at discerning crossing, merging and fanning axonal fiber bundle configurations inside a voxel. Tractography graphically reconstructs the axonal connectivity of the cerebral white-matter in vivo and non-invasively, by integrating along the direction indicated by the local geometry of the spherical diffusion functions. Tractography is acutely sensitive to the local geometry and its correct estimation. In this work, we first proposed a polynomial approach for analytically bracketing and numerically refining with high precision all the maxima, or fiber directions, of any spherical diffusion function represented non-parametrically. This permits an accurate inference of the fiber layout from the spherical diffusion function. Then we proposed an extension of the deterministic Streamline tractography to HARDI diffusion functions that clearly discern fiber crossings. We also extended the Tensorline algorithm to these HARDI functions, to improve on the extended Streamline tractography. We illustrated our proposed methods using the Solid Angle diffusion Orientation Distribution Function (ODF-SA). We presented results on multi-tensor synthetic data, and real in vivo data of the cerebral white-matter that show markedly improved tractography results.

This work has been published in [30].

6.1.3.2. Tract-based statistical analyzes in dMRI in autism spectrum disorder

Participants: Rachid Deriche, Anne-Charlotte Philippe, Demian Wassermann [Harvard Medical School, Boston, MA], Pablo Barttfeld [Integrative Neuroscience Laboratory, Physics Dept. University of Buenos Aires, Buenos Aires, Argentina], Jorge Calvar [Fundación para Lucha contra las Enfermedades Neurológicas de la Infancia, Buenos Aires, Argentina], Ramon Leiguarda [Fundación para Lucha contra las Enfermedades Neurológicas de la Infancia, Buenos Aires, Argentina], Bruno Wicker [INCM CNRS, Marseille, France], Mariano Sigman [Integrative Neuroscience Laboratory, Physics Dept. University of Buenos Aires, Buenos Aires, Argentina].

This work was partly supported by the ECOS-Sud grant.

Abnormal face processing is one of the hallmark features of social impairments in autism spectrum disorder (ASD). Previous neuroimaging studies showed that the fusiform gyrus is involved in face perception and is not or abnormally activated in autistic subjects. The aim of this study was to quantify potential anatomical differences in the white matter tracts that traverse the fusiform gyrus, the prefrontal cortex and the superior temporal gyrus, and correlate them with ADOS scores in ASD subjects. We used Diffusion Tensor MRI (DT) images to assess the integrity of automatically segmented white matter bundles connecting these brain areas. Then, we performed statistical analysis on these fiber bundles using diffusivity measures calculated from DT to characterize tissue microstructure changes and correlate these changes with ADOS scores. 7 adults with high functioning autism or Asperger syndrome and 11 typical adults participated in the study. We found several clusters with dissimilarities between ASD and control subjects in FA measures on tracts traversing the fusiform gyrus in both hemispheres of the brain. We observed a significant reduction of FA values in a cluster on a bundle joining the superior temporal gyrus to the prefrontal.
This work has been published in [37]. A related work on large-scale network analysis reflecting big-world characteristics in ASD has been published in [35].

6.1.3.3. **Unsupervised automatic white matter fiber clustering using a Gaussian mixture model**  
**Participants:** Rachid Deriche, Meizhu Liu [Department of CISE, University of Florida, Gainesville, USA], Baba Vemuri [Department of CISE, University of Florida, Gainesville, USA].

Fiber tracking from diffusion tensor images is an essential step in numerous clinical applications. There is a growing demand for an accurate and efficient framework to perform quantitative analysis of white matter fiber bundles. In this work, we proposed a robust framework for fiber clustering. This framework is composed of two parts: accessible fiber representation, and a statistically robust divergence measure for comparing fibers. Each fiber is represented using a Gaussian mixture model (GMM), which is the linear combination of Gaussian distributions. The dissimilarity between two fibers is measured using the total square loss function between their corresponding GMMs (which is statistically robust). Finally, we performed the hierarchical total Bregman soft clustering algorithm on the GMMs, yielding clustered fiber bundles. Further, our method is able to determine the number of clusters automatically. We performed experimental results depicting favorable performance of our method on both synthetic and real data examples.

This work is currently under submission.

6.1.3.4. **Riemannian geometry based brain white matter fiber clustering**  
**Participants:** Rachid Deriche, Ali Demir [Sabanci University, Istanbul, Turkey], Gozde Unal [Sabanci University, Istanbul, Turkey].

This work was partly supported by the PHC Bosphore grant.

Clustering of reconstructed brain white matter fibers into meaningful anatomical bundles becomes an important tool for detailed analysis of brain white matter diseases via diffusion MRI. In this work we developed a Riemannian geometry based geodesic distance measure between fiber pairs, which is then utilized in fiber clustering. A second contribution is a fiber selection algorithm, which compresses the dataset and speed up the computation time. We demonstrated methods on synthetic kissing fibers dataset, and validated on a brain white matter atlas.

This work is currently under submission.

6.1.3.5. **White Matter Clustering Revisited**  
**Participants:** Rachid Deriche, Alvaro-Alejandro Sanchez-Moscosa.

This work was partly supported by the Association France Parkinson and the ANR NucleiPark project.

In [70], we have introduced an interesting hierarchical agglomerative based algorithm that represents and clusters white matter bundles under a Gaussian Process framework. In this work, a new implementation which drastically improves the performance of the clustering algorithm before mentioned is proposed and validated. This implementation notably improves the performance of the clustering algorithm [70] and has been validated on real data. This approach has the advantage of running in a lower abstraction level, which leads to lowered memory requirements, shorter running times and ultimately provides the possibility to process more densely seeded tractographies. The new implementation is then used to process densely seeded streamline tractographies which provide more localized fiber bundles. Additionally, as Parkinson’s Disease is believed to induce changes in the axonal bundles, tract-based statistical analysis is performed on interesting fiber tracts to find significant differences in diffusion scalar measures.

6.1.3.6. **Using Radial NMR Profiles to Characterize Pore Size Distributions**  
**Participants:** Rachid Deriche, John Treilhard [Queen’s University, CA].
Extracting information about axon diameter distributions in the brain is a challenging task which provides useful information for medical purposes; for example, the ability to characterize and monitor axon diameters would be useful in diagnosing and investigating diseases like amyotrophic lateral sclerosis (ALS) or autism. In [75], three families of operators are defined, whose action upon an NMR attenuation signal extracts the moments of the pore size distribution of the ensemble under consideration; also a numerical method is proposed to continuously reconstruct a discretely sampled attenuation profile using the eigenfunctions of the simple harmonic oscillator Hamiltonian – the SHORE basis. The work we have performed here extends this method to other bases that can offer a better description of attenuation signal behaviour – in particular, we proposed the use of the radial Spherical Polar Fourier (SPF) basis. Testing is performed to contrast the efficacy of the radial SPF basis and SHORE basis in practical attenuation signal reconstruction. The robustness of the method to additive noise is tested and analyzed. We demonstrated that a low-order attenuation signal reconstruction outperforms a higher-order reconstruction in subsequent moment estimation under noisy conditions. We proposed the simulated annealing algorithm for basis function scale parameter estimation. Finally, analytic expressions are derived and presented for the action of the operators on the radial SPF basis (obviating the need for numerical integration, thus avoiding a spectrum of possible sources of error).

This work is currently under submission.

6.2. Brain functional imaging using MEG/EEG

6.2.1. EEG forward problem

6.2.1.1. OpenMEEG software library

Participants: Maureen Clerc, Emmanuel Olivi, Alexandre Gramfort, Théodore Papadopoulo.

This work was partly supported by the Regional Council of Provence Alpes Cote d’Azur and the ANR ViMAGINE.

To recover the sources giving rise to electro- and magnetoencephalography in individual measurements, realistic physiological modeling is required, and accurate numerical solutions must be computed. The OpenMEEG software library solves the electromagnetic forward problem in the quasistatic regime, for head models with piecewise constant conductivity. The core of OpenMEEG consists of the symmetric Boundary Element Method, which is based on an extended Green Representation theorem. OpenMEEG is able to provide lead fields for four different electromagnetic forward problems: Electroencephalography (EEG), Magnetoencephalography (MEG), Electrical Impedance Tomography (EIT), and intracranial electric potentials (IPs). OpenMEEG is open source and multiplatform. It can be used from Python and Matlab in conjunction with toolboxes that solve the inverse problem; its integration within FieldTrip is operational since release 2.0.

Some new developments have concerned the organization of the computations to compute the lead fields. A lead-field matrix is obtained by concatenating the forward fields computed for thousands of sources characterized by their positions, orientations and strengths. A line of this lead-field matrix represents the physical quantity (potential for EEG, or some components of the magnetic field for MEG) at a sensor for each source. The number of sources largely exceeds the number of sensors (up to 256 electrodes for EEG, and less than 600 squids for MEG). When solving the forward problem with a BEM (Boundary Element Method), the lead-field matrix is generally computed column-by-column, i.e. source by source, which represents nsources resolutions of the forward problem. Using the adjoint operator of the forward problem, one can reduce the computations to sensors resolutions. Some previous works [72], [73] have used similar techniques for efficient computation of the lead-fields using finite element methods. The adjoint method [69] generalizes the Helmholtz reciprocity theorem and here is proposed its implementation using the BEM provided by the open-source software OpenMEEG

This work has been published in [15] and [36].

6.2.1.2. Conductivity calibration for the EEG forward problem

Participants: Maureen Clerc, Emmanuel Olivi, Alexandre Gramfort, Théodore Papadopoulo, Jean-Michel Badier [INSERM U751, La Timone, Marseille], Martine Gavaret [INSERM U751, La Timone, Marseille], Laurent Koessler [CRAN Nancy].
Bioelectric phenomena at low temporal frequency can be described by the electrostatic Poisson equation

$$\text{div} \sigma \nabla V = \text{div} J^p,$$

where $J^p$ are primary current sources and $\sigma \nabla V$ the Ohmic current. Appropriate boundary conditions (b.c.) must be set on the domain boundary, typically imposing the potential (Dirichlet b.c.) or the normal current (Neumann b.c.).

Solving this electrostatics equation for the electric potential is a problem common to different fields such as electroencephalography (EEG), electrocardiography (ECG), functional electrical stimulation. The main difficulty of the model concerns the conductivity field, which is not homogeneous, and whose values depend on the tissue type. Although the tissue structure can be revealed by imaging methods such as CT, Magnetic Resonance Imaging, diffusion Magnetic Resonance Imaging, conductivity values must nevertheless be assigned to the different tissues. In order to calibrate conductivity, injected current Electrical Impedance Tomography (EIT) can be used: it consists of injecting current on the outer boundary, and measuring the associated electric potential.

The thrust of OpenMEEG is to propose accurate forward problems, in several instances, including electro- and magneto-encephalography (EEG-MEG) and Electrical Impedance Tomography (EIT). OpenMEEG allows to compute the electric potential and magnetic fields due to boundary current injection or to sources within the compartments.

We apply this methodology to conductivity calibration in the context of high-density EEG pre-surgical epileptic exploration. High-density EEG measurements may be used to solve the inverse problem of source localization, in order to localize the foci of the epileptic activity within the brain. The solution of the inverse problem relies on a forward problem, linking sources to measurements. In turn, this forward problem is dependent on the conductivity of the head tissues.

Prior work has shown that the scalp-to-skull conductivity ratio is a sensitive parameter for source localization, because it has an influence on the depth of the estimated dipoles [68]. There have been several studies demonstrating the feasibility of injected-current Electrical Impedance Tomography to calibrate the scalp-to-skull conductivity ratio [57], [49]. We are currently collaborating with our partners from La Timone in Marseille in a clinical assessment of the use of injected current Electrical Impedance Tomography to calibrate the scalp-to-skull conductivity ratio.

This work has been presented at the international conference on Electrical Impedance Tomography, see [27] and [28].

6.2.1.3. Coupling numerical methods for the forward problem

**Participants:** Maureen Clerc, Emmanuel Olivi, Théodore Papadopoulos, Mariette Yvinec [Geometrica Project-Team, INRIA Sophia Antipolis Méditerranée].

This work was partly supported by the ANR grant ViMAGINE.

Electroencephalography (EEG) and magnetoencephalography (MEG) are two modalities that aim at measuring brain activity. Source localization from external data such EEG or MEG, requires a good understanding of the electromagnetic behavior of the patient head. Several models can be used, representing more or less complex geometrical shapes, and conductivity profiles. Different numerical methods allow to cope with different types of models: the Finite Element Method (FEM) can handle very general conductivity models, whereas the Boundary Element Method (BEM) is limited to piecewise constant conductivity. On the other hand, BEM is more capable than FEM to accurately represent sources in isotropic media.
Using a domain decomposition approach, we propose to independently use BEM or FEM in different sub-domains. In the EEG forward problem considered, the BEM is limited to the domain where the sources lie (the brain) while the other tissues are handled with the FEM. This leads to an accurate description of the sources while allowing for inhomogeneous and anisotropic conductivity. The proposed method is first validated against analytical solutions in multi-sphere models. Results of the forward problem are presented for a four-layer realistic head-model incorporating a burr-hole in the skull. Convergence of the iterative algorithm is analyzed numerically. The domain decomposition framework provides a way of taking the best advantage of both methods, thus significantly improving the accuracy in the resolution of the forward EEG problem, as well as time and memory consumption.

This work is part of Emmanuel Olivi’s PhD thesis [11], and a journal article is under submission.

6.2.1.4. White matter anisotropy

Participants: Maureen Clerc, Emmanuel Olivi, Alexandre Gramfort, Théodore Papadopoulo.

This work was partly supported by the ANR grant ViMAGINE.

Conductivity of tissues in the vicinity of the sources is especially influential on the MEG and EEG forward fields. Those tissues include white matter, whose conductivity is anisotropic because of its fiber structure. While white matter anisotropy can be measured thanks to Diffusion-Weighted MRI, it is rarely incorporated in MEG and EEG head models. Boundary Element Methods can only deal with piecewise constant conductivities, therefore ruling out white matter anisotropy that has a complex structure, and Finite Element Methods have been developed to deal with anisotropic conductivity, but require very fine meshes, thus huge linear systems. We have extended the BEM framework to incorporate white matter anisotropy by treating anisotropic conductivity as a perturbation of an isotropic one. With this extension we have been able to compute the influence of a fiber within the brain white matter on the electric potential, and to validate the result by comparison with a Finite Element Method.

This work has been published in [34].

6.2.2. Inverse problems in MEG and EEG

6.2.2.1. Rational Approximations

Participants: Maureen Clerc, Théodore Papadopoulo, Juliette Leblond [APICS Project Team, INRIA Sophia Antipolis Méditerranée], Jean-Paul Marmorat [Centre de Mathématiques Appliquées, Ecole des Mines].

In functional neuroimaging, a crucial problem is to localize active sources within the brain non-invasively, from the knowledge of the electromagnetic measurements outside the head. Identification of point sources from boundary measurements is an ill-posed inverse problem. In the case of electroencephalography (EEG), measurements are only available at electrode positions, the number of sources is not known in advance, and the medium within the head is inhomogeneous. We pursue our ongoing work on EEG source localization, based on rational approximation techniques in the complex plane. The method is used in the context of a nested sphere head model, in combination with a cortical mapping procedure. Results on simulated data prove the applicability of the method in the context of realistic measurement configurations.

This work has been submitted to a journal and published as a Research Report in [38].

6.2.3. Brain Computer Interfaces

6.2.3.1. New features for Motor Imagery

Participants: Maureen Clerc, Joan Fruitet, Théodore Papadopoulo, Eoin Thomas.

This work was partly supported by ANR grant CoAdapt.

Our goal is to build a training free BCI based on beta rebound detection and discrimination during the first stage of use, while the learning of the conventional sensorimotor rhythms is done. We show in this preliminary study that it is possible to use the beta rebound to discriminate, real and imagined, right versus left hand movement with either no or very little training.
6.2.3.2. A bandit algorithm for exploring mental imagery

Participants: Maureen Clerc, Joan Fruitiert, Alexandra Carpentier [Sequel Project Team, INRIA Lille Nord Europe], Rémi Munos [Sequel Project Team, INRIA Lille Nord Europe].

This work was partly supported by ANR grant Co-Adapt.

This study presents a new procedure to automatically select a discriminant motor task for an asynchronous brain-controlled button. This type of control pertains to Brain Computer Interfaces (BCI). When using sensorimotor rhythms in a BCI, several motor tasks, such as moving the right or left hand, the feet or the tongue, can be considered as candidates for the control. This report presents a method to select as fast as possible the most promising task. We develop for this purpose an adaptive algorithm UCB-classif based on the stochastic bandit theory and build an EEG experiment to test our method. By not wasting time on inefficient tasks, our algorithm can focus on the most promising ones, resulting in a faster task selection and a more efficient use of the BCI training session. This leads to better classification rates for a fixed time budget, compared to a standard task selection.

This work has been published in [39] and is currently under submission to a journal.

6.3. Multi-Imaging Modalities

6.3.1. Coupling neuronal and haemodynamic models

6.3.1.1. Modeling of the neurovascular coupling in epileptic discharges

Participants: Maureen Clerc, Théodore Papadopoulo, Nicole Voges [former Athena postdoc], Christian Bénar [INSERM U751 Marseille], Solenna Blanchard [INSERM U642 Rennes], Fabrice Wendling [INSERM U642 Rennes], Habib Benali [INSERM U678 Paris], Olivier David [INSERM U594 Grenoble].

This work was partly supported by ANR MultiModel.

Despite the interest in simultaneous EEG-fMRI studies of epileptic spikes, the link between epileptic discharges and their corresponding hemodynamic responses is poorly understood. In this context, biophysical models are promising tools for investigating the mechanisms underlying observed signals. We have applied a metabolic-hemodynamic model to simulated epileptic discharges, in part generated by a neural mass model. We analyzed the effect of features specific to epileptic neuronal activity on the blood oxygen level dependent (BOLD) response, focusing on the issues of linearity in neurovascular coupling and on the origin of negative BOLD signals. We found both sub- and supra-linearity in simulated BOLD signals, depending on whether one observes the early or the late part of the BOLD response. The size of these non-linear effects is determined by the spike frequency, as well as by the amplitude of the excitatory activity. Our results additionally indicate a minor deviation from linearity at the neuronal level. According to a phase space analysis, the possibility to obtain a negative BOLD response to an epileptic spike depends on the existence of a long and strong excitatory undershoot. Moreover, we strongly suggest that a combined EEG-fMRI modeling approach should include spatial assumptions. The present study is a step towards an increased understanding of the link between epileptic spikes and their BOLD responses, aiming to improve the interpretation of simultaneous EEG-fMRI recordings in epilepsy.

This work has been published in [17].

6.3.1.2. A nested cortex parcellation combining analysis of MEG forward problem and diffusion MRI tractography

Participants: Anne-Charlotte Philippe, Maureen Clerc, Théodore Papadopoulo, Rachid Deriche.
Understanding the relationship between structure and function is a major challenge in neuroscience. Diffusion MRI (dMRI) is the only non-invasive modality allowing to have access to the neural structure. Magnetoencephalography (MEG) is another non-invasive modality that allows a direct access to the temporal succession of cognitive processes. Functional cortex parcellation being one of the most important ways to understanding structure-function relationship, we propose an innovative method merging MEG and dMRI to parcellate the cortex. The combination of MEG forward problem and connectivity information reveals cortical areas generating a similar magnetic field at sensors while having a similar connectivity. Results show suitable clusters that forecast interesting studies for inter- and intra-subjects comparisons of the cortex parcellations. The automatic nested cortex parcellation we propose could be a first step to analyse sources that are seeds of long or short range connectivity and to differentiate these connectivities in the white matter.

This work is currently under submission.

6.3.1.3. Improved computer-aided detection of small polyps in CT colonography using interpolation for curvature estimation

**Participants:** Rachid Deriche, Jiamin Liu [Imaging Biomarkers and Computer-Aided Diagnosis Laboratory, Radiology and Imaging Sciences, Clinical Center, National Institutes of Health, Bethesda], Suraj Kabadi [Imaging Biomarkers and Computer-Aided Diagnosis Laboratory, Radiology and Imaging Sciences, Clinical Center, National Institutes of Health, Bethesda], Robert Van Uitert [Imaging Biomarkers and Computer-Aided Diagnosis Laboratory, Radiology and Imaging Sciences, Clinical Center, National Institutes of Health, Bethesda], Nicholas Petrick [Center for Devices and Radiological Health, U.S. Food and Drug Administration, Maryland], Ronald M. Summers [Imaging Biomarkers and Computer-Aided Diagnosis Laboratory, Radiology and Imaging Sciences, Clinical Center, National Institutes of Health, Bethesda].

Surface curvatures are important geometric features for the computer-aided analysis and detection of polyps in CT colonography (CTC). However, the general kernel approach for curvature computation can yield erroneous results for small polyps and for polyps that lie on haustral folds. Those erroneous curvatures will reduce the performance of polyp detection. This work presents an analysis of interpolation’s effect on curvature estimation for thin structures and its application on computer-aided detection of small polyps in CTC. In this work, we demonstrated that a simple technique, image interpolation, can improve the accuracy of curvature estimation for thin structures and thus significantly improve the sensitivity of small polyp detection in CTC. Our experiments showed that the merits of interpolating included more accurate curvature values for simulated data, and isolation of polyps near folds for clinical data. After testing on a large clinical data set, it was observed that sensitivities with linear, quadratic B-spline and cubic B-spline interpolations significantly improved the sensitivity for small polyp detection. In conclusion, the image interpolation can improve the accuracy of curvature estimation for thin structures and thus improve the computer-aided detection of small polyps in CTC.

This work has been published in [16].
6. New Results

6.1. Model Transformation

Model transformation and in particular our ATL model transformation language continues playing a key role in our MDE strategy. During 2011 the new results in this area have been:

- The development of an execution algorithm for the lazy execution of ATL transformations [31]. The increasing adoption of Model-Driven Engineering in industrial contexts highlights scalability as a critical limitation of several MDE tools. When these tools are built around model-to-model (M2M) transformations, the efficiency of the transformation engine risks to become a performance bottleneck for the whole MDE environment. This new execution mode solves this problem by providing on-demand execution of model transformations. The computation required to generate a data element of the target model is only triggered once the user requests to read that data element.

- Towards a general semantics for transformation languages. In the mid-term, we would like to be able to achieve interoperability among existing transformation languages (e.g. to create mixed transformations or simply to compare alternative transformation solutions for the same scenario). In this direction, we have worked on a general composition semantics for rule-based transformation languages [32] and an extensive survey of inheritance support in existing languages [33]. Moreover, to make ATL closer to other transformation languages, in special graph transformations, we have developed a new ATL refining mode [43] that allows executing in-place transformations.

- Also relevant, this year AtlanMod has coorganized the main international conference on model transformations [41].

6.2. Model Representation

As part of our work on core techniques for the specification and internal representation of models we would like to highlight:

- Improved model typing. In order to represent metadata more accurately, we have worked on a functional typing system for megamodeling [18]. The basic idea is to consider transformations as functions, and to give them functional types that can facilitate the reasoning on them.

- Virtual EMF [21] for the transparent Composition, Weaving and Linking of Models. Virtual EMF facilitates the global manipulation of an heterogeneous but related set of models by providing the illusion of having a single and unified view of the modeled system.

- EMF Profiles [25], a mechanism to enable users annotate existing models without polluting them (i.e. without directly changing their content).

- Batch scripting support for the retrieval and manipulation of models from model repositories thanks to our new language MoScript [24].

6.3. Model Quality

Our work on model quality defends the idea that there is not a silver bullet technique to verify the quality of models and that a combined approach offers the best trade-off. Lightweight techniques can provide a quick feedback even if it is partial and, when necessary, more complete ones can be utilized to complement the results. In this sense, this year we have developed:

- Lightweight techniques for the verification of ATL transformations [27] and UML Executable models [26].
• Proposed a method for the automatic generation of correct dynamic models for a given domain [11]. Basic operations to modify the information the software needs to store and manipulate about the domain are generated. The generation process ensures that all generated operations are strongly executable.
• Created a brand new Eclipse Lab project aimed at facilitating the verification of any kind of (EMF-based) model with the EMFtoCSP tool (see the tool description in the tools section of this report)
• And applied some of these ideas to the verification and testing of web applications [15]

6.4. Domain Specific Language

There is a growing interest in the research community on the definition of a new generation of language workbenches to facilitate the definition of non-trivial domain specific languages. In this area, we are working on the definition of a set of quality properties that will help language designers to validate if their language is well-adapted to the needs of the language users. This is done by mining repositories containing a corpus of examples of the language.

To begin with we have been reusing the notion of software clones [16] [30], a well-known property in the programming domain and see if it is also meaningful for languages at the model level [29].

6.5. Reverse Engineering

We have continued our work on MoDisco, specially wrt the dissemination activities around the platform [19] [40] and the extension of the tooling support mainly through the spin-off of the EMFFacet Eclipse project, explained in the tools section of this report

6.6. Systems interoperability

MDE can be used as an intermediate representation between two different technical spaces / platforms / tools to facilitate their interoperability. During this year, we have followed this approach in the following results:

• Automation of the interactions with APIs by automatically discovering and expressing them as models thanks to our API2MOL approach [14]
• Bridging the business and the technical domains, developing among others the Portolan tool [42] for the cartography of Information Systems.
• MDE itself can benefit from the work and techniques available in a different technical space. In this context we have combined MDE and constraint programming to see how the combination improves the solution of classical problems like the configuration of a set of components/plug-ins [22]. We have even organized a workshop on the topic of merging MDE and logic programming [20] to better understand how they can benefit each other.
6. New Results

6.1. Visual Analytics of EA Data

Participants: Jean-Daniel Fekete, Évelyne Lutton [correspondant].

An experimental analysis of Evolutionary Algorithms (EAs) usually generates a huge amount of multidimensional data, including numeric and symbolic data. It is difficult to efficiently navigate in such a set of data, for instance to be able to tune the parameters or evaluate the efficiency of some operators. Usual features of existing EA visualisation systems consist in visualising time- or generation-dependent curves (fitness, diversity, or other statistics). When dealing with genomic information, the task becomes even more difficult, as a convenient visualisation strongly depends on the considered fitness landscape. In this latter case the raw data are usually sets of successive populations of points of a complex multidimensional space.

The purpose of this study was to evaluate GraphDice on complex sets of EA data (for artificial and real test-cases), and to sketch future developments of this tool, in order to better adapt it to the needs of EA experimental analysis (Fig. 6). An output of this study is the acceptation of the EASEA-Cloud ANR-Emergence project, in which developments will aim at adding tools in GraphDice specific for:

- visualisation of Evolutionary Algorithms written in the EASEA language,
- monitoring the execution of these algorithms on a cloud of computers (CPU + GPU).
6.2. Interactive Evolutionary Algorithms for Visual decision making

**Participants:** Nadia Boukhelifa, Waldo Cancino, Jean-Daniel Fekete, Evelyne Lutton [correspondant].

When dealing with very large datasets with many dimensions, it is often difficult to efficiently navigate and find interesting viewpoints, significative compound variables, unexpected behaviour, and other remarkable characteristics.

Our aim within the System@tic CSDL project (Complex Systems Design Lab, 2009–2012) is to use interactive evolutionary algorithm to assist the user in its exploration task. Finding an interesting, non obvious, viewpoint on a complex dataset can be formulated as an interactive optimisation problem. Population-based evolutionary search mechanisms can then efficiently be exploited for suggesting new viewpoints on data, that progressively adapt to the needs of an user.

In September 2011 (arrival of Nadia Boukhelifa and Waldo Cancino) we started to build a prototype based on GraphDice, that proposes new dimensions in the scatterplot matrix. These secondary set of dimensions are compositions of the dimensions of the initial datased. Starting from an initial set of suggested dimensions (PCA analysis of the dataset), an evolutionary algorithm progressively refines the compound dimensions according to a measurement of the activity of the user on the corresponding views.

6.3. Optimisation of Food Models

**Participant:** Évelyne Lutton [correspondant].

*In collaboration with Alberto Tonda and Romain Reuillon, ISC-PIF*

The European project DREAM (http://dream.csregistry.org/) managed by INRA-CEPIA, aims at building decision support tools for better managing product quality and, by the way, manufacturing processes in the domain of agrifood industry.

Our contribution to this project is focused on the evolutionary optimisation of Bayesian Networks models, on the development of efficient cooperative-co-evolution schemes to solve some food modeling problems (milk gel, cheese ripening), and on the efficient visualisation of output data of these algorithms.

6.4. A Study on Dual-Scale Data Charts

We presented the results of a user study that compares different ways of representing dual-scale data charts (see Fig. 7). Dual-scale charts incorporate two different data resolutions into one chart in order to emphasize data in regions of interest or to enable the comparison of data from distant regions. While some design guidelines exist for these types of charts, there is currently little empirical evidence on which to base their design. We filled this gap by discussing the design space of dual-scale cartesian-coordinate charts and by experimentally comparing the performance of different chart types with respect to elementary graphical perception tasks such as comparing lengths and distances. Our study suggests that cut-out charts which include collocated full context and focus are the best alternative, and that superimposed charts in which focus and context overlap on top of each other should be avoided.

6.5. Information Visualization Evaluation

Figure 7. Three different dual-chart techniques made with different publicly available charting tools. The left image shows a cut-out chart made with the Google Charts API in which the top part depicts parts of the data at larger scale. The middle image shows a superimposed chart made by Microsoft Excel where the red line is plotted according to the left and the blue according to the right y-axis. The right chart is a Broken Chart made with Gnuplot in which the left and right panel show parts of the data at different scale.

Petra Isenberg has contributed to three articles on evaluation methodologies: The first article “Collaborative Visualization: Definition, Challenges, and Research Agenda” [12] deals with challenges of collaborative visual analytics and includes a discussion on the challenges of evaluating tools during multi-person use. The second article, “Information Visualization Evaluation in Large Companies: Challenges, Experiences and Recommendations” [14], discusses challenges of evaluating and deploying visual analytics tools in a large company setting. It lists several challenges and provides concrete guidance to others who seek to evaluate tool within domain experts in their work environment. Finally, “Seven Guiding Scenarios for Information Visualization Evaluation” [33] is a pre-print of an journal article (in press) which provides a new viewpoint on evaluation in information visualization. Instead of giving an overview of methods, it cites evaluation goals and questions and can, thus, provide clear considerations for practitioners and researchers in the area.
AXIS Project-Team

5. New Results

5.1. Introduction

This year we obtained new results in our three sub-objectives and also related to Focuslab platform and software valorization:

1. **Sub-objective 1 - Mining for Knowledge Discovery in Information Systems**: this we get five results (with one achieved PhD thesis).

   Let us note that six past works on this sub-objective described in previous AxIS annual reports have been published this year as articles in international journals ([22],[11]) or conferences, one in a national journal [50], two in a french-speaking conference [35],[46], one book [20] and one book chapter [52] at international level. Indeed
   - The work in 2009 on mining data streams by Marascu in her thesis [96] has been published in [11] with more details in the algorithms and in the experiments.
   - The work published in 2008 on discovering frequent behaviors [107] has been published in [22] with more details in the algorithms and in the experiments.
   - Our previous work on satellite image mining in 2010 [99] has been published in French at EGC [35].
   - Our past work on Functional data analysis involving data described by regular functions rather than by a finite number of real valued variables has been published as a scientific book chapter [52]. In this paper we propose to use a clustering approach that targets variables rather than individual to design a piecewise constant representation of a set of functions. The contiguity constraint induced by the functional nature of the variables allows a polynomial complexity algorithm to give the optimal solution.
   - In the context of the WRUM project (Morocco) and Zemmouri’s PhD thesis, we have a long paper accepted at JFO 2011 related to past works (2010) on how to integrate domain knowledge in a multi-view KDD process [46].

2. **Sub-objective 2 - Information and Social Networks Mining for Supporting Information Retrieval**: Three results (with one achieved Ph-D thesis). Let us remind the best paper [15] obtained By E. Smirnova at ECIR 2011 for her research on expert finding.

3. **Sub-objective 3 - Multidisciplinary Research For Supporting User Oriented Innovation**: this interdisciplinary research is dedicated to the design, tailoring and refinement of methodologies and tools for a better users’ involvement in innovation processes. We have seven results this year.

Concerning our activity in terms of **FocusLab Experimental Platform and Software**, a) we first applied ATWUEDA on another context of evolutive data (on system monitoring data at EDF) which is different of Web usage data) to show the genericity of the approach [9], and b) we develop a Web-based version of the FocusLab experimental platform for analysis usage data (hardware and software parts).

5.2. Mining for Knowledge Discovery in Information Systems

5.2.1. **Mining Data Streams: Clustering and Pattern extraction**

Participant: Chongsheng Zhang.
In Zhang’s thesis [19] (supervised by F. Masseglia), which was partially founded by ANR MIDAS (cf. 6.2.1), we present our study of the management and mining issues on data streams with evolving tuples, caused by model updates or tuple revisions. For instance, in an online auction system where bids on auction items are streaming, it is possible that some users may bid for more than one item within the user-specified time interval. As a result, the profiles of the users can be updated or revised in such applications. Data streams having evolving tuples bring new challenges as well as research opportunity. In this work, he develops novel and efficient models and methods for managing and mining data streams with evolving tuples. (I) To model data streams with evolving tuples, we propose the Anti-Bouncing Streaming model (ABS) for usage streams. ABS fits data streams with evolving tuples and it enables methods for processing of data streams to handle tuple updates or revisions. (II) To find frequent itemsets from data streams with evolving tuples over pane-based sliding windows, we conduct theoretical analysis and propose theorems which can avoid scanning the past slides to check for possible itemsets that may become frequent. We also design novel data structures which can manage the data streams with evolving tuples efficiently and facilitate the mining of frequent itemsets. Moreover, we devise an efficient counting algorithm to verify the frequentness of the candidate frequent itemsets. We also propose two running frameworks for this problem. (III) To extract important feature set from data streams (including the ones with evolving tuples), based upon ABS, we devise the streaming feature set selection algorithm for data streams which is the first in the literature. This method is based on information theory to extract the informative feature sets. To further accelerate the extraction of the most informative feature set from high-dimensional data, we propose a framework that reduces the huge search space to a rather small subset while still guarantee the quality of the discovered feature sets.

In 2011, Chongsheng Zhang has mainly worked on a data stream mining method, intending to extract frequent itemsets. This method has not been published yet and is described in Chapter 5 (page 79) of his thesis document [19].

5.2.2. Clustering on Multiple Dissimilarity Matrices

Participants: Yves Lechevallier, Francisco de A.T. de Carvalho, Thierry Despeyroux, Alessandra Silva Anyzewski.

In [23] we introduce hard clustering algorithms that are able to partitioning objects taking into account simultaneously their relational descriptions given by multiple dissimilarity matrices [49]. The aim is to obtain a collaborative role of the different dissimilarity matrices in order to obtain a final consensus partition. These matrices could have been generated using different sets of variables and a fixed dissimilarity function or using a fixed set of variables and different dissimilarity functions, or using different sets of variables and dissimilarity functions.

These methods, which are based on the dynamic hard clustering algorithm for relational data as well as on the dynamic clustering algorithm based on adaptive distances, are designed to furnish a partition and a prototype for each cluster as well as to learn a relevance weight for each dissimilarity matrix by optimizing an adequacy criterion that measures the fitting between clusters and their representatives.

These relevance weights change at each algorithm iteration and can either be the same for all clusters or different from one cluster to another. The usefulness of these partitioning hard clustering algorithms are shown on two time trajectory real world datasets.

5.2.3. Clustering of Constrained Symbolic Data

Participants: Marc Csernel, Francisco de A.T. de Carvalho.

In the context of our FACEPE collaboration with Brazil (cf. section 6.4.3.1), we have presented a method which allows clustering of symbolic descriptions constrained by presence rules in a polynomial time instead of a combinatorial one. This method allows to deal with “false missing values”. Such a method can be applied on various classification problems [26].

5.2.4. Web Page Clustering based on a Community Detection Algorithm

Participants: Yves Lechevallier, Yacine Slimani.
Extracting knowledge from Web user’s access data in Web Usage Mining (WUM) process is a challenging task that is continuing to gain importance as the size of the web and its user-base increase. That is why meaningful methods have been proposed in the literature in order to understand the behaviour of the user in the web and improve the access modes to information. In this work [42], we are interested in the analysis of the user browsing behavior. The objective is to understand the navigational practices of users (teachers, students and administrative staff). First we clean the data by removing irrelevant information and noise. During the second step, remaining data are arranged in a coherent way in order to identify user sessions. After we defined a new approach [42] of knowledge extraction. This approach treats the data resulting from the preprocessing phase (first and second steps) as being a set of communities. Our approach extends the Modularity measure, proposed by Newman and Girvan [97], in the Web Mining context in order to benefit from their classifying capacity in the communities discovery.

This work is done in collaboration with the LRIA laboratory – Université Ferhat Abbas, Sétif, Algérie

5.2.5. **Critical Edition of Sanskrit Texts**

**Participants:** Marc Csernel, Nicolas Béchet, Ehab Hassan, Yves Lechevallier.

New progresses concerning the computer assisted elaboration of Sanskrit texts have been made. First Nicolas Béchet and Marc Csernel have worked on the problem of moved texts. After an alignment between two versions of the texts, we discover that some parts of the text appears to have been moved according to the technics developed in [48]. Until now, we were not able to discover when a text has been moved in a manuscript.

Now using a words-grams technique proposed in [48], we were able to obtain quite good results on the moved texts problem and we were able to optimize the different possible parameters. A paper on the subject has been submitted to the Cicling 2012 conference (http://www.cicling.org/2012/).

After the new treatment related to the moved text problem, we need to provide an interactive display of the critical edition. During his internship, Ehab Hassan has been working on the subject and obtained good results. These results need to be deeply examined by Sanskritists to see if they always fulfill their needs.

5.3. **Information and Social Networks Mining for Supporting Information Retrieval**

5.3.1. **Clustering of Relational Data and Social Network Data**

**Participants:** Yves Lechevallier, Amine Louati.

The automatic detection of communities in a social network can provide this kind of graph aggregation. The objective of graph aggregations is to produce small and understandable summaries and can highlight communities in the network, which greatly facilitates the interpretation.

Social networks allow having a global view of the different actors and different interactions between them, thus facilitating the analysis and information retrieval.

In the enterprise context, a considerable amount of information is stored in relational databases. Therefore, relational database can be a rich source to extract social network. The extracted network has in general a huge size which makes its analyses and visualization difficult tasks. In [45], we propose a social network extraction approach from relational database.

Oftentimes, the network has a large size which makes its analysis and visualization difficult. The aggregation step is a necessary task, so we offer [33] and [32] an aggregation step based on the k-SNAP algorithm [109] that produces a summary graph by grouping nodes based on attributes and relationships selected by the user.

This work is done in collaboration with Marie-Aude Aufaure, head of the Business Intelligence Team, Ecole Centrale Paris, MAS Laboratory.
5.3.2. Networks Solutions for Expert Finding and People Name Disambiguation

Participants: Elena Smirnova, Yi-Ling Kuo, Brigitte Trousse.

The task of finding people who are experts on a given topic has recently attracted close attention. State-of-the-art expert finding algorithms uncover knowledge areas of candidate experts based on textual content of associated documents. While powerful, these models ignore social structure that might be available. Therefore, we develop a Bayesian hierarchical model for expert finding that accounts for both content and social relationships. The model assumes that social links are determined by expertise similarity between candidates. The results of EGC experiments on UvT expert collection have demonstrated the effectiveness of our algorithm [43].

E. Smirnova visited Intellius, people search technology company (Aug 8 - Oct 5, 2011): the goal of this visit was to validate the research on expert finding in social networks on real dataset and further advance it. As a real dataset, we have taken a sample of United States LinkedIn public profiles. We built an organizational network from user’s current location in the United States. We used Amazon’s Mechanical Turk framework (http://aws.amazon.com/code/923) to collect user-oriented judgements for model evaluation. We found that the user-oriented model is statistically significantly preferred to the baseline model on 72.5% of queries.

Her work on name disambiguation done in 2010 has been integrated in an article related to the problem of quick detection of top-k Personnalized PageRank (PPR) in [24]. The effectiveness of the chosen approach based on Monte Carlo methods for quick detection of top-k PPR lists has been demonstrated on the Web and Wikipedia graphs.

Yi-Ling Kuo during her internship has worked on Person Name Disambiguation and started by managing the analysis of the very huge Yahoo! Web graph.

This topic has been done in the context of Smirnova’s thesis [18] which has been defended on december 15 (thesis supervised by B. Trousse (AxIS) and K.Avrachenkov (Maestro)).

5.3.3. Towards an On-Line Analysis of Tweets Processing

Participant: Nicolas Béchet.

Tweets exchanged over the Internet represent an important source of information, even if their characteristics make them difficult to analyze (a maximum of 140 characters, etc.). In [25], we define a data warehouse model to analyze large volumes of tweets by proposing measures relevant in the context of knowledge discovery. The use of data warehouses as a tool for the storage and analysis of textual documents is not new but current measures are not well-suited to the specificities of the manipulated data. We also propose a new way for extracting the context of a concept in a hierarchy. Experiments carried out on real data underline the relevance of our proposal.

This work is done inside a collaboration with LIRMM and CEMAGREF.

5.4. Multidisciplinary Research For Supporting User Oriented Innovation

5.4.1. Usability Design and Evaluation Methods

Participants: Dominique Scapin, Yves Lechevallier, Pascal Marie-Dessoude, Claudia Detraux.

We pursued our work on articulation of usage mining approach and human factors expertise for the design and evaluation of information systems. Namely, collaborative clustering techniques were used to analyze data issued from users via a card sorting technique, with respect to an a priori (“expert”) clustering. Considering the difficulties that people have in managing large information sets in their everyday life, for either professional or non-professional purposes (administration, social relationships, leisure, etc.), our recent research focuses on personal information space for which information bits are currently scattered many places.
In this PIMs field, there is little research with a user-centric approach, with the view that users-based knowledge might help specifying computer-based tools and a state-of-the-art [37] showed little work specifically on usability. Studies address a variety of questions from user needs to accessibility (including studies on older people) or user acceptance, among others. In the context of user-centered and long-term studies to understand the evolution of user information practice, we looked in a study at the intuitive way people organize their personal information, with or without computer systems, in order to help the design of future systems. Also, we recently surveyed 15 tools that claim to support personal information management.

5.4.2. Living Lab Landscape

Participants: Marc Pallot, Brigitte Trousse, Bernard Senach, Dominique Scapin.

In order to provide to the research community a comprehensive landscape of research streams in the Living Lab domain, we launched a study on the state-of-the-art about the ubiquitous notion of User Experience. During this continuous study, a landscape [34], [69] has progressively emerged that we organized through 4 main axes: focus granularity (individual/group), user’s role in the design process (observed subject/value creator), collaboration style (structured/unstructured), and evaluation purpose (reliability/adoptability). Our landscape of research streams has been used by Finnish colleagues who conducted an empirical study on the use of the Living Lab research domain landscape as a tool for assessing the maturity level of 16 Finnish Living Labs [36]. The Living Lab research domain Landscape has allowed the study team to identify four categories of Living Labs.

5.4.3. Future Internet Domain Landscape

Participants: Marc Pallot, Brigitte Trousse, Bernard Senach.

There are many different Internet research areas and corresponding technologies that were already investigated, experimented and progressively deployed such as peer-to-peer, autonomous, cognitive and ad hoc networking, that have already demonstrated how to improve network performance and user experience. Peer-to-peer networking for large-scale distributed systems and widely used applications has proved both the feasibility and economic potential for delivering services to millions of users. Others emerged more recently in the context of the future Internet (FI), such as Cloud Computing for transparently sharing among users scalable elastic resources over a limitless network. As it remains difficult to visualise the conceptual evolution and articulate the various Internet research areas, we conducted a study for identifying the appropriate concepts that could populate the FI domain landscape [69], [71] over three different periods of time (1990-1999, 2000-2005 and 2006-2011). Several INRIA research teams are involved in FIRE (Future Internet Research Experimentation) Testbed projects, namely: PlanetLab, OneLab, TEFIS, SensLAB, and BonFIRE whose scientific leaders were interviewed during the development of the FI domain landscape. Four dimensions were used for landscaping the Future Internet research domain: evolution approaches (from incremental evolution design to Clean Slate re-design or radical evolution), Internet routing (from the basic data packet delivery towards more sophisticated content distribution and retrieval capacities such as content Centric Networking), network type (from wired communication to wireless communication networks), evolution trend (from computer network towards network computing). The resulting tentative landscape of FI research areas shown in Figure 1 is intended to provide a faster and broader understanding of the different Internet research streams and related topics.

5.4.4. Future of Internet and User-open innovation for Smart Cities

Participants: Caroline Tiffon, Marc Pallot, Brigitte Trousse, Bernard Senach.

The goal of the Fireball project is to bring together three different constituencies: user driven open innovation, Future Internet, and Smart Cities [34], [39]. It aims at defining a roadmap [29], based on analysis of needs, opportunities and gaps, to benefit a wide scale implementation of the methodologies and concepts elaborated. A first objective in the project was to get a clear picture of the state-of-the-art in each domain. During the review, progressively emerges a landscape [69] that we organized along 4 main axes: wiring (wired/wireless), user’s role (subject/actor), Internet evolution approach (structured/unstructured), evaluation purpose (reliability/adoptability). A large variety of FI research have been engaged. If initial efforts in Future
Internet research have been directed towards the goal of providing the technical infrastructure supporting the next network generation, a rising trend in this research field is to consider now a higher level layer, the layer of services.

### 5.4.5. Method and Tool for Selection of Open Innovation Software Tools

**Participants:** Mylène Leitzelman, Brigitte Trousse.

In spite of an important number of tools supporting open innovation, there is few comparative evaluation and no grid or evaluation criteria helping to choose a product. A 2011 review in the Computer Aided Innovation field provides a large overview of available tools in relation with a wide range of innovation cycle features. This useful top-down categorization approach is of little help to choose a specific tool. To find the best OI tool supporting idea exchanges among a community of participants, we built an exploratory method on the Web and we elaborate an assessment grid of OI tools based on the QSOS method which is a method designed to qualify, select and compare free and open source software in an objective, traceable and argued way. It publicly available under the terms of the GNU Free Documentation License. In our QSOS method, evaluation criteria are organized in a tree-hierarchy grid with, a scoring method procedure of each tree-leaf criteria (from 0 - not covered to 2 - completely covered). To achieve the construction of the OI tools criteria assessment grid (first step), we used different mining tools for Web crawling, network analysis, criteria classification and from the 29 top rated OI tools, we finally selected 6 of them from which we extracted the tree-map categorization used to build the reference software criteria sheet. In the following steps, after appropriate weighting, we used the provided OS3 Web application and we were able to compare 4 top selected OI tools.

To support our method, we developed a QSOS-based OI Grid for supporting the OI tool selection. The QSOS Grid to compare OI tools, which is in an XML format, has been translated into a MindMap. As a first mock-up, the QSOS Web Interface O3S will be installed at the beginning of 2012 on our server. For the future, we

---

6 Hüsig, University Regensburg & Khon, Otto Beisheim School of Management
will extend our own QSOS comparative method to other softwares and to other categories interesting for the Living Lab community.

5.4.6. Extension of Methods for Idea Generation Process

Participants: Anne-Laure Negri, Caroline Tiffon, Bernard Senach, Brigitte Trousse.

Internet of Things (IoT) is supposed to be a physical world where everyday objects, rooms and machines are connected to one another and to the larger digital world. In this web of people and objects, individuals as well as things will have their own unique URL and, according to interactions between all these entities, social networks will be articulated with a ring of connected objects. This mash up of "hyper groups" and "hyper objects" will be the next step towards a deeper level of automation in which the user interface has vanished, the explicit control over the world is no longer the rule and where the users will have to understand the dynamic changes of their environment in relation to their social interactions and to their physical behaviour. The design of IoT based services therefore raises many challenges related to the user experience and requires a deep understanding of users’ needs in their real life environment as well as many field experiments; this is why the Living Lab approach appears as the qualification device which has been lacking so far. As described in a paper accepted for ServDes2012 conference (February 2012) among 80 papers submitted, we developed and tested two methods designed for Internet of Things service idea generation: GenIOT (Generative Technique for the Internet of Things) and Aloha! (Animation Lens: Object/Human Actoring!) methods.

- The GenIOT method aims at providing citizen a tool for identifying and sharing examples of situations where they may benefit from an Internet of Things based service. Indeed the objective is to help the introspective effort of analysing one’s daily behavior and unveil situated data in order to develop grounded internet of things services ideation. Fake sensors are placed by the participants in their daily environment and pictures of the sensors in situ are shared and tagged on a collaborative platform. Other participants are invited to discuss online the ideas behind the pictures. Gamification rules are implemented in the platform in order to enhance collaboration and participation.

- The Aloha! method tackles another creative dimension as it asks participants to role or play characters or objects and bodystorm a collaborative scenario meeting the characters need. Participants report it to be a fun and effective method, alternative to traditional brainstorming and integrating serendipity as a creative asset.

For the exploration step in the context of ELLIOT, we developed NiceAir, an android mock-up for visualizing air quality data on Google map in Nice as well as some interest points (free bikes, free park places, bus stop, etc.). Such a mock-up will be available in the co-creation step of green services in the ELLIOT project and during the European Mobility Week.
5.4.7. Mock-ups for two innovation processes (exploration step)

Participants: Lucile Gramusset, Guillaume Pilot, Mohamed Gaieb, Bernard Senach, Brigitte Trousse.

In the context of two contracts (TICTAC and ELLIOT) related to user oriented innovation process, we have developed two mock-ups

- Based on the user feedback from the first experiment in TICTAC (CF. section 6.1.1, we decided to develop a mock-up MobilTIC of a real-time information service related to public transportation (Envibus & SNCF) useable for any smartphone with internet access for Sophia-Antipolis workers. We designed a Web interface the most simple based on PHP/Mysql technologies and accessible from a computer or 3G mobile phone. Usage analysis of MobilTIC has been anticipated by providing rich logs. An exploration task with citizen is planned in January 2012 with a new experiment with an improved version.

- A first mock-up called Nice Air has been developed in the context of ELLIOT (CF. section 6.3.1.1 by L. Gramusset and M. Gaieb on androïd smartphone for providing information related to air quality and noise on a map of the area of Nice Cote d’Azur with some interest points such as bus stops and Vélib parkings.

5.5. FocusLab Experimental Platform and Software

5.5.1. ATWUEDA based Clustering Approach for System Monitoring

Participant: Yves Lechevallier.

Progressive advances in hardware and software technologies have enabled the production and storage of system monitoring data streams in a wide range of fields (e.g. telecommunications, sensor networks, etc.). Traditional clustering methods are unable to deal with data of such a voluminous and dynamic nature. In this work [51], we propose an efficient clustering approach (ATWUEDA) for monitoring massive time-changing data streams. This work considers a real case study on condition monitoring data streams of an electric power plant provided by EDF.

This work is done in collaboration with Alzennyr Da Silva of Bilab laboratory (Telecom ParisTech and EDF R&D Common Laboratory)

5.5.2. FocusLab Experimental Platform (CPER Telius 2008-2012)

Participants: Xavier Augros, Mohamed Gaieb, Brigitte Trousse, Yves Lechevallier.

The FocusLab platform aims to be a major delivery mechanism of previous and current work in AxIS. It is a way to make methodological contributions (including software) available for the scientific community, but also a way for stimulating further research. This work has slowly started on the software part due to the absence of human resource funding and due to the absence of engineers in the team until 2010. Mid 2011, we started the specification and the development of a first version of a platform with three parts (hardware, software and methods) with the arrival of two engineers on the ELLIOT and TIC TAC contracts. A first version is available since the end of september as a Web portal and a second one is planned for the end of 2012 with advanced features for the software part (cf. service oriented platform, SOA architecture and interoperability).

Related to the software part we are in the process of developing several AxIS methods as Web services: we started with SCDS (cf. 4.2.3) which was demonstrated in the context of the MIDAS project on two applications (Orange labs mobile portal and vehicle trajectories) and in the ELLIOT platform (linked to the San rafaelle Hospital media use case) at the first review meeting (cf. 6.3.1.1) applied on data issued from San rafaelle Hospital use case. ATWUEDA (cf. 4.3.2), GEAR (Marascu’s thesis) are under development as web services.

Our work on mining evolutive data (ATWUEDA) and data streams (such as SCDS) have been used in real applications in the context of Internet of things and sensors: ATWUEDA (system monitoring for EDF (cf. section 5.5.1) and SDMS (cf. section 4.2.3).
6. New Results

6.1. Numerical schemes and algorithms for fluid mechanics.

Participants: Rémi Abgrall [Corresponding member], Guillaume Baurin, Pietro Marco Congedo, Cécile Dobrzynski, Marc Duruflé, Dante De Santis, Algiane Froehly, Gianluca Geraci, Robin Huart, Arnaud Krust, Cédric Lachat, Mario Ricchiuto, Birte Schmidtman, Héloïse Beaugendre, Sébastien Blaise.

6.1.1. Residual distribution schemes

This year, many developments have been conducted and implemented in the Realfluids and SLOWS software after the initial ideas discussed in [55] and in [64], [61], [65], which have opened up many doors.

First of all, the parallel three dimensional high order extension of the scheme of [55] has been finally validated on several external aerodynamics configurations [3], including the classical ONERA M6 wing case on a large mesh containing $5.5 \times 10^6$ vertices (simulation run on 256 processors), and a business jet configuration in supersonic conditions, on a mesh obtained by the GAMMA3 EPI.

Meanwhile, the improvement of the treatment of viscous terms has been investigated within the PhD theses of G. Baurin and D. DeSantis [46], [19]. The validation on laminar flows of a classical formulation based on a Petrov-Galerkin approach [60] [17] has shown its limitations. An improved formulation, based on a recovery of the solution gradient, has been proposed and tested. In both the second and third order cases, while showing the improvement in accuracy for steady state laminar flows, the results also show a slow iterative convergence, and a systematic small accuracy drop when the cell Reynolds number is of order one. These issues are currently under investigations, while the current formulation is being enhanced by adding a Spalart Almaras turbulent model. Contributions to these activities come from the PhD of Guillaume Baurin, who has implemented the third order version of our methods in a real industrial platform (N3S Natur of SAFRAN developed by Incka), and from the PhD of Dante DeSantis who is developing the turbulent implementation in Realfluids within the EU project IDIHOM.

Meanwhile, we are refining and validating the extension of the schemes to elements using improved approximations based on Bézier and NURBS polynomials. the initial two-dimensional implementation [56], [59] of third and fourth order schemes on curved meshes is now being enhanced by adding a local mesh refinement procedure and is also currently being extended to three space dimensions. Contributions to this topic come from the PhD of Algiane Froehly.

R. Abgrall has extended the RDS formalism to Lagrangian hydrodynamics. The results are comparable to what can be obtained for more standard methods, a publication is in preparation.

Concerning time dependent flows, the ideas of [61], [64] have led to two main lines of developments. On one hand, the unconditionally second order and stable space-time approach of [61] has been further validated [14] and extended to higher orders of accuracy [51]. The main advantage of this technique is its ability to preserve monotonicity unconditionally w.r.t. the time step. This has interesting applications in shallow water flows [36] in which the schemes previously developed [65] did allow to preserve the positivity of the water depth, however with an inefficient implicit procedure constrained by an explicit-type time step restriction.

In parallel, the genuinely explicit formulation of [64] has been combined with the positivity preserving approach of [65] to obtain a genuinely explicit positivity preserving scheme for shallow water simulations [16]. With a time step restriction quite close to that necessary for the scheme of [65], the approach proposed allows a very efficient explicit time stepping with a tenfold reduction of the computational time for the same accuracy level.
These developments are implemented in the SLOWs platform and are thoroughly summarized in the manuscript [2]. We now dispose of a spectrum of numerical tools allowing either classical temporal integration based on implicit multistep schemes, or on unconditionally stable and positivity preserving space-time schemes, or on a genuinely explicit approach. Current developments aim at extending these tools to arbitrary accuracy, and at developing hybrid implicit/explicit approaches.

In this work, Héloïse Beaugendre, Boniface Nkonga and Christelle Wervaecke proposed a strongly coupled numerical formulation for the Spalart-Allmaras model, in the framework of Stabilized Finite Element Methods. Computations are performed for compressible Newtonian fluids (2D and 3D) on unstructured grids of high aspect ratio. Results are compared with experimental data and also with solutions obtained by different numerical strategies. The additional transport equations for subscale model are often numerically weakly coupled to Navier-Stokes equations through operator splitting. These variables are strongly coupled for the transport process within a stabilized finite element formulation. The stabilization tensor is defined, such as to reduce mesh dependencies and to still be consistent at the asymptotic of highly anisotropic meshes. Indeed, this tensor involves a measure of the local length scale \( h \) which can be difficult to define in the case of a stretched element. In this work, the local length scale is implicitly given by the inverse of the absolute flux Jacobian matrix as proposed in Barth (1998) and more recently in Abgrall (2006). The stabilized finite element strategy is also suitable for complex geometries and the resulting schemes have a compact stencil which we exploit for efficient parallel strategies combining domain decomposition and message passing tools (MPI).

6.1.3. Uncertainty quantification

R. Abgrall and P.M. Congedo have made a detailed comparison between the semi-intrusive method developed last year with more classical non intrusive polynomial chaos methods, and Monte Carlo results. The effectiveness of this method is illustrated for a modified version of Kraichnan-Orszag three-mode problem where a discontinuous pdf is associated to the stochastic variable, and for a nozzle flow with shocks. The results have been analyzed in terms of accuracy and probability measure flexibility. Finally, the importance of the probabilistic reconstruction in the stochastic space is shown up on an example where the exact solution is computable, the viscous Burgers equation. These results have been reported in [25], [47].

Following this studies, two contributions have been obtained within the context of Gianluca Geraci’s thesis. First one is an adaptive strategy, inspired by the Harten multi-resolution framework that has been developed in order to compute efficiently statistics. This preliminary work aims to show the potentialities of this approach in order to evaluate the possibility to include this strategy in the semi-intrusive method developed in the recent years. We obtained [34] well-converged results with a lower computational cost due to a reduction of the numerical evaluations.

Second contribution [48] is a study concerning the Sparse Grid techniques coupled with Polynomial Chaos for multi-dimensional stochastic problems. Sparse grid techniques have been used to compute the multi-dimensional integrals needed to evaluate the coefficients of the polynomial expansion. We also investigated the possibility to reduce the number of random variables by means of an ANOVA analysis.

P.M. Congedo investigated the possibility to perform a stochastic inverse analysis by using an hybrid method within a Polynomial Chaos/Genetic Algorithms framework. This strategy has been applied on the numerical simulation of a dense gas shock-tube. Previous theoretical and numerical studies have shown that a rarefaction shock wave (RSW) is relatively weak and that the prediction of its occurrence and intensity are highly sensitive to uncertainties on the initial flow conditions and on the fluid thermodynamic model. The objective of this work has been to introduce an innovative, flexible and efficient algorithm combining computational fluid dynamics (CFD), uncertainty quantification (UQ) tools and metamodel-based optimization in order to obtain a reliable estimate for the RSW probability of occurrence and to prescribe the experimental accuracy requirements ensuring the reproducibility of the measurements with sufficient confidence.

Uncertainty quantification tools have been used to perform some applicative studies on epistemic uncertainties, in particular on some complex equations of state [8], and some turbulence [12] models. We have also started
considering the influence of model parameters uncertainties in free surface models for long-waves such as tsunamis [52], coupling the numerics developed in the team for shallow-water flows and the tools available for uncertainty quantifications. This is certainly a field of application where these developments will demonstrate very useful.

Within the associated team AQUARIUS activities (collaboration with Stanford University), two efficient global strategy for robust optimization have been developed. First one is based on the extension of simplex stochastic collocation to the optimization space, while the second one consists in an hybrid strategy using ANOVA decomposition. The Simplex Stochastic Collocation (SSC) method has been developed for adaptive uncertainty quantification (UQ) in computational problems with random inputs. In this work [30], we showed how this formulation based on Simplex space representation, discretization of non-hypercube probability spaces and adaptive refinements can be easily coupled with a well-known optimization method, i.e. Nelder-Mead algorithm, also known as Downhill Simplex Method. Numerical results showed that this method is very efficient for mono-objective optimization and minimizes global number of deterministic evaluations in order to determine optimal design. This method has been then applied to a realistic problem of robust optimization of a two-component race-car airfoil.

We proposed also an efficient strategy [29] for robust optimization when a large number of uncertainties is taken into account. ANOVA analysis is used in order to perform a variance-based decomposition and to reduce stochastic dimension. A massive use of metamodels allows reconstructing response surfaces for sensitivity indexes and fitness function in the design variables plan. Proposed strategy has been applied to the robust optimization of a turbine cascade for thermodynamically complex flows.

### 6.1.4. Multiphase flows

Starting from [58], R. Abgrall and H. Kumar are developing a method that is able to compute multiphase flows when the interfacial area takes any value. In the previous version, either we could take into account infinite interfacial areas or pure interface problems. M.G. Rodio is developing, along similar lines, a scheme for the Navier Stokes equations.

### 6.1.5. Numerical schemes for advanced materials

Two parallel lines of work on developments of numerical models for advanced materials have seen important developments this year.

On one hand, Rémi Abgrall and Pierre-Henri Maire (CEA Cesta) are extending the Lagrangian method developed a couple years ago and currently implemented in the CHIC code to elastodynamics. The stress tensor is no longer diagonal and here we consider the Wilkins model. The main difficulty is to understand the role of the second principle and how to deal with the von Mises criteria.

In parallel, Mario Ricchiuto and the group led by Gérard Vignoles at LCTS (UMR-5801 LCTS) have been developing a finite element numerical model of the evolution of the liquid oxide evolution during the healing-phase taking place in the silicon-based composite materials similar to those used in SAFRAN’s new aero-engines [50]. This micro-model is meant to be used as a numerical closure for the LCTS’ structural mechanics solver [31], allowing to obtain a faithful description of the material’s behavior, including the effects of the healing process.

### 6.1.6. Discontinuous Galerkin schemes, New elements in DG schemes

Rémi Abgrall and Pierre-Henri Maire (CEA CESTA), with François Vilar (PhD at CELIA funded by a CEA grant started in October 2009), are working on fully Lagrangian schemes within the Discontinuous Galerkin schemes. The idea is to start from the formulation of the Euler equation in full Lagrange coordinates: the spatial derivative are written in Lagrangian coordinates. The mesh element are now curved and we are working on the geometrical conservation law. The application to several standard test case indicate the potential of the method.

---

6.1.7. Penalization techniques with unstructured adapted meshes

Penalization methods are an efficient alternative to explicitly impose boundary conditions but their accuracy is generally of first order. In this work we combine the easiness of penalization techniques with the precision of unstructured anisotropic mesh adaptation. Level sets are used to describe the geometry so that geometrical and topological changes due to physics are straightforward to follow. Navier-Stokes simulations are performed and a new way to impose a slipping wall boundary condition is proposed.

6.1.8. Mesh adaptation

A work on high order mesh generation has been pushed further. Starting with a $P^1$ (triangle) mesh and some information on the boundary (control point), we are able to generate a valid third order curved mesh. The algorithm is based on edge swaps and is similar to a boundary enforcement procedure. This method is very robust but not efficient of the boundary layer. Indeed the edge swaps destroy a part of the boundary layer. To solve this problem, we investigate the use of linear elasticity to curve a $P^1$ mesh.

Moreover, we started to make high order mesh adaptation. That means we are able to refine high order meshes where the error is maximum and so we generate non uniform meshes of order $k$ with $k > 2$. We compute Euler compressible simulations on those meshes to validate the mesh adaptation strategy.

In parallel to these developments, we have started work on a generalized formal approach to obtain discrete adjoint equations for residual based and Petrov-Galerkin finite element schemes. We have shown that these discrete adjoint equations can now be used as a local error estimator for mesh refinement, giving to these methods the same potential for adaptation of Galerkin schemes.

6.2. High performance simulation for plasma physics

Participants: Rémi Abgrall, Robin Huart, Xavier Lacoste, François Pellegrini, Pierre Ramet [Corresponding member].

In the Realfluids code, the Rusanov scheme for Ideal MHD has already shown its ability to capture discontinuities and its robustness many times in 2D problems. But other spatial schemes could be interesting for applications in tokamak experiments, since we may not encounter strong shocks in these cases. Hence, according to the type of the problem, coupled schemes could be used. We already developed the 4 well known base RD schemes : Narrow, LDA, Rusanov and SU (a RD version of the SUPG scheme). Coupling may not be challenging, a working shock sensor is already implemented for stabilized methods. Very high order of accuracy (at least 3rd order) should be reachable in all cases, the main parts of this work have already been done for several types of elements. The non-dimensionalized equations of resistive MHD (with viscosity and heat transfer) have been added to the code with a Continuous Galerkin discretization. Also, 2nd order implicit and explicit methods were developed in all cases. Once we succeed in ensuring a very good iterative convergence, taking into account the hyperbolic divergence cleaning technique in an unsteady context, we will be able to simulate plasma instabilities. This is really the key issue for now. These results will be presented in the PhD defense of R. Huart planned at January 2012.

The JOREK code is now able to use several hundred of processors routinely. Simulations of ELMs are produced taking into account the X-point geometry with both closed and open field lines. But a higher toroidal resolution is required for the resolution of the fine scale filaments that form during the ELM instability. The complexity of the tokamak’s geometry and the fine mesh that is required leads to prohibitive memory requirements. In the current release, the memory scaling is not satisfactory: as one increases the number of processors for a given problem size, the memory footprint on each process does not reduce as much as one can expect.

In the context of the new ANR proposal (ANEMOS project), we are working to reduce memory consumers in the JOREK code. Compression techniques can be foreseen to reduce the footprint of the matrix without having to pay large computation expenses. Moreover, the storage of the factorized preconditioning matrix inside the direct solver takes also a large amount of memory. We have defined and developed a general programming interface for sparse linear solvers for which we also provided some test programs and documentation. Our goal is to normalize the application programming interface of
sparse linear solvers and to provide some very simple ways of doing some fastidious tasks such as parallel matrix assembly for instance. This interface has been validated in Realfluids and JOREK for HIP9 and PaStiX. Using this common interface, we are looking for a fair distribution of data over the parallel processes in order to reduce memory consumption. The effective parallelization of this assembly step is one of the main bottlenecks up to now, as far as memory usage is concerned. The GMRES driver is also a large consumer in terms of memory and we plan to consider an up-to-date parallel implementation of this step.

6.3. Algorithms and high-performance solvers

Participants: Astrid Casadei, Cécile Dobrzynski, Sébastien Fourestier, Damien Genêt, Hervé Guillard (Pumas), Laurent Hascoët (Tropics), Cédric Lachat, Xavier Lacoste, François Pellegrini, Pierre Ramet [Corresponding member].

6.3.1. Parallel domain decomposition and sparse matrix reordering

Most of the work carried out within the Scotch project (see section 5.7) has been carried out in the context of the PhD of Sébastien Fourestier.

The first axis concerns dynamic repartitioning and remapping. A new set of sequential routines has been devised, which offers new features: mapping (including plain partitioning) with fixed vertices, remapping, and remapping with fixed vertices. All of the above developments are about to be released in the major release 6.0 of Scotch. The porting of the remapping algorithms in parallel is being carried out, and will be part of release 6.1.

A work carried out in the Joint Laboratory for Petascale Computing (JLPC) between INRIA and UIUC resulted in the inclusion of Scotch as a load balancer in the Charm++ parallel environment. A jointly written conference paper has been submitted on this subject. Another potential use of the remapping features of Scotch concerns multi-phase mapping. Experiments are being carried out at UIUC regarding the use of Scotch as a multi-phase mapper for the OpenAtom scientific code.

6.3.2. Parallel mesh adaptation

This research topic deals with the design of efficient and scalable software tools for parallel dynamic remeshing. This is a joint work with Cécile Dobrzynski, in the context of the PhD of Cédric Lachat, funded by a CORDI-S grant managed by the PUMAS team.

PaMPA (see Section 5.11) is a middleware library dedicated to the management of distributed meshes.

The software development of PaMPA is going on. The internal data structure for representing meshes has been frozen, and developments are in progress. The first developments aimed at proving the efficiency of the planned API for handling distributed meshes. A simple P1 FEM Laplacian solver has been written over PaMPA by the PUMAS team to demonstrate how to iterate over PaMPA entities (elements and nodes) and access values borne by the entities, so as to perform FEM computations. These features are available in version 0.1, which has not yet been diffused to other interested parties. Several new potential users are already willing to try out this version, e.g. ONERA.

PaMPA is already used as the data structure manager for two solvers being developed at INRIA: the Plato solver being developed by the PUMAS team, and the Aerosol new generation fluid dynamics solver being developed in the context of the PhD of Damien Genêt. The interaction with these users allows us to refine the interface to match their needs.

This work now focuses on the core of the PhD of Cédric Lachat: interfacing PaMPA with MMG3D to demonstrate the ability of PaMPA to perform parallel mesh adaptation.
6.3.3. **High-performance direct solvers on multi-platforms**

New supercomputers incorporate many microprocessors which include themselves one or many computational cores. These new architectures induce strongly hierarchical topologies. These are called NUMA architectures. In the context of distributed NUMA architectures, in collaboration with the INRIA RUNTIME team, we study optimization strategies to improve the scheduling of communications, threads and I/O. Sparse direct solvers are a basic building block of many numerical simulation algorithms. We have developed dynamic scheduling designed for NUMA architectures in the PaStiX solver. The data structures of the solver, as well as the patterns of communication have been modified to meet the needs of these architectures and dynamic scheduling. We are also interested in the dynamic adaptation of the computation grain to use efficiently multi-core architectures and shared memory. Experiments on several numerical test cases have been performed to prove the efficiency of the approach on different architectures.

In collaboration with the ICL team from the University of Tennessee, and the RUNTIME team from INRIA, we are evaluating the way to replace the scheduling driver of the PaStiX solver by one of the generic frameworks, DAGuE (see [http://icl.cs.utk.edu/dague/overview/](http://icl.cs.utk.edu/dague/overview/)) or StarPU (see [http://runtime.bordeaux.inria.fr/StarPU](http://runtime.bordeaux.inria.fr/StarPU)), to execute the task graph corresponding to a sparse factorization. This work now focuses on the core of the PhD of Xavier Lacoste, the aim is to study and design algorithms and parallel programming models for implementing direct methods for the solution of sparse linear systems on emerging computer equipped with GPU accelerators. This is a joint work with the MUMPS team and algorithms will have to be adapted in order to exhibit parallelism that can be more suitable for the dynamic scheduling of computational tasks on such heterogeneous architectures.

6.3.4. **Hybrid direct-iterative solver based on a Schur complement approach.**

In HIPS, we propose several algorithmic variants to solve the Schur complement system that can be adapted to the geometry of the problem: typically some strategies are more suitable for systems coming from a 2D problem discretisation and others for a 3D problem; the choice of the method also depends on the numerical difficulty of the problem. We have a parallel version of HIPS that provides full iterative methods as well as hybrid methods that mixes a direct factorization inside the domain and an iterative method in the Schur complement.

Graphs or meshes partitioners are now able to deal with problems that have more than several billion of unknowns. Solving linear systems is clearly the limiting step to reach this challenge in numerical simulations. During her PhD, Astrid Casadei will have to propose solutions to get an efficient algorithmic coupling of direct and iterative methods that allow a powerful management of whole the levels of parallelism. As a preliminary study, we focus on memory issues to build a Schur complement in our direct solver. During factorization step, memory overhead may occur for two reasons. The first one is due to the fan-in approach, that is to say the local storage of non-local contributions. The second overhead is due to the coupling matrices (between direct part and Schur complement), which remain allocated during the whole computation and are freed only at the end. Our first ideas to reduce memory consumption was to postpone the allocation of each block and, thanks to a right-looking algorithm, a column-block may be freed as soon as it has been treated. However, many blocks may be allocated very quickly, and a solution would be to use a left-looking scheme when dealing with local contributions. Thus, we introduce a mixed version: a right-looking algorithm is used, except for local contributions in the direct part where a left-looking scheme is applied. Some experiments have been performed and first results show that some substantial memory reductions can be achieved.
6. New Results

6.1. Sex-specific impact of meiotic recombination on nucleotide composition

Meiotic recombination is an important evolutionary force shaping the nucleotide landscape of genomes. For most vertebrates, the frequency of recombination varies slightly to considerably between the sexes (heterochiasmy). We extended the examination of the evolutionary impact of heterochiasmy beyond primates to include four additional eutherian mammals (mouse, dog, pig, and sheep), a metatherian mammal (opossum), and a bird (chicken). We compared sex-specific recombination rates with nucleotide substitution patterns evaluated on transposable elements. Our results, based on a comparative approach, revealed a great diversity of the relationship between heterochiasmy and nucleotide composition. We found that the stronger male impact on this relationship is a conserved feature of human, mouse, dog, and sheep. In contrast, variation in genomic GC content in pig and opossum is more strongly correlated with female, rather than male, recombination rate. We also showed that the sex-differential impact of recombination is mainly driven by the chromosomal localisation of recombination events, not the overall average recombination rate. We proposed a new explanation for the evolutionary impact of heterochiasmy on nucleotide composition. This work has been submitted for publication. This work was done in collaboration with D. Mouchiroud.

6.2. Modelling the influence of karyotype on the distribution of meiotic recombination

Given the important evolutionary role of recombination, recent work has focused on understanding the dynamics of this molecular process. We analysed the variation of recombination rate among species in relation to their karyotype. Specifically, we developed a non-linear model between the total genetic and physical lengths of chromosomes. Our model incorporates important biological knowledge of the recombination process. It further allows the estimation of two main parameters of recombination: the additional recombination rate per Mb and the per-species average strength of interference. Since the model is defined on data from genetic maps, at the global level of the karyotype, it can be applied even on low-resolution data and, hence, can result in the exploration of multiple species. By analysing the variability of our models recombination parameters among species, we showed that the recombination rate and the interference strength are regulated at the Mb scale of the genomes. We found that the genome size is a strong predictor of the recombination rate, while the average physical length of chromosomes is positively correlated with the interference parameter of our model. These relations represent valuable tools for the estimation of recombination parameters even for species lacking genetic maps. This work is in submission. This work was done in collaboration with D. Mouchiroud.

6.3. Finding long and multiple repeats with edit distance

We developed an algorithm, FILMRED, for detecting long similar fragments occurring at least twice in a set of biological sequences (a conference paper [25] has already appeared, a journal version is in preparation). The problem becomes computationally challenging when a non negligible number of insertions, deletions and substitutions are allowed. The algorithm is exact and manages instances whose size and combination of parameters cannot be handled by other currently existing method. This is achieved by using a filter as a preprocessing step, and then the information that this filter has gathered in the following inference phase. FILMRED can deal with very long repeats (up to a few thousands) occurring possibly several times, with a difference rate (substitutions and indels) of 10% or more. This work was done in collaboration with N. Pisanti and P. Peterlongo. The software will be made available in a near future.
6.4. Genomics of symbiosis

Insect symbioses are model systems for studying the evolution of bacterial genomes. Importantly, evolution is directly related to the type of interaction and may also be influenced by the presence of other symbionts [11]. We are currently studying the genomes of different symbionts. The first one is the genome of the *Wolbachia* strain that has recently become obligatory for the reproduction of *Asobara tabida*. First results indicate that this genome may have been recently invaded by mobile elements. The second project concerns the sequencing of the different symbionts that co-exist in the insect *Bemisia tabaci*. The initial sequences are promising and we hope to close the genome of four different symbionts in this system, which will allow the study of the complementation between symbionts and lateral gene transfers among symbionts sharing the same intracellular arena. This work is done in collaboration among others with L. Mouton.

6.5. Bacterial syntenies

The automatic identification of syntenies across multiple species is a key step in comparative genomics that helps biologists shed light both on evolutionary and functional problems. We developed a versatile algorithm to extract all syntenies from multiple bacterial species based on a clear-cut and very flexible definition of the synteny blocks that allows for gene quorum, partial gene correspondence, gaps, and a partial or total conservation of the gene order [8]. We then applied this algorithm to two different kinds of studies. The first one is a search for functional gene associations. In this context, we compared our algorithm to a widely used heuristic - I-ADHORE - and showed that at least up to ten genomes, the problem remains tractable with our exact definition and algorithm. The second application was linked to evolutionary studies: we verified in a multiple alignment setting that pairs of orthologs in synteny are more conserved than pairs outside, thus extending a previous pairwise study. We then showed that this observation is in fact a function of the size of the synteny: the larger the block of synteny is, the more conserved the genes are. This work was done in collaboration with F. Boyer.

6.6. Spatial synteny in Eukaryotes

Folding and intermingling of chromosomes has the potential of bringing close to each other loci that are very distant genômically or even on different chromosomes. On the other hand, genomic rearrangements also play a major role in the reorganisation of loci proximities. Whether the same loci are involved in both mechanisms has been studied in the case of somatic rearrangements, but never from an evolutionary standpoint. From the joint study of the network of spatial proximities of human genomic loci and a dataset of evolutionary breakpoints between human and mouse, we were able to provide evidence that evolutionary breakpoints tended to cluster spatially in human cells, which led us to propose the new notion of spatial synteny, which generalises the concept of genomic synteny. This work was submitted in 2010 and was accepted in 2011 [24]. It was done in collaboration with C. Lemaitre.

6.7. Chimeric transcripts in Eukaryotes

In the framework of the extension of the ENCODE project to chromosomes 21 and 22, we had the opportunity to identify a new category of transcripts, which we call chimeric transcripts, since they contain exons from different genes, which can themselves be located far apart on the same chromosome, or on different chromosomes [9]. We further found that the network formed by these connected genes is enriched in cliques of sizes 3 and 4, which seems to indicate that transcription and/or splicing of these sets of genes co-occur in time and space, as is confirmed by the confrontation of our expression dataset to a dataset indicating the co-localisation of DNA fragments in 3D. This work was done in collaboration with, among others, R. Guigó.

6.8. KisSplice: de-novo calling alternative splicing events from RNA-seq data

We addressed the problem of identifying polymorphisms in RNA-seq data when no reference genome is available, and avoiding an assembly. Based on the fundamental idea that each polymorphism will correspond to a recognisable pattern in a De Bruijn graph constructed from the RNA-seq reads, we propose a general
model for all polymorphisms in such graphs. We then introduce an exact algorithm to extract alternative splicing events and show that it enables to identify more correct events than current transcriptome assemblers. Additionally, when we applied our method on a 50M reads dataset from human, we were able to identify 3884 events, out of which 57% are not present in the annotations, which confirms recent estimates showing that the complexity of alternative splicing has been largely underestimated so far. This work has been submitted to publication. This work was done in collaboration with P. Peterlongo.

6.9. Transcriptomics of symbiosis in the Asobara tabida-Wolbachia association

*Wolbachia* has evolved a very peculiar phenotype in the host *Asobara tabida* where it is obligatory for oogenesis. Through transcriptomic approaches (Sanger sequencing of mRNA, in vitro subtraction of transcriptomes), we have established a first reference transcriptome of this insect. The analyses done demonstrate that *Wolbachia* interferes with different host pathways, and notably regulation of oxidative stress, apoptosis and autophagy, which are known to be involved in host-pathogen interactions. RNAseq has now been performed on this system and analyses are underway, which will allow a finer investigation of the interaction using the algorithm **KISSPLICE** (see above) developed in the EPI for the analysis of NGS data without reference genome.

6.10. Navigating through unexplored pre-miRNA candidates

The computational search for novel miRNA precursors often involves some sort of structural analysis with the aim of identifying which type of structures are prone to being recognised and processed by the cellular miRNA-maturation machinery. A natural way to tackle this problem is to perform clustering over the candidate structures along with known miRNA precursor structures. Mixed clusters allows then the identification of candidates that are similar to known precursors. Given the large number of candidate pre-miRNAs that can be identified in single-genome approaches, even after applying several filters for robustness and stability, a conventional structural clustering approach is unfeasible. We presented a method, **MinDist**, to represent candidate structures in a feature space which summarises key sequence/structure characteristics of each candidate. We demonstrated that proximity in this feature space is related to sequence/structure similarity, and we selected candidates which have a high similarity to known precursors. Additional filtering steps were then applied to further reduce the number of candidates to those with greater transcriptional potential. Our method was compared to another single-genome method (**TRIPL**ET**SVM**) in two datasets, showing better performance in one and comparable performance in the other. Additionally, we showed that our approach allows for a better interpretation of the results. The MinDist method is available upon request and will be made available online. This work has been submitted to publication. This work was done in collaboration with A. T. Freitas and R. Backofen.

6.11. Exploration of the genetic network of Buchnera aphidicola

Aphids are important agricultural pests which can grow and reproduce thanks to their intimate symbiosis with the *γ*-proteobacterium *Buchnera aphidicola* that furnishes them with essential amino acids lacking in their phloem sap diet. We investigated how *B. aphidicola*, with its reduced genome containing very few transcriptional regulators, responds to variations in the metabolic requirements of its host by concentrating attention on the leucine metabolic pathway [23]. We showed that leucine is a limiting factor for aphid growth and displays a stimulatory feeding effect. Our metabolic analyses demonstrated that symbiotic aphids are able to respond to leucine starvation or excess by modulating the neosynthesis of this amino acid. Taken together, our data showed that the response of *B. aphidicola* to the leucine demand of its host is multimodal and dynamically regulated, providing new insights concerning the genetic regulation capabilities of this bacterium in relation to its symbiotic functions.
6.12. Annotation database system to ease the development and update of BioCyc databases

In recent years, genomes from an increasing number of organisms have been sequenced, but their annotation remains a time-consuming process. The BioCyc databases offer a framework for the integrated analysis of metabolic networks. The PATHWAY TOOL SOFTWARE SUITE allows the automated construction of a database starting from an annotated genome, but it requires prior integration of all annotations into a specific summary file or into a GenBank file. To allow the easy creation and update of a BioCyc database starting from the multiple genome annotation resources available over time, we developed an ad hoc data management system that we called Cyc Annotation Database System (CYCADS) [22]. The CYCADS pipeline for annotation management was used to build the ACYPICYC database for the pea aphid Acyrthosiphon pisum, TRICACYC for Tribolium castaneum and DROMECYC for Drosophila melanogaster. This work will be extended to create a database for other arthropods. This work was done in collaboration among others with S. Collela.

6.13. Representation and curation of metabolic pathways: UniPathway

UniPathway (http://www.unipathway.org) is a manually curated database for the representation and annotation of metabolic pathways developed in collaboration with the Swiss Institute of Bioinformatics (Swiss-Prot group). UniPathway provides explicit chemical representations of enzyme-catalysed and spontaneous chemical reactions, as well as a hierarchical representation of metabolic pathways. This hierarchy uses linear subpathways as the basic building block for the assembly of larger and more complex pathways, including species-specific pathway variants. All of the pathway data in UniPathway has been extensively cross-linked to existing pathway resources such as KEGG and MetaCyc, as well as sequence resources such as the UniProt KnowledgeBase (UniProtKB). UniPathway has been used to provide a controlled vocabulary for pathway annotation within UniProtKB records since UniProt release 14.7 (January 2009). In release 2011_08 of UniProt, UniPathway provides annotation for 118,390 distinct Swiss-Prot protein records and 783,299 TrEMBL protein records. On the UniProtKB web site, each of these records is linked to the appropriate pathway description in the UniPathway web site. In 2011, the complete description of the UniPathway database has been published in Nucleic Acids Research (Jan. 2012 Database Issue) and has been chosen by the editors of Nucleic Acids Research to appear on the Featured Articles page (top 5% of NAR papers: http://www.oxfordjournals.org/our_journals/nar/featured_articles.html) [16].

RHEA (http://www.ebi.ac.uk/rhea) is a project developed in collaboration with the Swiss Institute of Bioinformatics (SIB) and the European Institute for Bioinformatics (EBI). It aims at providing a comprehensive resource of expert-curated biochemical reactions. RHEA provides a non-redundant set of chemical transformations for use in a broad spectrum of applications, including metabolic network reconstruction and pathway inference. RHEA includes enzyme-catalysed reactions (covering the IUBMB Enzyme Nomenclature list), transport reactions and spontaneously occurring reactions. RHEA reactions are described using chemical species from the Chemical Entities of Biological Interest ontology (ChEBI) and are stoichiometrically balanced for mass and charge. They are extensively manually curated with links to source literature and other public resources on metabolism including enzyme and pathway databases. This cross-referencing facilitates the mapping and reconciliation of common reactions and compounds between distinct resources, which is a common first step in the reconstruction of genome scale metabolic networks and models. The complete description of the database will appear in the Jan. 2012 NAR Database issue [5].

6.15. Metabolic reconstruction of Klebsiella pneumoniae str. Kp13

Klebsiella pneumoniae str. Kp13 is a multidrug resistant pathogen involved in nosocomial outbreaks in Brazil. The objectives of this study still underway are two-fold: (1) to perform a graph-based metabolic reconstruction of the small-molecules network of strain Kp13 and (2) from the reconstructed network evaluate what makes this pathogen so successful in colonising its human host. Manual annotation of the network was performed
and a choke-point analysis was carried out, which yielded interesting targets such as L-rhamnose biosynthesis enzymes that may be related to the virulence of this bacterium. The MetAnnot platform within MetExplore was used for the manual curation of the network and graph export/import. A paper is in preparation. This work is being done in collaboration with A. T. Vasconcelos and M. Nicolás.

6.16. Clustering of elementary modes and metabolic modules identification

While it is commonly admitted that metabolism is modular, the identification of metabolic modules remains an open topic. In fact, what remains open comes even upstream of any identification problem, and refers instead to the question of defining a good model for modules in metabolic networks. One would hope that such a model might enable, for instance, to automatically derive the metabolic pathways that have been discovered and painstakingly established by biochemists over the years. Elementary modes, that are informally defined as metabolic subnetworks that can function at steady state, meaning that all internal metabolites are produced and consumed in equal rates (that is, nothing accumulates internally), represent one starting point for a definition of modules that has been considered. There are two difficulties related to this however. One is that enumerating elementary modes has itself been proven (by members of the EPI) to be a hard problem, while the second is that even small networks (around 100 reaction nodes) can have millions of elementary modes. Clustering them based on, for instance, the amount of overlap, that is of shared reactions, is one idea that has been used. We attempted another definition of modules using elementary modes that is related to a form of node-covering. This has been submitted to publication. The corresponding software is available on request. This work was done in collaboration with C. E. Ferreira, E. Moreno, and P. Crescenzi.

6.17. Enumeration of metabolic stories

In many cases, we are interested in understanding how metabolism reacts when an organism is submitted to some environmental stress, that is, to establish which metabolic processes are involved in an organism’s adaptation to such stress. In order to do it, elements of the metabolism such as metabolites are monitored to determine which are over- or under-produced during the stress response as compared to the organism’s state in normal conditions. Such quantitative and qualitative measurements are called metabolomics. The affected part may represent only a small portion of the network, that is, involve a small subset of metabolites. The aim then is to identify subnetworks that enable to link together all elements in this subset. More formally, given such subset and a metabolic network represented as a digraph where nodes are metabolites and edges link two metabolites when one is the input of a reaction that produces the other, we are interested in identifying all maximal directed acyclic graphs that cover all the metabolites in the subset of interest, and have no sources or targets that are not one of these metabolites. Such maximal DAGs are called metabolic stories. We established already that finding one metabolic story is easy (paper submitted) and used the algorithm developed, GOBBOLINO (see the Softwares Section), for practical purposes (second publication in preparation). This work was done in collaboration with P. Crescenzi, A. Marchetti-Spaccamela, L. Stougie, A. Marino, F. Jourdan, and L. Cottret.

6.18. Identification of all the minimal precursor sets for a given set of targets

Once the metabolic network of an organism has been defined, the question of how are produced the essential metabolites for the organism arises. In particular, it is important to know which are the metabolites that the organism needs to obtain from its environment to produce those essential metabolites. In the case of symbiosis, this environment could be the host, and determining such metabolites one way of exploring the dialog that is established between different organisms that entertain a close and often long term relation. We call such metabolites that must be obtained from the environment precursors. We had already in 2008 established the complexity of the problem of, given a network and a set of targets of interest, enumerating all minimal sets of precursors enabling to produce the targets, and given one first algorithm. The algorithm has since been much improved (journal paper submitted). The algorithm has been developed into a software called Pitufo (see the Softwares Section). This work was done in collaboration with A. Marchetti-Spaccamela, L. Stougie, and L. Cottret.
6.19. Metabolic network comparison

All living organisms have very similar metabolic needs as they all uptake nutrients from their environment, degrade them into basic building blocks such as amino acids and nucleotides, which in turn are essential input for protein and DNA synthesis. A natural expectation is therefore that they share an even reduced core of metabolic functions necessary to carry out this basic small molecule metabolism. Comparing the small molecule metabolism of 58 bacteria carefully selected and representing a range of lifestyles, we found not a single enzymatic reaction common to all of them. This absence of a metabolic core is essentially due to intracellular symbionts. These results were in preparation in 2010 and are now submitted. The work was done in a collaboration with Ludovic Cottret (INSA Toulouse) and Ana Tereza Vasconcelos.

6.20. Wolbachia detection

Wolbachia is a large monophyletic genus of intracellular bacteria, traditionally detected using PCR assays. Its considerable phylogenetic diversity and impact on arthropods and nematodes make it urgent to assess the efficiency of these screening protocols. The sensitivity and range of commonly used PCR primers and of a new set of 16S primers were evaluated on a wide range of hosts and Wolbachia strains [20]. We showed that certain primer sets are significantly more efficient than others but that no single protocol can ensure the specific detection of all known Wolbachia infections. This work was done in collaboration among others with S. Charlat.

6.21. Genetic architecture of parasite infection

The problem here is to understand the genetic architecture of a parasitic invasion by investigating the different phenotypes such invasion produces in the host. One such phenotype is called "cytoplasmic incompatibility". Briefly, when a parasite invades a male host, it induces developmental arrest, ultimately, death of the host’s offspring unless the fertilised embryo carries the same symbiont inherited from its mother, that is, unless the female is also infected. This has been tentatively explained by a toxin/antitoxin model that involves a toxin deposited by the parasites in the male’s sperm that induces the death of the zygote unless neutralised by an antidote produced by the parasites present in the egg. One toxin/antitoxin pair is linked to one gene. Given a set of observed cytoplasmic incompatibilities, the question is how many genes are required to explain it. Formally, and skipping many intermediate modelling steps, this translates into, given a 0/1 matrix M for pairs of male/female (a 0 indicating that either the male is not infected or, if it is, then so is the female meaning that there is no incompatibility, and a 1 indicating that the male is infected while the female is not), what is the minimum number of "rectangles" that enable to cover all the 1s in M? A “rectangle” in this case is a subset of columns and rows such that, if permuted, they can be arranged in the form of a rectangle with only 1s (publication Nor et al., 2010 by the BAMBOO Team and collaborators). One rectangle corresponds to a gene. The model can then be made more complex by considering that genes may have different alleles (different forms), and are expressed in variable quantities. The quantitative version of the problem in particular translates into having to find a minimum number of "triangles" that cover all 1s. All the above problems translate also into different versions of edge covers of a bipartite graph that are for the most part algorithmically original, and always not fully resolved (meaning, there remains open questions, notably regarding complexity). Work on these problems within the Associate Team SIMBIOSI and the results already obtained should lead to a publication in 2012. This work was done in collaboration among others with S. Charlat.

6.22. Population structure and dynamics

We recently started a collaboration with the Pasteur Institute in Cambodia (Dr. P. Buchy) and the CIRAD at Montpellier (Dr. R. Frutos) on viral population structure and dynamics. In this context, we developed an exploratory statistical approach to characterise mutational patterns in viral populations. The basic idea is to use Multiple Correspondence Analysis (MCoA) on a multiple alignment of nucleic sequences. To this purpose, the alignment is encoded as a boolean table where rows correspond to the sequences and columns to the presence/absence of characters. This can be done simply by considering each of the four possible bases as a
different character, or by considering only two possible states: one for the major base and one for all other (minor) bases. This technique turned out to be very effective in representing co-mutation patterns within a population of sequences. As for simple CoA, the plot is quite easy to interpret by biologists, both in terms of proximities of sequences and characters (i.e. mutations). Moreover, it has some strong relationships with parsimony phylogeny that need to be clarified. In [10], we applied this technique to study the structure and time evolution of the Dengue virus (serotype I) population in Cambodia, using heterochronous sequence samples. Beside its methodological aspect, this work also introduced new topics related to population genetics in BAMBOO (e.g. the use of coalescent theory to reconstruct population dynamics). Another approach, widely used in ecology, to measure biodiversity and to determine the species composition of environmental samples is the "DNA-barcoding" technique. In collaboration with the Laboratoire d’Ecologie Alpine (Univ. Joseph Fourier Grenoble), we developed a new software for identifying new barcode markers and their associated PCR primers [19].
5. New Results

5.1. Proliferation dynamics and its control

5.1.1. Cell division dynamics in structured cell populations

Participants: José Luis Avila Alonso [DISCO project-team, INRIA Saclay IdF], Annabelle Ballesta, Houa Benjelloun [INSA Rouen], Frédérique Billy, Frédéric Bonnans [Commands project-team, INRIA Saclay IdF], Catherine Bonnet [DISCO project-team, INRIA Saclay IdF], Jean Clairambault, Luna Dimitrio, Marie Doumic-Jaffret, Xavier Dupuis [Commands project-team], Olivier Fercoq [MaxPlus project-team, INRIA Saclay IdF], Stéphane Gaubert [MaxPlus project-team, INRIA Saclay IdF], Germain Gillet [IBCP, Université Cl. Bernard Lyon 1], Philippe Gonzalo [IBCP, Université Cl. Bernard Lyon 1], Pierre Hirsch [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Thomas Lepoutre [now in DRACULA project-team, INRIA Rhône-Alpes, Lyon], Jonathan Lopez [IBCP, Université Cl. Bernard Lyon 1], Pierre Magal [University Bordeaux II], Anna Marciniak-Czochra [Institute of Applied Mathematics, Universität Heidelberg], Jean-Pierre Marie [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Faten Merhi [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Roberto Natalini [IAC-CNR, Università Sapienza, Rome], Silviu Niculescu [DISCO project-team, INRIA Saclay IdF], Hitay Özbay [Bilkent University, Ankara, Turkey], Benoît Perthame, Ruoping Tang [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Vitaly Volpert [CNRS Lyon, UMR5208, Camille Jordan Institute, Lyon], Jorge Zubelli [IMPA, Rio de Janeiro].

1. Transition kernels in a McKendrick model of the cell division cycle. A focus has been set on transitions between phases of the cell division cycle. The underlying biological question is: “Is desynchronisation between cells in proliferating cell populations a hallmark of cancer?”. It has been considered by relating in a natural way transition kernels with the probability density functions of transition times in the cell population. It has been shown -which was expected, but never proved to our knowledge so far- that the more desynchronised cells are with respect to cell cycle phase transitions, the higher is the growth exponent of the cell population [48], otherwise said: desynchronised cell populations grow faster. This has been proven when transition kernels are time-independent, i.e., when no external controlled is exerted on transitions. The same question is currently experimentally investigated by our biologist partners in the European network ERASysBio+ C5Sys, coordinated by F. Lévi (Villejuif) and D. Rand (Warwick). Simulations using experimentally identified transition kernels in proliferating cell cultures controlled by theoretical time-dependent (circadian) control functions have verified the relevance of this mathematical result for theoretical cancer treatment optimisation (cf. infra “Periodic (circadian) control of cell proliferation in a theoretical model of the McKendrick type”).

2. Modelling haematopoiesis with applications to AML. The stability of a delay system based on a PDE model designed by M. Adimy and F. Crauste, structured by a discrete differentiation variable and multiple delays, with applications to Acute Myeloblastic Leukaemia (AML, clinical advisers: J.-P. Marie and P. Hirsch; technical adviser: RP Tang) is studied with possible therapeutic implications [36]. This model is currently experimentally investigated, with the aim to identify its parameters in leukaemic cells, in the DIGITEO project ALMA (cf. infra “DIGITEO and Cancéropôle IdF” in “Regional initiatives”), coordinated by C. Bonnet (DISCO team, INRIA Saclay IdF) and in the recently launched DIGITEO project ALMA2 (coordinated by J. Clairambault), that takes over the combined experimental-modelling activity in ALMA. Two INRIA postdocs, F. Merhi (in ALMA, 2010-2011) and A. Ballesta (in ALMA2, 2011-2013) have been devoted to this task. From a theoretical point of view, the Adimy-Crauste model has been modified so as a) to include quick
self-renewal of cells in each stage of maturation and b) to represent each phase of the proliferating compartment (i.e., $G_1$, $S$, $G_2$ and $M$) separately. For the time being, only the $M$ phase is supposed to have a fixed time duration as it is generally admitted that the short time (typically half an hour if the total proliferating phase duration is normalised to 24 hours) necessary to perform mitosis is hardly submitted to any variation.

In a complementary manner, a new model for cell differentiation was introduced and analysed in [17], in collaboration with A. Marciniak and J.P. Zubelli. It assumed that differentiation of progenitor cells is a continuous process. From the mathematical point of view, it is based on partial differential equations of transport type. Specifically, it consists of a structured population equation with a nonlinear feedback loop. This models the signaling process due to cytokines, which regulate the differentiation and proliferation process. We compared the continuous model to its discrete counterpart, a multicompartamental model of a discrete collection of cell subpopulations recently proposed by Marciniak-Czochra et al. [Stem Cells Dev., 18 (2009), pp. 377–386] to investigate the dynamics of the hematopoietic system. We obtained uniform bounds for the solutions, characterized steady state solutions, and analyzed their linearized stability. We showed how persistence or extinction might occur according to values of parameters that characterize the stem cells’ self-renewal. We also performed numerical simulations and discuss the qualitative behavior of the continuous model vis-à-vis the discrete one.

3. **Hybrid models**

Systems combining PDEs and discrete representations in hybrid models, with applications to cancer growth and therapy, in particular for AML, are the object of study of the ANR program *Bimod*, coordinated by V. Volpert (Lyon), associating CNRS (V. Volpert, Lyon), Bordeaux II University (P. Magal) and the Bang project-team.

4. **Molecular model of apoptosis.**

With G. Gilllet (prof. at IBCP/Lyon), we have designed a mathematical ODE model for the mitochondrial pathway of apoptosis, focused on the early phase of apoptosis (before the cytochrome C release). We have validated it with experimental data carried out in G. Gilllet’s lab and applied it to propose new therapeutic strategies against cancer. This work has led to a nearly submitted article [47].

5. **Molecular model of the activity of the p53 protein.** Following her first year of PhD in Rome with R. Natalini, working on cytoplasmic transport along microtubules presented in [38], L. Dimitrio has begun her third PhD year, going on studying at INRIA nucleocytoplasmic transport with applications to p53 activity. Her PhD thesis work is supervised in co-tutela between Sapienza University in Rome (R. Natalini) and INRIA (J. Clairambault). The protein p53 plays a capital part as “guardian of the genome”, arresting the cell cycle and launching cell apoptosis or DNA repair in case of DNA damage. Results expected from this newly developed theme will provide a rational link between molecular pharmacokinetics-pharmacodynamics (cf. infra) of anticancer drugs and modelling of the cell division cycle in proliferating cell populations. L. Dimitrio has presented her ongoing work in different meetings in France and in Italy, and a paper in preparation will be submitted in 2012.

### 5.1.2. Physiological and pharmacological control of cell proliferation

**Participants:** Annabelle Ballesta, Frédérique Billy, Jean Clairambault, Sandrine Dulong [INSERM Villejuif (U 776)], Olivier Fercq [MaxPlus project-team], Stéphane Gaubert [MaxPlus project-team], Thomas Lepoutre [Dracula project-team], Francis Lévi [INSERM Villejuif (U 776)].

1. **Periodic (circadian) control of cell proliferation in a theoretical model of the McKendrick type.** The impact of a periodic control exerted on cell cycle phase transitions has continued to be studied [16] with the collaboration of S. Gaubert (MaxPlus INRIA project-team, Saclay IdF) and T. Lepoutre (Dracula INRIA project-team, Lyon) and is currently investigated experimentally in the new C5Sys European network (cf. supra “Transition kernels in a McKendrick model of the cell division cycle”
215  
Observation, Modeling, and Control for Life Sciences - New Results - Project-Team BANG

and “”). Thanks to the work of Frédérique Billy (Postdoc in Bang) and Olivier Fercoq (PhD student in MaxPlus), together with permanent members of Bang, Dracula and MaxPlus teams, it has led to three publications [37], [39], [48].

2. Intracellular pharmacokinetic-pharmacodynamic (PK-PD) models for anticancer drugs. This theme is actively worked on in collaboration, mainly with the teams of F. Lévi and J.-P. Marie (cf. supra “Transition kernels in a McKendrick model of the cell division cycle” and “Modelling haematopoiesis with applications to AML”). After a PK-PD model for 5-FU with folinic acid [86], it has led for the anticancer drug Irinotecan, the main object of A. Ballesta’s PhD thesis [1], to an article published in PLoS Computational Biology [8], reporting a combined modelling and experimental approach to the effects of a combination of mathematical modelling and experimentation in cell cultures, and to another one [7], focusing on drug delivery optimisation.

3. Whole body physiologically based model of anticancer drug pharmacokinetics. This theme has also been studied in A. Ballesta’s PhD thesis. The use of identification, in genetically different laboratory mouse strains, of parameters characterising an ODE model of the action of Irinotecan (cf. supra “Intracellular pharmacokinetic-pharmacodynamic (PK-PD) models for anticancer drugs”) in cell cultures, transposed at the whole-body level, has been designed as a proof of concept for individual adaptation of drug delivery in the context of (future) personalised medicine, a perspective sketched in [15] and among other collaborative contexts linking mathematics and medicine in [14], [3].

5.1.3. Optimisation of cancer chemotherapy

Participants: Annabelle Ballesta, Frédérique Billy, Frédéric Bonnans [Commands project-team], Jean Clairambault, Sandrine Duloung [INSERM Villejuif (U 776)], Xavier Dupuis [Commands project-team], Olivier Fercoq [MaxPlus project-team], Stéphane Gaubert [MaxPlus project-team], Thomas Lepoutre [Dracula project-team], Alexander Lorz, Francis Lévi [INSERM U 776, Villejuif], Michael Hochberg [ISEM, CNRS, Montpellier], Benoît Perthame.

Optimising cancer chemotherapy, especially chronotherapy, is the final aim of the activities mentioned above. This has been lately discussed in [16] and also in works involving the C5Sys network [37], [48], and in the more general review [39]. Until now had been taken into account as constraints in optimisation strategies only the unwanted toxic side effects of anticancer drugs on healthy cells. More recently, another issue of anticancer treatment has been considered, namely the different mechanisms of resistance to drugs in cancer cells. This has led to include the effect of ABC transporters (active efflux pumps, as is the P-glycoprotein) in the intracellular PK-PD models mentioned above [86], in A. Ballesta’s PhD joint work with F. Lévi’s team [1], [8], [7], and to a perspective paper [15].

In project is also the use of methods of optimal control developed by the Commands project-team (F. Bonnans, X. Dupuis) to optimise therapies in the treatment of Acute Myeloblastic Leukaemia (AML, cf. supra “Modelling haematopoiesis with applications to AML”).

Another way to represent and overcome drug resistance in cancer from a cell Darwinian point of view using concepts of adaptive dynamics in proliferating cell populations is also currently being investigated along the line of other recent works [28] and is currently developed within the multidisciplinary GDR DarEvCan coordinated by M. Hochberg, Montpellier (cf. infra “GDR DarEvCan” in “National initiatives”) and in a proposed ANR project also coordinated by M. Hochberg.

An open question that should have therapeutic implications consists of the interrogation: Is the emergence of drug resistance in cell populations a genetic (resulting from mutations at mitosis) or an epigenetic phenomenon (resulting from amplification of physiological mechanisms, such as ABC transport, which has nothing to do with genetic mutations)? And is it a reversible or irreversible phenomenon? These questions will be studied both theoretically and experimentally within the DarEvCan consortium and could result in new developments in the so-called Darwinian medicine.
5.1.4. Protein polymerisation and application to amyloid diseases (ANR grant TOPPAZ)

**Participants:** Annabelle Ballesta, Vincent Calvez [ENS Lyon], Frédérique Charles, Marie Doumic-Jaufret, Pierre Gabriel, Hadjer Wafaâ Haffaf, Benoît Perthame, Stéphanie Prigent [BPCP, INRA Jouy-en-Josas], Human Rezaei [BPCP, INRA Jouy-en-Josas], Léon Matar Tine [SIMPAF project-team, INRIA Lille Nord-Europe].

With H. Rezaei, a new and very complete PDE model for protein polymerisation has been designed. Following F. Charles’ work, A. Ballesta has applied this model to Huntington’s disease (PolyQ expansion) and compared it with its ODE counterpart, leading to a better understanding of the leading mechanisms responsible for PolyQ fibrillization. This part is nearly submitted.

The eigenvalue problem playing a major role in the representation of Prion proliferation dynamics and, in a more general way, of many fragmentation-coalescence phenomena, the article [11] investigated the dependency of the principal eigenvector and eigenvalue upon its parameters. We exhibited possible non-monotonic dependency on the parameters, conversely to what would have been conjectured on the basis of some simple cases.

5.1.5. Inverse problem in growth-fragmentation equations

**Participants:** Marie Doumic-Jaufret, Marc Hoffmann [ENSAE], Patricia Reynaud [CNRS, Nice Univ.], Vincent Rivoirard [Paris IX Univ.], Léon Matar Tine [SIMPAF project-team, INRIA Lille Nord-Europe].

In collaboration with statisticians (M. Hoffman, Professor at Université de Marne-la-Vallée, V. Rivoirard, MC at Université d’Orsay, and P. Reynaud, CR CNRS at Université de Nice), in [18] we have explored a statistical viewpoint on the cell division problem. In contrast to a deterministic inverse problem approach, we take the perspective of statistical inference. By estimating statistically each term of the eigenvalue problem and by suitably inverting a certain linear operator, we are able to construct an estimator of the division rate that achieves the same optimal error bound as in related deterministic inverse problems. Our procedure relies on kernel methods with automatic bandwidth selection. It is inspired by model selection and recent results of Goldenschluger and Lepski. This work is accepted in SIAM J. Num. Anal..

With L. Matar Tine, in [53] we have generalized the inverse techniques proposed in [88], [67] and [66], in order to adapt them to general fragmentation kernels and growth speeds. The potential applications of this problem are numerous, ranging from polymerisation processes to the cell division cycle. This work is submitted.

5.2. Tissue growth, regeneration and cell movements

5.2.1. Chemotaxis, self-organisation of cell communities

**Participants:** Nikolaos Bournaveas [Univ. Edinburgh], Axel Buguin [UPMC, Institut Curie], Vincent Calvez [ENS Lyon], François James [univ. Orléans], Alexander Lorz, Grégoire Nadin [UPMC], Benoît Perthame, Jonathan Saragosti [Institut Curie], Pascal Silberzan [Institut Curie], Min Tang [SJTU], Nicolas Vauchelet.

We have continued our observation and simulation of models for large bacterial communities and more generally cells self-organisation as initiated several years ago [12], [31]. This is a rich domain because on the one hand several Partial Differential Equations arise, parabolic models, kinetic equations, hyperbolic systems and on the other hand complex patterns occur that are a sign of the complex underlying dynamics.

In their article [65], Y. Dolak and C. Schmeiser have proposed a mathematical model describing the individual behavior of bacteria responding to a chemical substance. Numerical simulations of this kinetic model have been investigated in [93]. In a macroscopic level of description, we perform a hydrodynamical limit which leads to an aggregation model, for which regular solutions blows up in final time [82]. The rigorous study of the behavior of the aggregates relies on a careful analysis of some non-linear scalar conservation laws in the framework of measures [24] and has been investigated in [55].
With the group of P. Silberzan in Curie Institute, in 2010 we have given an explanation of traveling bands first observed by Adler in the 80’s for *E. coli* in microchannels. In a continuation of this work, based on analysis of individual trajectories, we have shown directional persistence which improves the efficiency of collective migration. Kinetic models with tumbling kernels that keep memory of the incoming velocity are able to reproduce accurately the wave parameters [35].

Computing effectively traveling wave can be difficult in unstable cases. An algorithm is proposed in [29] for the NonLocalFisher equation which catches the traveling wave and not the more stable pulsating wave.

A. Lorz has studied a system consisting of the elliptic-parabolic Keller–Segel equations coupled to Stokes equations by transport and gravitational forcing. We show global-in-time existence of solutions for small initial mass in 2D. In 3D we establish global existence assuming that the initial $L^{3/2}$-norm is small. Moreover, we give numerical evidence that for this extension of the Keller–Segel system in 2D, solutions exist with mass above $8\pi$, which is the critical mass for the system without fluid. The model is written as

$$
\begin{align*}
\frac{\partial c}{\partial t} + u \cdot \nabla c &= \Delta c + n - a_1 c, \\
\frac{\partial n}{\partial t} + u \cdot \nabla n &= \Delta n - \nabla \cdot (\chi n \nabla c), \\
a_2 \frac{\partial u}{\partial t} + \nabla P - \eta \Delta u + n \nabla \phi &= 0, \\
\nabla \cdot u &= 0.
\end{align*}
$$

(2)

Here $c$ denotes the concentration of a chemical, $n$ a cell density and $u$ a fluid velocity field described by Stokes equations. The fluid couples to $n$ and $c$ through transport and gravitational forcing modelled by $\nabla \phi$. The pressure $P$ can be seen as the Lagrange multiplier enforcing the incompressibility constraint. The chemical $c$ diffuses, it is produced by the cells and it degrades. The cell density diffuses and it moves in the direction
of the chemical gradient. The constant $a_1 \geq 0$ measures self-degradation of the chemical and the constants $a_2 \geq 0$, $\eta > 0$ determine the evolution undergone by $u$.

### 5.2.2. Single cell-based models of tumour growth, tissue regeneration, embryonic development

**Participants:** Annabelle Ballesta, Gregory Batt [CONTRINTES project-team], François Bertaux, Chadha Chettaoui, Ibrahim Cheddadi, Dirk Drasdo, Adrian Friebel, Rolf Gebhardt [Univ. of Leipzig, Germany], Adriano Henney [Director Virtual Liver Network and VLN consortium], Jan G. Hengstler [Leibniz Research Center, Dortmund, Germany and CANCERSYS consortium], Stefan Höhme, Elmar Heinzle [University of Saarbrücken and NOTOX consortium], Isabelle Hue [INRA], Nick Jagiella, Ursula Klingmüller [German Cancer Center, Heidelberg and LungSys Consortium], Axel Krinner, Emanuele Leoncini, Johannes Neitsch, Benoît Perthame, Ignacio Ramis-Conde, Luc Soler [ IRCAD, Coordinator EU-project PASSPORT and PASSPORT consortium], Irène Vignon-Clémentel [REO project-team], Juhui Wang [INRA], William Weens.

Structure formation in tissues as well as malfunctions on the multi-cellular level are inherently of multi-scale nature. Modifications on the molecular level by intrinsic or extrinsic factors affect the architecture and function on the multi-cellular tissue level. Much of the current research so far focuses on the analysis of intracellular pathways, genetic and metabolic regulation on the intracellular scale and on continuum equations for local densities of cells to capture multi-cellular objects on large spatial scales but only recently have increasing efforts been made at the interface between these two: individual cell based models (IBMs) which permit to include the molecular information on the one hand and to extrapolate to the multi-cellular tissue level on the other hand and hybrid models that combine continuum with individual-based models for different components.

![Figure 2. Left: Modeling ammonia detoxification during regeneration after drug-induced damage in a multi-lobule model. Here, a compartment model of ammonia detoxification has been coupled to the regeneration of liver mass. The colour indicates the gradient of ammonia after regeneration. The upper graphics indicate that our model directly calculates the blood concentrations of ammonia, urea and glutamine during the liver regeneration process. Right: In the meantime it is possible to simulate whole mice lobes up to 10 cells thick.](image)

In order to fill the existing gap we have studied intracellular regulation networks [87], [72], multi-scale IBMs where intracellular regulation and differentiation was explicitly represented within each individual cell [90], [85], [91], lattice-free IBMs [69] and continuum models that can capture their large scale behaviour [63], and cellular automaton (CA) models where each lattice site can be occupied either by at most one cell [61] or by many cells [89], [71] and their corresponding continuum equation [68]. Moreover, for a simple, but for rigorous coarse graining not accessible, growth situation we were able to obtain quantitatively matching results with continuum and individual-cell-based models without any fit parameter.
Besides the methodical aspects we focus on a number of applications:

- Unstructured cell populations growing in a monolayer with free border [69], [74], or constraint by the presence of a granular or cellular embedding medium [19].
- Multicellular spheroids in liquid suspension [69], [70], and embedding granular or cellular matter [19]. For non-small-lung-cancer cell lines growing as multi-cellular spheroids, we could, starting with a complete parameterisation of the model by labelling experiments, simultaneously explain the proliferation, apoptosis, extracellular matrix and growth pattern of multi-cellular spheroids under different nutrient conditions within one consistent mathematical model.
- Vascular tumour growth.
- Regulatory and evolutionary aspects in tumour growth [81], [78], recently with resolution of intracellular signal transduction pathway variants found in normal vs. malignant cells [33].
- Cell differentiation and lineage commitment of mesenchymal stem cells [85], [73]. In our earlier work we have established a model of cell aging for in-vitro cultured stem cell populations. Stem cell concepts developed earlier [85], [73] have been extended to include cell aging [83]. By this extension it is possible to explain the clonal heterogeneity that was not captured by the previous model. The cell age was coupled with the generation number. It is published in ref. [84] and [56].
- Complex tissue architectures in regenerative tissues, particularly in the liver.

Examples are:

- Regeneration of liver lobules after toxic damage [80], [79], [76]), [40], [41], [42] within the German BMBF-funded network “Systems Biology of the Hepatocyte”). As extension of this project we linked the regeneration of liver architecture after toxic damage to a model of ammonia detoxification by the individual hepatocyte and the liver as a proof of concept to study the link between architecture and function. The comparison of experimental findings by our collaboration partners with our model results suggests that the detoxification during regeneration after drug-induced damage is mainly determined by the total population size of healthy hepatocytes (Fig. 2). Adjustments of enzymatic activities of the individual hepatocytes seem to have only minor effects.
- Liver regeneration after partial heptectomy ([44]). Based on the work on regeneration of a liver after toxic damage where we focused on a single liver lobule, we within the EU project
CANCERSYS set up a model on liver regeneration after partial hepatectomy enabling us to model up to the whole liver lobe scale of a mouse, 4 cells thick. This models permits to bridge the gap between the single-cell-model scale and the whole-liver organ scale. Calibrating this model with mouse data we were able to predict the proliferation pattern in pig as a proof of principle that modelling can be used to bridge the gap between different animals. Experiments performed so far confirm the prediction. This is a fundamental issue as it is a longstanding unsolved question in how far experiments in animal models can be used to predict therapeutic responses in the Human. We also expanded the software towards whole liver lobe bright field image analysis. Being able to use a mathematical model calibrated with data from a model animal, for example, mouse to predict tissue organisation processes in another animal, for example, human opens new possibilities to assess drug toxicity [43].

- The fundamental objective is to move towards modelling from the molecular up to the whole organ scale. A conceptual framework for this was presented in ref. [23].

- Cancer development in an environment of granular particles and cells. For the first part we studied how an embedding medium such as granular particles or cells modify the spatial and temporal growth pattern of expanding cell populations [19]. The model could explain the growth kinetics found by Helmlinger et. al. (1997) for growing tumor spheroids embedded in agarose gel. If the friction between the embedding objects and the environment is larger than the friction between the growing clone and its environment we found a fingering instability reminiscent of a Saffman-Taylor instability observed in a Hele-Shaw cell. We systematically studied which model parameters promote the instability. The motivation for this project was to analyse in how far invading tumour fronts can be explained by physical mechanisms alone as in some tumour phenotypes invasive fronts can be observed.

In order to extend this project towards carcinoma development mechanisms of liver cancer development in mice were studied [42]. Within systematic sensitivity analyses we were able to identify parameters explaining the experimentally found tumor phenotypes (Fig. 3). The critical parameters were stiffness of sinusoids, the micro-blood vessels within the liver lobules, tumor cell - sinusoidal adhesion, tumor cell polarity, and the ability of tumour cells to digest neighbouring vessels. As part of the project, in close collaboration with experimental partners, critical differences between liver in normal and transgenic mice have been studied by image analysis [62].

- Synthetic biology. By multi-scale simulations including intracellular pathways in our single-cell-based simulation framework we were able to mimic conditions under which tissue homeostasis and tissue location could be achieved in monolayer culture.

The applications are guided by quantitative comparisons to experimental data either from published knowledge or - in most cases - generated by experimental partners. One main focus is on the understanding of mechanisms that control the growth dynamics and growth phenotypes of multi-cellular systems and use these later to predict and optimise therapy or biotechnological growth processes.

The adjustment of the models developed to applications requires data analysis both, of molecular data such as gene expression profiles and of image data such as spatial-temporal growth pattern. For this purpose we recently considered the geometric and topological measures to quantify tumour shapes [92], and developed an image processing chain to quantitatively analyse liver regeneration processes in liver lobules [79, 76, 44, 40, 41]. As a further step we published executables and descriptions of important elements of our code to spread our model as it turns out that agent-based cell modelling enjoys increasing interest in different communities (engineering, mathematical biology, systems biology, physics) [81]. Current directions moreover include a stronger focus on models of in-vivo systems (within the German medical systems biology consortium “LungSys” (lung cancer treatment); and within the EU-network “CancerSys” (cancerogenesis in liver)). Within LungSys we recently developed a realistic 2D and 3D spatial temporal model of blood flow in xenografts to compare to DCE MRI images visualising the tumour perfusion. Modelling cancer development requires to take into account invasion, mutations and angiogenesis, three hallmarks of cancer and of linking the molecular to the multicellular scale [71]. Moreover, we extend the topic of liver regeneration to regeneration
Observation, Modeling, and Control for Life Sciences - New Results - Project-Team BANG

after partial hepatectomy (within the EU-project “Passport”), and extend our modelling activities to understand early embryonic development (Trophoblast development, collaboration with INRA).

Almost each of our projects is in close collaboration with experimental partners within grant projects performing experiments to permit parameterisation and validation of our models.

5.3. Modeling in computational neurosciences

Participants: Maria Caceres [Univ. Granada], Jose Carrillo [ICREA Barcelona], Benoît Perthame, Jonathan Touboul.

Networks of interacting neurons can be well described by nonlinear PDEs like the Noisy Integrate and Fire model. These are Fokker-Planck-Kolmogorov equations on the probability density of neurons, the main parameters in the model being the connectivity of the network and the noise. In [10], we analyse several aspects of the NNLIF model: the number of steady states, a priori estimates, blow-up issues and convergence toward equilibrium in the linear case. In particular, for excitatory networks, blow-up always occurs for initial data concentrated close to the firing potential. These results show how critical is the balance between noise and excitatory/inhibitory interactions to the connectivity parameter.

At a larger scale, neurons form large-scale spatially extended populations receiving similar input and interconnected in a specific way. Each neuron receives noisy inputs, and as such their membrane potential is adequately described as the solution of stochastic network equations. In [58], we study the asymptotic regimes of such spatially extended networks with delays and obtain a complex mean-field equation the dynamics of which is analyse in [57]. We observe that noise induces transitions from stationary spatially homogeneous solutions to oscillatory solutions, and the transition is characterized by chaotic Turing patterns of activity.

5.4. Free surface geophysical flows

Participants: Emmanuel Audusse [LAGA - Université Paris 13, Institut Galilée], Sakina Ayata, Anne-Céline Boulanger, Marie-Odile Bristeau, Benoît Perthame, Jacques Sainte-Marie [CETMEF and MACS project-team].

We are involved in research concerning the numerical simulation of free surface geophysical flows such as rivers, lakes, coastal areas and also overland flows. Many applications related to environmental problems are concerned: floodings, dam breaks, swell, transport and diffusion of pollutants, water quality, upwellings, sustainability of aquatic ecosystems, ...

The basic model for these problems is the 3D free surface Navier-Stokes system leading to a 3D solver [64] with a moving mesh. However for efficiency reasons, vertically averaged models such as the Saint-Venant system [75] are often used.

The Saint-Venant equations are deduced of the Navier-Stokes system with two main assumptions:

- the pressure is hydrostatic,
- the horizontal velocity is represented by its average.

We have developed extensions of the Saint-Venant system where the basic Saint-Venant solver [60] is still used and, in that way, the robustness, the efficiency and the easiness to treat the free surface are preserved while the domain of validity is larger.

In these extensions, we relax the two above assumptions. Actually, we have derived a non-hydrostatic shallow water model and a multilayer Saint-Venant system.

We have coupled the hydrodynamics of free surface flows with other phenomena such as biology (phytoplankton culture) or erosion.
Figure 4. Map of Japan with the seism epicentre and the DART buoys 21418 and 21413.

Figure 5. Free surface elevation of the sea, comparison between the recorded data by the buoys 21418 and 21413 and the simulation obtained with our 3d Navier-Stokes code.
5.4.1. Hydrodynamics and biology coupling

Cultivating oleaginous microalgae in specific culturing devices is seen as a potential source of biofuel for the future. The complexity of this process coupling non linear biological activity to hydrodynamics makes the optimization problem very delicate. The large amount of parameters to be taken into account paves the way for a useful mathematical modeling. Due to the high heterogeneity of raceways along the depth dimension regarding temperature, light intensity or nutrients availability, we adopt a multilayer approach for hydrodynamics and biology. For hydrodynamics, we use a multilayer Saint-Venant model that allows mass exchanges, forced by a simplified representation of the paddlewheel. Then, starting from an improved Droop model that includes light effect on algae growth, we derive a similar multilayer system for the biological part. A kinetic interpretation of the whole system results in an efficient numerical scheme. We show through numerical simulations in two dimensions that our approach is capable of discriminating between situations of moving water or calm pond and show the influence of light intensity. Moreover, in this paper [49] we exhibit that a posteriori treatment of our velocity fields can provide Lagrangian trajectories which are of great interest to assess the actual light pattern perceived by the algal cells and therefore understand its impact on the cell factory.

![Figure 6. Trajectories of three particles during the simulations. In every figure, the large curve represents the water height at the middle of the pool. The other plot is the height of a given particle through time. The algae undergo sudden changes of depth every time it meets the wheel.](image)

5.4.2. Analytical solutions for the free surface hydrostatic Euler equations

In this paper [50] we propose a large set of analytical solutions for the hydrostatic incompressible Euler system in 2d and 3d. These solutions mainly concern free surface flows but flows with partially free surface or in a deformable pipe are also considered. These analytical solutions that can admit entropic shocks can be especially useful for the validation of numerical schemes.

5.4.3. Phytoplankton growth in marine ecosystem

Four different phytoplankton growth models have been implemented. The simplest model assumes constant chlorophyll/carbon and carbon/nitrogen ratios. The more complex ones take into account photoadaptation through a variable chlorophyll/carbon ratio and they also assume a variable carbon/nitrogen cellular quota.
Observation, Modeling, and Control for Life Sciences - New Results - Project-Team BANG

(non-redfieldian stochiometry). These models have been coupled to a 1D ecosystem model at BATS, a station located in an oligotrophic area of the North-Western Atlantic Ocean. The different models have been calibrated from in situ data recorded at BATS using a micro-genetic algorithm to optimize the parameter values. The models with optimized parameters were then compared with each others. The results highlighted the necessity to take into account photoadaptation and variable cellular quotas to simulate the seasonal dynamics of chlorophyll and primary production in oligotrophic areas. They also demonstrated that the chlorophyll did not have to be represented by a prognostic variable and could be represented by a diagnostic variable instead, see [46].

5.4.4. Erosion processes: modelling and simulation

We are interested in the modelling of sediment transport phenomena. We mostly focus on bedload transport and we do not consider suspension sediment processes. We first propose a coupled numerical scheme for the classical Saint-Venant – Exner model. It is based on a relaxation approach and it works with all sediment flux function. We exhibit that this coupled approach is more stable than the splitting approach that is mostly used in industrial softwares. Then we derive an original three layers model in order to overcome the difficulties that are encountered when using the classical Exner approach and we write a related relaxation model, see [45].
5. New Results

5.1. Astrocyte Regulation of Synaptic Depression and Facilitation

**Participants:** Hugues Berry, Maurizio De Pitta, Vladislav Volman, Eshel Ben-Jacob.

Synaptic plasticity is the capacity of a preexisting connection between two neurons to change in strength as a function of neuronal activity. Because it admittedly underlies learning and memory, the elucidation of its constituting mechanisms is of crucial importance in many aspects of normal and pathological brain function. Short-term presynaptic plasticity refers to changes occurring over short time scales (milliseconds to seconds) that are mediated by frequency-dependent modifications of the amount of neurotransmitter released by presynaptic stimulation. Recent experiments have reported that glial cells, especially hippocampal astrocytes, can modulate short-term plasticity, but the mechanism of such modulation is poorly understood. Here, we explore a plausible form of modulation of short-term plasticity by astrocytes using a biophysically realistic computational model. Our analysis indicates that astrocytes could simultaneously affect synaptic release in two ways. First, they either decrease or increase the overall synaptic release of neurotransmitter. Second, for stimuli that are delivered as pairs within short intervals, they systematically increase or decrease the synaptic response to the second one. Hence, our model suggests that astrocytes could transiently trigger switches between paired-pulse depression and facilitation. This property explains several challenging experimental observations and has a deep impact on our understanding of synaptic information transfer [16].

5.2. A theory of rate coding control by intrinsic plasticity effects

**Participants:** J Naudé, J Paz, Hugues Berry, Bruno Delord.

Intrinsic plasticity (IP) is a ubiquitous activity-dependent process regulating neuronal excitability and a cellular correlate of behavioral learning and neuronal homeostasis. Because IP is induced rapidly and maintained long-term, it likely represents a major determinant of adaptive collective neuronal dynamics. However, assessing the exact impact of IP has remained elusive. Indeed, it is extremely difficult to disentangle the complex non-linear interaction between IP effects, by which conductance changes alter neuronal activity, and IP rules, whereby activity modifies conductance via signaling pathways. Moreover, the two major IP effects on firing rate, threshold and gain modulation, remain unknown in their very mechanisms. Here, using extensive simulations and sensitivity analysis of Hodgkin-Huxley models, we show that threshold and gain modulation are accounted for by maximal conductance plasticity of conductance in two separate domains of the parameter space corresponding to sub- and supra-threshold conductance (i.e. activating below or above the spike onset threshold potential). Analyzing equivalent integrate-and-fire models, we provide formal expressions of sensitivities relating to conductance parameters, unraveling unprecedented mechanisms governing IP effects. Our results generalize to the IP of other conductance parameters and allow inference of calcium-gated conductance, yielding a general picture that accounts for a large repertoire of experimental observations. The expressions we provide can be combined with IP rules in rate or spiking models, offering a general framework to systematically assess the computational consequences of IP of pharmacologically identified conductance with both fine grain description and mathematical tractability. We provide an example of such IP loop model addressing the important issue of the homeostatic regulation of spontaneous discharge. Because we do not formulate any assumptions on modification rules, the present theory is also relevant to other neural processes involving excitability changes, such as neuromodulation, development, aging and neural disorders [20].

5.3. Impact of receptor clustering on ligand binding

**Participants:** Hédi A. Soula, Bertrand Caré.
Cellular response to changes in the concentration of different chemical species in the extracellular medium is induced by ligand binding to dedicated transmembrane receptors. Receptor density, distribution, and clustering may be key spatial features that influence effective and proper physical and biochemical cellular responses to many regulatory signals. Classical equations describing this kind of binding kinetics assume the distributions of interacting species to be homogeneous, neglecting by doing so the impact of clustering. As there is experimental evidence that receptors tend to group in clusters inside membrane domains, we investigated the effects of receptor clustering on cellular receptor ligand binding. We implemented a model of receptor binding using a Monte-Carlo algorithm to simulate ligand diffusion and binding. In some simple cases, analytic solutions for binding equilibrium of ligand on clusters of receptors are provided, and supported by simulation results. Our simulations show that the so-called “apparent” affinity of the ligand for the receptor decreases with clustering although the microscopic affinity remains constant. Changing membrane receptors clustering could be a simple mechanism that allows cells to change and adapt their affinity/sensitivity toward a given stimulus [14].

5.4. Illegitimate and Homologous Rearrangements, an intricate relationship?

**Participants:** David P. Parsons, Guillaume Beslon, Carole Knibbe.

We have introduced homologous horizontal transfer in the aevol model. First results show that this process interacts in a complex way with both non-homologous transfer (that creates homologous sequences) and mutation rate (that destroys homologous sequences). We have shown that homologous transfer is useful only in strict conditions (small mutation rate and small - but non-null - non-homologous rate) [27]. This result confirms the genericity of the indirect selection mechanism we previously shown to be at the origin of scaling laws in genomes and transcriptomes [25].

5.5. An error threshold due to chromosomic rearrangements

**Participants:** Stephan Fischer, Guillaume Beslon, Carole Knibbe, Samuel Bernard.

Error threshold is a well known theory in evolutionary biology. However, the theory of error threshold only takes into account point mutation rate and states that this rate generates a maximum level of coding sequences in a given genome. Using aevol and mathematical formulations, we have shown other types of mutations are also likely to create error thresholds. In particular we have shown the chromosomic rearrangement (duplications and deletions) generate a very strong threshold.

5.6. Enhanced Stimulus Encoding Capabilities with Spectral Selectivity in Inhibitory Circuits by STDP

**Participants:** Guillaume Beslon, Hédi A. Soula, Antoine Coulon.

The ability to encode and transmit a signal is an essential property that must demonstrate many neuronal circuits in sensory areas in addition to any processing they may provide. It is known that an appropriate level of lateral inhibition, as observed in these areas, can significantly improve the encoding ability of a population of neurons. We have shown that a homeostatic mechanism by which a spike-timing-dependent plasticity (STDP) rule with a symmetric timing window (swSTDP) spontaneously drives the inhibitory coupling to a level that ensures accurate encoding in response to input signals within a certain frequency range. Interpreting these results mathematically, we find that this coupling level depends on the overlap of spectral information between stimulus and STDP window function. Generalization to arbitrary swSTDP and arbitrary stimuli reveals that the signals for which this improvement of encoding takes place can be finely selected on spectral criteria. We finally show that this spectral overlap principle holds for a variety of neuron types and network characteristics. The highly tunable frequency-power domain of efficiency of this mechanism, together with its ability to operate in very various neuronal contexts, suggest that it may be at work in most sensory areas [15].
6. New Results

6.1. Modern methods of data analysis

Participants: H. Cardot, P. Cénac, O. Collignon, J-M. Monnez, P. Vallois.

In 2011, our contributions to data analysis in a Biological context are twofold:

- At a theoretical level, we have kept on working on the so-called online data analysis alluded to at the Scientific Foundations Section. Specifically, we have carried on the construction of a fast and recursive algorithm for clustering large data sets with the \( k \)-medians methods.
- At a practical level, our efforts have focused on an interesting study concerning peanuts allergy, for which our expertise in data analysis allows for a good prediction of allergy severity by means of rigorous methods.

Let us now describe more precisely our articles:

(i) A fast and recursive algorithm for clustering large data sets with \( k \)-medians. Clustering with fast algorithms large samples of high dimensional data is an important challenge in computational statistics. Borrowing ideas from MacQueen [56], who introduced a sequential version of the k-means algorithm, a new class of recursive stochastic gradient algorithms designed for the \( k \)-medians loss criterion is proposed in [16], [17]. By their recursive nature, these algorithms are very fast and well adapted to deal with large samples of data that are allowed to arrive sequentially. It is proved that the stochastic gradient algorithm converges almost surely to the set of stationary points of the underlying criterion. A particular attention is paid to the averaged versions, which are known to have better performances, and a data-driven procedure that allows automatic selection of the value of the descent step is proposed. The performance of the averaged sequential estimator is compared on a simulation study, both in terms of computation speed and accuracy of the estimations, with more classical partitioning techniques such as k-means, trimmed k-means and PAM (partitioning around medoids). Finally, this new on-line clustering technique is illustrated on determining television audience profiles with a sample of more than 5000 individual television audience measured every minute over a period of 24 hours.

(ii) Discriminant analyses of peanut allergy severity scores. Peanut allergy is one of the most prevalent food allergies. The possibility of a lethal accidental exposure and the persistence of the disease make it a public health problem. Evaluating the intensity of symptoms is accomplished with a double blind placebo-controlled food challenge (DBPCFC), which scores the severity of reactions and measures the dose of peanut that elicits the first reaction. Since DBPCFC can result in life-threatening responses, we propose in [2] an alternate procedure with the long-term goal of replacing invasive allergy tests. Discriminant analysis of DBPCFC score, the eliciting dose and the first accidental exposure score were performed in 76 allergic patients using 6 immunoassays and 28 skin prick tests. A multiple factorial analysis was performed to assign equal weights to both groups of variables, and predictive models were built by cross-validation with linear discriminant analysis, k-nearest neighbors, classification and regression trees, penalized support vector machine, stepwise logistic regression and Adaboost methods. We developed an algorithm for simultaneously clustering eliciting doses and selecting discriminant variables. Our main conclusion is that antibody measurements offer information on the allergy severity, especially those directed against \( rAra-h1 \) and \( rAra-h3 \). Further independent validation of these results and the use of new predictors will help extend this study to clinical practices.

6.2. Local linear estimator of the conditional distribution function

Participants: S. Ferrigno, M. Maumy, A. Muller.
Consider \((X,Y)\), a random vector defined in \(\mathbb{R} \times \mathbb{R}\). Here \(Y\) is the variable of interest and \(X\) the concomitant variable. As usual in the statistics literature, we work under the assumption that a sample \(\{(X_i,Y_i)_{1 \leq i \leq n}\}\) of independent and identically replica of \((X,Y)\) is available.

In order to explain the relationship between the variable of interest \(Y\) and the factor \(X\), the standard way is to rely on the regression function \(E(Y|X = x)\). Because of numerous applications, the problem of estimating the regression function has been the subject of considerable interest during the last decades. However, it can be easily argued that the function \(x \mapsto E(Y|X = x)\) alone does not capture the complexity of the relations between \(X\) and \(Y\).

In order to go one step further in this direction, we have chosen to work with another function. Namely, we study the conditional distribution function \(F(y|X = x) = P(Y \leq y|X = x)\) and a nonparametric estimator associated to this quantity. The distribution function has the advantage of completely characterizing the law of the random variable at stake, allowing to obtain the regression function, the density function, the moments and the quantile function. It should also be noticed that conditional distribution functions are used for the estimation of references curves in medical applications.

At a more technical level, our study is based on a local linear nonparametric estimator of the conditional distribution function instead of the widely spread Nadaraya-Watson estimator. Indeed, it is a well-known fact that the asymptotic bias of the Nadaraya-Watson estimator behaves somehow badly. Observe however that local polynomial techniques are good alternatives. Based on these techniques, here are the steps we have focused on in 2010-2011:

- Our main result is the uniform law of the logarithm concerning the local linear estimator of the conditional distribution function (see \([21]\)). We investigate convergence in probability and almost sure convergence results.
- The uniform law of the logarithm has then been used to construct uniform asymptotic certainty bands for the conditional distribution function.
- The certainty bands alluded to above have been applied to simulated data.
- A variant of the test has been introduced in \([20]\).

Let us also mention that applications of these theoretical results to survival analysis are currently the object of active research.

### 6.3. Markovian models for tumor growth

Participants: T. Bastogne, R. Keinj, P. Vallois.

Our research in this direction includes two contributions in 2011:

- A multinomial model for cell growth allowing to calibrate radiotherapies given in \([3]\).
- A study of tumor growth based on the lifespan of each cell (see \([13]\)).

More specifically, our two contributions can be summarized as follows:

\((i)\) Hit and target models of tumor growth typically assume that all surviving cells have a constant and homogeneous sensitivity during the radiotherapy period. In \([3]\), we propose a multinomial model based on a discrete-time Markov chain, able to take into account cell repair, cell damage heterogeneity and cell proliferation. The proposed model relies on the ‘Hit paradigm’ and ‘Target’ theory in radiobiology and assumes that a cancer cell contains \(m\) targets which must be all deactivated to produce cell death. The surviving cell population is then split up into \(m\) categories to introduce the variation of cancer cell radio-sensitivity according to their damage states. Two other parameters have been introduced : the probability \(q\) for a target to be deactivated by radiation and the probability \(r\) for an inactive target in an alive cell to be reactivated. The parameter \(q\) is related to the radiation dose \(u_0\) through the intrinsic sensitivity of a target to radiation. Moreover, the multinomial model is a generalization of typical hit models. Based on the multinomial model, new expressions of the TCP (Tumor Control Probability) and NTCP (Normal Tissue Complication Probability)
have been proposed for nonuniform radiations which permits to deduce the optimal total dose to be delivered. We point out the important influence of the repair parameter \( r \) which could lead to reduce both the total radiation dose to be delivered and the risk of side effects.

(iii) We have proposed in [13] an original approach that expresses the probability distribution of the cancer and normal cells lifespans in terms of the number of dose fractions in radiotherapy. Conversely to previous models that examines the number of surviving cells in the treated population at fixed time instants, our modeling approach better reveals the dynamics of the tumor response.

We start by considering the lifespan of a single cancer cell that behaves as described in [3]. We study this random time by calculating its mean, variance and cumulative distribution function. We then assume that a tumor is a group of independent cells. This allows to define the lifespan of the tumor as the maximum of individual lifespans. When the initial number \( n_0 \) of cancer cells is not too large, then we can explicitly calculate the mean, variance and the cumulative distribution function of the tumor lifespan. When \( n_0 \) is large, the previous parameters are no longer calculable. However, we are able to show that, under some assumptions, the mean lifespan of the tumor behaves as a logarithmic function of the initial number \( n_0 \). The second goal is to show that TCP and NTCP can be completely formulated with respect to the tumor and normal tissue lifespans. These expressions of TCP and NTCP are finally used to propose a ROC curve, called ECT (Efficiency-Complication Trade-off), suited to the determination of the appropriate treatment schedule. This synthetic representation summarizes both efficiency and complication of the treatment. Moreover, it allows several possibilities of choice for the radiotherapist: treatment efficiency, priority to safety of normal tissue, or a trade-off between them.

6.4. A stochastic model for bacteriophage therapies

In the last years Bacteriophage therapies are attracting the attention of several scientific studies. They can be a new and powerful tool to treat bacterial infections or to prevent them applying the treatment to animals such as poultry or swine. Very roughly speaking, they consist in inoculating a (benign) virus in order to kill the bacteria known to be responsible of a certain disease. This kind of treatment is known since the beginning of the 20th century, but has been in disuse in the Western world, erased by antibiotic therapies. However, a small activity in this domain has survived in the USSR, and it is now re-emerging (at least at an experimental level). Among the reasons of this re-emersion we can find the progressive slowdown in antibiotic efficiency (antibiotic resistance). Reported recent experiments include animal diseases like hemorrhagic septicemia in cattle or atrophic rhinitis in swine, and a need for suitable mathematical models is now expressed by the community.

Let us be a little more specific about the (lytic) bacteriophage mechanism: after attachment, the virus’ genetic material penetrates into the bacteria and use the host’s replication mechanism to self-replicate. Once this is done, the bacteria is completely spoiled while new viruses are released, ready to attack other bacteria. It should be noticed at this point that among the advantages expected from the therapy is the fact that it focuses on one specific bacteria, while antibiotics also attack autochthonous microbiota. Roughly speaking, it is also believed that viruses are likely to adapt themselves to mutations of their host bacteria.

At a mathematical level, whenever the mobility of the different biological actors is high enough, bacteriophage systems can be modeled by a kind of predator-prey equation. Namely, set \( S_t \) (resp. \( Q_t \)) for the bacteria (resp. bacteriophages) concentration at time \( t \). Then a model for the evolution of the couple \((S, Q)\) is as follows:

\[
\begin{align*}
\frac{dS_t}{dt} &= [\alpha - k Q_t] S_t dt + \varepsilon S_t dW^1_t \\
\frac{dQ_t}{dt} &= [d - m Q_t - k Q_t] S_t + k b e^{-\mu c Q_t - \zeta c} S_t - \zeta c dt + \varepsilon Q_t dW^2_t.
\end{align*}
\]
where $\alpha$ is the reproducing rate of the bacteria and $k$ is the adsorption rate. In equation (1), $d$ also stands for the quantity of bacteriophages inoculated per unit of time, $m$ is their death rate, we denote by $b$ the number of bacteriophages which is released after replication within the bacteria cell, $\zeta$ is the delay necessary to the reproduction of bacteriophages (called latency time) and the coefficient $e^{-\mu \zeta}$ represents an attenuation in the release of bacteriophages (given by the expected number of bacteria cell’s deaths during the latency time, where $\mu$ is the bacteria’s death rate). A given initial condition $(S_0, Q_0)$ is also specified, and the term $\varepsilon \, dW_i$ takes into account a small external noise standing for both uncertainties on the measures and the experiment conditions (for similar modeling see e.g. [34]). One should be aware of the fact that the latency time $\zeta$ (which can be seen as the reproduction time of the bacteriophages within the bacteria) cannot be neglected, and is generally of the same order (about 20mn) as the experiment length (about 60mn).

With this model in hand, our main results in this direction (see [15]) have been the following:

- Quantification of the exponential convergence to a bacteria-free equilibrium of equation (1) when $d$ is large enough.
- Use of the previous result plus concentration inequalities in order to study the convergence of the noisy system to equilibrium in a reasonable time range.
- Simulation of the stochastic processes at stake in order to observe the convergence to equilibrium.

6.5. Convergence of stochastic gene networks

Participants: A. Crudu, A. Debussche, A. Muller, Aurélie, O. Radulescu.

We propose simplified models for the stochastic dynamics of gene network models arising in molecular biology. Those gene networks are classically modeled by Markov jump processes, which are extremely time consuming. To overcome this drawback, we study the asymptotic behavior of multiscale stochastic gene networks using weak limits of Markov jump processes.

We consider a set of chemical reactions $R_r$, $r \in \mathbb{R}$; $\mathbb{R}$ is supposed to be finite. These reactions involve species indexed by a set $S = 1, \cdots, M$, the number of molecules of the species $i$ is denoted by $n_i$, and $X \in \mathbb{N}^M$ is the vector consisting of the $n_i$’s. Each reaction $R_r$ has a rate $\lambda_r(X)$ which depends on the state of the system, described by $X$ and corresponds to a change $X \rightarrow X + \gamma_r$, $\gamma_r \in \mathbb{Z}^M$.

Mathematically, this evolution can be described by the following Markov jump process. It is based on a sequence $(\tau_k)_{k \geq 1}$ of random waiting times with exponential distribution. Setting $T_0 = 0$, $T_i = \tau_1 + \cdots + \tau_i$, $X$ is constant on $[T_{i-1}, T_i)$ and has a jump at $T_i$. The parameter of $\tau_i$ is given by $\sum_{r \in \mathbb{R}} \lambda_r(X(T_{i-1}))$:

$$
P(\tau_i > t) = \exp \left( - \sum_{r \in \mathbb{R}} \lambda_r(X(T_{i-1})) t \right).$$

At time $T_i$, a reaction $r \in \mathbb{R}$ is chosen with probability $\lambda_r(X(T_{i-1}))/\sum_{r \in \mathbb{R}} \lambda_r(X(T_{i-1}))$ and the state changes according to $X \rightarrow X + \gamma_r$: $X(T_i) = X(T_{i-1}) + \gamma_r$. This Markov process has the following generator:

$$
Af(X) = \sum_{r \in \mathbb{R}} [f(X + \gamma_r) - f(X)] \lambda_r(X).
$$

In the applications we have in mind, the numbers of molecules have different scales. Some of the molecules are in small numbers and some are in large numbers. Accordingly, we split the set of species into two sets $C$ and $D$ with cardinals $M_C$ and $M_D$. This induces the decomposition $X = (X_C, X_D)$, $\gamma_r = (\gamma_r^C, \gamma_r^D)$. For $i \in D$, $n_i$ is of order 1 while for $i \in C$, $n_i$ is proportional to $N$ where $N$ is a large number. For $i \in C$, setting $\bar{n}_i = n_i/N$, $\bar{n}_i$ is of order 1. We define $x_C = X_C/N$ and $x = (x_C, X_D)$. 
For this kind of system, we are able to give in [18] some relevant information on the asymptotic regime $N \to \infty$ when different type of reactions are involved. Depending on the time and concentration scales of the system we distinguish four types of limits:

- Continuous piecewise deterministic processes (PDP) with switching.
- PDP with jumps in the continuous variables.
- Averaged PDP.
- PDP with singular switching.

We justify rigorously the convergence for the four types of limits.

### 6.6. Inference for Gaussian systems

**i) LAN property for fractional Brownian motion.** Local asymptotic normality (LAN) property is a fundamental concept in asymptotic statistics, which gives the asymptotic normality of certain estimators such as the maximum likelihood estimator for instance (see [66] for details on this property). In [11], we focus on the LAN property for the model where we observe a sample of $n$ observations $X_n = (X_1, ..., X_n)$ of a Gaussian stationary sequence. The sequence $(X_n)_{n \in \mathbb{N}}$, whose spectral density $f_{\theta}$ is indexed by a parameter $\theta$, can admit antipersitence, long memory or short memory and be noninvertible. To be more specific, our main assumption is:

$$f_{\theta}(x) \sim_{x \to 0} |x|^{-\alpha(\theta)} L_\theta(x)$$

with $L_\theta$ a slowly varying function and $\alpha(\theta) \in (-\infty, 1)$. We prove the LAN property by studying an asymptotic expansion of the log likelihood and using some results on Toeplitz matrices (see [39], [53]). In particular, our assumptions are fulfilled by fractional Gaussian noises and autoregressive fractionally integrated moving average processes (ARFIMA($p, d, q$)). We also obtain the LAN property for fractional Brownian motion.

**ii) Inference for dynamical systems driven by Gaussian noises.** As mentioned at the Scientific Foundations Section, the problem of estimating the coefficients of a general differential equation driven by a Gaussian process is still largely unsolved. To be more specific, the most general ($\mathbb{R}$-valued) equation handled up to now as far as parameter estimation is concerned (see [64]) is of the form:

$$X^\theta_t = a + \theta \int_0^t b(X_u) \, du + B_t,$$

where $\theta$ is the unknown parameter, $b$ is a smooth enough coefficient and $B$ is a one-dimensional fractional Brownian motion. In contrast with this simple situation, our applications of interest (see the Application Domains Section) require the analysis of the following $\mathbb{R}^n$-valued equation:

$$X^\theta_t = a + \int_0^t b(\theta; X_u) \, du + \int_0^t \sigma(\theta; X_u) \, dB_t,$$  \hspace{1cm} (4)

where $\theta$ enters non linearly in the coefficient, where $\sigma$ is a non-trivial diffusion term and $B$ is a $d$-dimensional fractional Brownian motion. We have thus decided to tackle this important scientific challenge first.
To this aim, here are the steps we have focused on in 2011:

- A better understanding of the underlying rough path structure for equation (2), carried out in [4], [5]. This step allows a proper definition of our equation of interest in a wide range of contexts.
- Gaussian type bounds for equations driven by a fractional Brownian motion, obtained in [9]. This is an important preliminary step for likelihood estimates for stochastic processes.
- Numerical aspects of a maximum likelihood type procedure for an equation of the form (2), expressed in terms of Malliavin calculus tools (see [10]).
- Convergence of a least square type estimator for an equation of the form (2) where the noise enters additively, handled in [14]. This is the first occurrence of a converging estimator for a general coefficient $b(\theta, \cdot)$.

### 6.7. Local self-similarity properties and stable or Gaussian random fields

Participants: Hermine Biermé, Jacques Istas, Céline Lacaux, Renaud Marty, Hans-Peter Scheffler.

- Recently, an important class of anisotropic random fields called operator scaling random fields has been studied in [30]. To be more specific, the classical self-similarity property is replaced in [30] by the following operator scaling property:

$$\forall c > 0, \ (X(c^E x))_{x \in \mathbb{R}^d} \overset{d}{=} c (X(x))_{x \in \mathbb{R}^d},$$

where $c^E := \exp (E \ln(c))$.

The Hölder regularity properties of operator scaling Gaussian or stable harmonizable random fields have been studied in [30] and can be expressed in terms of the matrix $E$. In particular, they do not vary along the trajectories, which can be too restrictive for some applications (see our osteoporosis project at the Application Domains Section). In order to obtain some anisotropic random fields whose Hölder regularity properties are allowed to vary, we introduce in [1] a local version of the operator scaling property (similar to the local version of the classical self-similarity property defined in [27]). This local property is illustrated in [1], where we also define and study harmonizable multi-operator scaling stable random fields. For such a multi-operator random field, we obtain an accurate upper bound of both the modulus of continuity and global and directional Hölder regularities at any point $x$. As expected, the Hölder regularity properties vary along the trajectories.

- In [24], we study the sample paths properties of an anisotropic random field, which is defined as limit of an invariance principle and is of the same type as a multifractional Brownian sheet. Our first aim was to generalize [37], that is to obtain some multifractional random fields indexed by $\mathbb{R}^d$ with $d \geq 2$ and to allow Hurst indices to be lower than $1/2$. To overcome the problem of the values of the Hurst indices which characterize the limit field, we focus on stationary sequences $(X_n(H))_{n \in \mathbb{N}}$, where $H \in (0, 1)^d$, defined by an harmonizable representation. Then, our limit field $S_h$ is defined as the limit of

$$S_h^N = \left\{ \sum_{n_1=1}^{[Nt_1]} \ldots \sum_{n_d=1}^{[Nt_d]} \frac{X_n(h_n^N)}{N^{r_n^N}} ; t \in [0, +\infty)^d \right\}$$

for some suitable families $(h_n^N)_{n,N}$ and $(r_n^N)_{n,N}$. We then study the sample paths property of this limit field. In particular, we obtain some local self-similarity properties for its increments of order $k$ and its pointwise and directional Hölder exponents. We also define (and obtain) some pointwise multi-Hölder exponents which characterize the Hölder property satisfied by the increments of order $d$ of $S_h$.

- We are also interested in self-similar processes indexed by manifolds in [23]. This study is motivated by the fact various spatial data are indexed by a manifold and not by the Euclidean space $\mathbb{R}^d$ in practical situations such as image analysis.
6. New Results

6.1. Mathematical methods and methodological approach to biology

6.1.1. Mathematical analysis of biological models

Participants: Jean-Luc Gouzé, Olivier Bernard, Frédéric Grognard, Ludovic Mailleret, Pierre Bernhard, Andrei Akhmetzhanov.

Mathematical study of semi-discrete models

Semi-discrete models have shown their relevance in the modelling of biological phenomena whose nature presents abrupt changes over the course of their evolution [77]. We used such models and analysed their properties in several situations that are developed in 6.2.3, most of them requiring such a modelling in order to take seasonality into account. Such is the case when the year is divided into a cropping season and a ‘winter’ season, where the crop is absent, as in our analysis of the sustainable management of crop resistance to pathogens [58] or in the co-existence analysis of epidemiological strains [17], [21]. Seasonality also plays a big role in the semi-discrete modelling required for the analysis of consumers’ adaptive behaviour in seasonal consumer-resource dynamics, where only dormant offspring survives the ‘winter’ [12], [52].

Mathematical study of models of competing species

When several species are in competition for a single substrate in a chemostat, and when the growth rates of the different species only depend on the substrate, it is known that the generic equilibrium state for a given dilution rate consists in the survival of only one of the species. In [28], we propose a model of competition of \( n \) species in a chemostat, where we add constant inputs of some species. We achieve a thorough study of all the situations that can arise when having an arbitrary number of species in the chemostat inputs; this always results in a Globally Asymptotically Stable equilibrium where all input species are present with at most one of the other species.

6.1.2. Model design, identification and validation

Participants: Olivier Bernard, Jean-Luc Gouzé.

Model design and identification

One of the main families of biological systems that we have studied involves mass transfer between compartments, whether these compartments are microorganisms or substrates in a bioreactor, or species populations in an ecosystem. We have developed methods to estimate the models of such systems [62]. These systems can be represented by models having the general structure popularized by [61], [65], [66], and based on an underlying reaction network:

\[
\frac{d\xi}{dt} = K r(\xi, \psi) + D(\xi_{in} - \xi) - Q(\xi)
\]

We address two problems: the determination of the pseudo-stoichiometric matrix \( K \) and the modelling of the reaction rates \( r(\xi, \psi) \).

In order to identify \( K \), a two-step procedure has been proposed. The first step is the identification of the minimum number of reactions to be taken into account to explain a set of data. If additional information on the process structure is available, we showed how to apply the second step: the estimation of the pseudo-stoichiometric coefficients.

This approach has been applied to various bioproduction processes, most recently on activated sludge processes [60], anaerobic digestion [71], [87] and anaerobic digestion of microalgae [22].
6.1.3. Nonlinear observers

Participants: Jean-Luc Gouzé, Olivier Bernard.

Interval observers

Interval observers give an interval estimation of the state variables, provided that intervals for the unknown quantities (initial conditions, parameters, inputs) are known. We have extended the interval observer design to new classes of systems. First, we designed interval observers, even when it was not possible in the original basis, by introducing a linear, time-varying change of coordinates. This approach was then extended to $n$-dimensional linear systems, leading to the design of interval observers in high dimensions. Extension to time-delay systems have also been proposed. The combination of the observers has also been improved in the case where various types of interval observers are run in parallel in a so-called "bundle of observers". The approach has been applied to estimation of the microalgae growth and lipid production.

In order to demonstrate the efficiency of the interval observer design, even with chaotic systems, a special application of the interval observer has been developed for Chua’s chaotic systems. The interval estimation of the state variables are performed considering parameters uncertainties of the system and biased output.

6.1.4. Metabolic and genomic models

Participants: Jean-Luc Gouzé, Madalena Chaves, Alfonso Carta, Ismail Belgacem, Xiao Dong Li, Olivier Bernard, Christian Breindl, Frédéric Grognard.

Qualitative control of piecewise affine models

In the control of genetic networks, the construction of feedback control laws is subject to many specific constraints, including positivity, appropriate bounds and forms of the input. In addition, control laws should be liable to implementation in the laboratory using gene and protein components. In this context, under the hypothesis that both the observations and control functions are qualitative (or piecewise constant), and using sliding mode solutions, we analysed the controllability and stabilizability with respect to either of the steady states, for a piecewise affine model of the bistable switch with single input. It is also possible to find a qualitative control law that leads the system to a periodic orbit passing through the unstable steady state. Moreover, we designed some preliminary control laws for the negative loop with two genes, which has an oscillatory behaviour.

Interconnections of Boolean modules: asymptotic behaviour

A biological network can be schematically described as an input/output Boolean module: that is, both the states, the outputs and inputs are Boolean. The dynamics of a Boolean network can be represented by an asynchronous transition graph, whose attractors describe the system’s asymptotic behaviour. We have shown that the attractors of the feedback interconnection of two Boolean modules can be fully identified in terms of cross-products of the attractors of each module. Based on this result, a model reduction technique is proposed to predict the asymptotic dynamics of high-dimensional biological networks through the computation of the dynamics of two isolated smaller subnetworks. Applications include a model of cell-fate decision (represented as an interconnection of two 3-input/3-output modules).

Structure estimation for unate Boolean models of gene regulation networks

Estimation or identification of the network of interactions among a group of genes is a recurrent problem in the biological sciences. Together with collaborators from the University of Stuttgart, we have worked on the reconstruction of the interaction structure of a gene regulation network from qualitative data in a Boolean framework. The idea is to restrict the search space to the class of unate functions. Using sign-representations, the problem of exploring this reduced search space is transformed into a convex feasibility problem. The sign-representation furthermore allows to incorporate robustness considerations and gives rise to a new measure which can be used to further reduce the uncertainties. The proposed methodology is demonstrated with a Boolean apoptosis signaling model.
Multistability and oscillations in genetic control of metabolism

Genetic feedback is one of the mechanisms that enables metabolic adaptations to environmental changes. The stable equilibria of these feedback circuits determine the observable metabolic phenotypes. Together with D. Oyarzun from Imperial College, we considered an unbranched metabolic network with one metabolite acting as a global regulator of enzyme expression. Under switch-like regulation and exploiting the time scale separation between metabolic and genetic dynamics, we developed geometric criteria to characterize the equilibria of a given network. These results can be used to detect mono- and bistability in terms of the gene regulation parameters for any combination of activation and repression loops [40]. We also find that metabolic oscillations can emerge in the case of operon-controlled networks; further analysis reveals how nutrient-induced bistability and oscillations can emerge as a consequence of the transcriptional feedback [27].

Uniqueness and global stability for metabolic models

We are interested in the uniqueness and stability of the equilibrium of reversible metabolic models. For biologists, it seems clear that realistic metabolic systems have a single stable equilibrium. However, it is known that some type of metabolic systems can have no or multiple equilibria. We have made some contribution to this problem, in the case of a totally reversible enzymatic system. We prove that the equilibrium is globally asymptotically stable if it exists; we give conditions for existence and behaviour in a more general genetic-metabolic loop [84].

Birhythmicity in the p53-Mdm2 network

The p53-Mdm2 network is one of the key protein module involved in the control of proliferation of abnormal cells in mammals. Recently, a differential model of the p53-Mdm2 biochemical network which shows birhythmicity has been proposed to reproduce the two experimentally observed frequencies of oscillations of p53. Our study aimed at investigating the mechanisms at the origin of this birhythmic behaviour. To do so, we approximated this continuous non-linear model into a lower dimensional piecewise affine model and performed a first return map analysis. Based on this analysis, an experimental strategy has been proposed to test the existence of birhythmicity in the p53-Mdm2 network [31], [11].

E. coli modelling and control

In the framework of ANR project Gemco, with the aim of better understanding how to build a controller for Escherichia coli growth, three reduced models of E. coli gene expression machinery have been developed: the wild-type model, the open-loop model and the closed-loop model. Each one of these models is made up of two piece-wise non-linear differential equations.

Notably, the wild-type model describes the qualitative dynamics of the unmodified bacterium in terms of two relevant protein concentrations (RNAP and CRP) and a carbon source as input, which can be either glucose or maltose. Bacteria prefer glucose, which leads to a higher growth rate in wild type.

The open-loop model describes the qualitative dynamics of RNAP and CRP concentrations when the gene encoding for RNAP is controlled externally by an IPTG-inducible promoter. This control, biologically implemented by our collaborators in Grenoble—yielding different E. coli growth rates depending on IPTG concentration—shows that a controller for the bacterial growth can be built acting on the gene expression machinery level. Moreover, lumped parameters related to RNAP dynamics and IPTG regulation function have been estimated by means of E. coli growth curves.

Finally, the closed-loop model implements a possible feedback control-loop able to theoretically generate inverse diauxie, i.e. higher growth on maltose than on glucose.

Observation problems of a class of genetic regulatory networks

A state reconstruction problem with Boolean measurements is considered for a piecewise affine genetic network model. The problem has two distinct aspects with respect to classical ones: 1) the model is a hybrid system, and 2) the measurements (of genes expression) are only qualitative due to the experimental techniques. A Luenberger-like observer is proposed which can present some sliding modes and has finite-time convergence. A transition graph is given for the coupled observer-nominal system. To minimize the
convergence time, different convergence scenarios are discussed for optimizing the choice of initial condition
of the observer [35], [57]. Robustness of the observer is checked for two types of parametric perturbed
systems: 1) the observer is used to identify an unknown but fixed variation on the synthesis coefficient, via an
adaptive dichotomy algorithm; and 2) the observer is robust in practical sense for the model with an uncertainty
on the threshold value [76].

6.2. Fields of application

6.2.1. Bioenergy

6.2.1.1. Modelling and optimization of microalgae production

Participants: Olivier Bernard, Antoine Sciandra, Frédéric Grognard, Philipp Hartmann, Rafael Munoz
Tamayo, Andrei Akhmetzhanov, Nina Moelants, Hubert Bonnefond.

Experiments have been carried out to study the effects of nitrogen limitation on the lipid production in
microalgae [74] and support model development. We have proposed a new model for lipid production
by microalgae which describes the fate of the CO$_2$ incorporated during photosynthesis [23]. This model
describes the accumulation of neutral lipids (which can be turned into biofuel), carbohydrates and structural
carbon. It has been calibrated and validated with experimental data. Experiments have also attempted to
simultaneously represent the effect of an osmotic stress [55]. This model highlights and explains the
phenomenon of hysteresis in lipid production which has been experimentally verified. It has been extended to
account for light/dark cycles [36].

On the other hand, a new dynamical model has been developed to describe microalgal growth in a photobiore-
actor under light and nitrogen limitations [13]. The strength of this model is that it takes into account the
strong interactions between the biological phenomena (effects of light and nitrogen on growth, photoacclima-
tion [34], [48] ...) and the radiative transfer in the photobioreactor (light attenuation due to the microalgae).
Using these two approaches, we have developed a model which describes lipid production in a photobioreactor
under light limitation. This model is used to predict lipid production in the perspective of large scale
biofuel production. Simpler models have also been developed and have been used to provide optimization
strategies: first, biomass production has been optimized in a constant light environment [79], yielding
results emphasizing the importance of the optical depth of the reactor. In a second work, we focused on the
optimal operating conditions for the biomass productivity under day/night cycles using Pontryagin’s
maximum principle (assuming a periodic working mode) [72], [73].

Another model has been developed to represent growth of microalgae colimited by nitrogen and phosphorus [69]. It has been shown, from qualitative analysis of the model that uptake of nitrogen and phosphorus are non
symmetric.

6.2.1.2. Modelling the effect of light and temperature on microalgae

Participants: Olivier Bernard, Antoine Sciandra, Frédéric Grognard, Philipp Hartmann, Rafael Munoz
Tamayo, Kerstin Ebert, Nina Moelants, Hubert Bonnefond.

The light distribution within a photobioreactor was estimated thanks to a multi photon Monte-Carlo simulation.
From measurements of absorption and scattering properties, it was thus possible to extrapolate and validate
the light distribution within a photobioreactor or a raceway.

The impact of the hydrodynamics on the light percept by a single cell was studied thanks to fluid dynamics
simulations of raceway pond [48]. The light signals that a cell experiences at the Lagrangian scale, depending
on the fluid velocity, were then estimated. A Droop-Han model was used to assess the impact of light
fluctuation on photosynthesis [48].

Finally, the effect of temperature on microalgae has been represented by adapting the CTMI model developed
for bacteria [88]. The proposed model [59], associated with a parameter identification procedure, was able
to correctly represent the growth response to temperature for 12 different species [48].
6.2.2. CO₂ fixation by microalgae

**Participants:** Olivier Bernard, Antoine Sciandra, Philipp Hartmann, Nina Moelants.

We have run experiments to observe the response of a population of microalgal cells to various periodic light/dark or nitrate signals. The measurements show the synchronicity of the cells for some conditions. These experiments support the hypothesis that uptake of nitrogen stops during cell division [82]. On this basis, we have developed a structured model representing the development of microalgal cells through three main phases of their cell cycle: G1, G2 and M. The model is made of three interdependent Droop models [13]. The model was validated through extensive comparison with experimental results in both condition of periodic light forcing and nitrogen limitation. The model turns out to accurately reproduce the experimental observations [81]. The effect of cell synchronization on lipid content were experimentally studied [18] and included into microalgae growth models [36].

The effect of CO₂ partial pressure increase on photosynthesis and calcification of the calcareous microalgae *Emiliania huxleyi* have been experimentally observed. It results that an increase of the coccolith size together with a decrease in the calcification rate has been observed.

Three models accounting for the possible coupling between photosynthesis and calcification were included in an ocean model, including settling and predation by grazers, and a bloom of coccolithophorids was simulated [67], [68]. It was shown using Monte Carlo simulations that the uncertainty on the mechanisms driving calcification together with parametric uncertainties lead to uncertainties which are in the same range as the effect of an increase or the CO₂ partial pressure.

6.2.3. Design of ecologically friendly plant production systems

6.2.3.1. Controlling plant pests

**Participants:** Frédéric Grognard, Ludovic Mailleret, Mickaël Teixeira-Alves.

*The influence of an alternative prey in biological control programs*

We have developed a model based on the classical Leslie-Gower predator prey model, that allows for the choice that a predator might have for its diet. In a biological control framework, this choice might be between a pest that we want to eradicate and another prey that could be fed to the predator in order to help the biological control efficiency or between the pest and an alternative prey that is present in the field and might keep the predator from acting as a natural enemy of the pest. We put the problem in a time-partitioning framework: the predator has to split its time between the two prey. We then compared two time-partitioning strategies: one where the predator always spends a fixed proportion of its time on each prey and one where the predator always chooses the prey that is instantaneously most profitable (adaptive foraging). We then studied the effect of the presence of one prey on the other (indirect effect since it is mediated by the presence of the predator). We showed that, in the Leslie-Gower framework, one of the two prey always benefits from the presence of the other and that this effect is even stronger in the adaptive foraging framework, where the presence of the other prey is never detrimental to the one considered. That way, with very little assumptions, we showed the existence of apparent predation, commensalism and apparent mutualism, while most existing theoretical results tend to evidence apparent competition [51]. Such mechanisms may explain why generalist biological control agents are, in general, not as efficient as specialists in controlling crop pests.

*The influence of plant dynamics on pest eradication*

Pests-biocontrol agents models have been developed in order to build biological control strategies that can achieve pest eradication through augmentative biological control [85]. In the present work, we aim at introducing a plant compartment since its dynamics clearly have an influence on that of the pests and since the final objective of biological control is to maintain a sufficient plant yield. In a first step, we focused on plant-insect interactions and showed how the level and timing of the pest invasion could influence the final plant yield. Introducing pests control interventions and studying its timing, we showed how it eventually could have important effects on the growth pattern and the final biomass. As a reference, we consider the novel invasive pest Tuta absoluta on tomato plants [56].
This work is done in collaboration with Yves Dumont (Cirad).

6.2.3.2. Controlling plant pathogens

**Participants:** Frédéric Grognard, Ludovic Mailleret.

*Sustainable management of plant resistance*

The introduction of plants strains that are resistant to one pathogen often leads to the appearance of virulent pathogenic strains that are capable of infecting the resistant plants. The resistance strain then becomes useless. It is therefore necessary to develop ways of introducing such resistance into crop production without jeopardizing its future efficiency. We did so by choosing the proportion of resistant plants that are mixed with the non-resistant ones. In this work, we studied a vector borne pathogen in a seasonal environment, with healthy crop being planted at the beginning of each season and cropped at its end, the pathogen surviving in the environment during the ‘winter’. Two strategies have been proposed, one that aims at minimizing the cumulated damage over a 15 years horizon and one that aims at preventing the virulent strain outbreak. In the first case, both plant strains need to be mixed, but it results in the loss of the resistance at the end of the 15 year period; in the second case, the damage is higher and the maximal proportion of resistant plant is smaller, but the resistance is preserved [58], [16].

This work is done in collaboration with Frédéric Fabre (INRA Avignon).

*Plant pathogen dynamics and cropping management practices*

The coexistence of closely related plant parasites is widespread. Yet, understanding the ecological determinants of evolutionary divergence in plant parasites remains an issue. Niche differentiation through resource specialization has been widely researched, but it hardly explains the coexistence of parasites exploiting the same host plant. Agricultural systems are characterized by the cyclical presence and absence of the crop, due to cropping practices such as harvest and planting. We studied the influence that time-partitioning, *i.e.* the specialization of a parasite for the beginning or the end of crop presence, can have on co-existence. In modelling the epidemiology through a semi-discrete model we showed through an evolutionary invasion analysis that evolutionary divergence, and thus co-existence of different strains, of the parasite phenotype can occur [17], [44]. Also, in a similar context, we underlined why modelling seasonal plant epidemiology did not necessarily lead to competitive exclusion; indeed, generating a compact model by rigorously isolating the slow dynamics from a large detailed model of plant epidemiology, we found out the possibility of coexistence [49], [21]. Such a result contrasts with classical competitive exclusion principles found in compact models which rely on the arguable density independent nature of the pathogen infections occurring during the very beginning of the cropping seasons.

This work is done in collaboration with Frédéric Hamelin (Agrocampus Ouest).

6.2.4. Biological depollution

6.2.4.1. Coupling microalgae to anaerobic digestion

**Participants:** Olivier Bernard, Antoine Sciandra, Jean-Philippe Steyer, Frédéric Grognard, Philipp Hartmann.

The coupling between a microalgal pond and an anaerobic digester is a promising alternative for sustainable energy production and wastewater treatment by transforming carbon dioxide into methane using light energy. The ANR Symbiose project is aiming at evaluating the potential of this process [90], [89].

In a first stage, we developed models for anaerobic digestion of microalgae. Two approaches were used: First, a dynamic model has been developed trying to keep a low level of complexity so that it can be mathematically tractable for optimisation [37], [32], [22]. Considering three main reactions, this model fits adequately the experimental data of an anaerobic digester fed with *Chlorella vulgaris* (data from INRA LBE). On the other hand, we have tested the ability of ADM1 [91] (a reference model which considers 19 biochemical reactions) to represent the same dataset. This model, after modification of the hydrolysis step [24], [38], [41] has then been used to evaluate process performances (methane yield, productivity...) and stability though numerical simulations.
In a second stage, a model describing the coupling between anaerobic digestion process and microalgae culture (including the feeding of the algae with anaerobic digestion effluents) has been developed. The model is based on the three steps model for anaerobic digestion, and on the photoacclimation model for microalgae [13]. The model also includes the modelling of heterotrophs in the microalgae pond.

6.2.4.2. Life Cycle Assessment of microalgae production

Participants: Olivier Bernard, Jean-Philippe Steyer.

This work is the result of a collaboration with Laurent Lardon and Arnaud Helias of INRA-LBE through the co-supervision of Pierre Collet’s PhD thesis.

An analysis of the potential environmental impacts of biodiesel production from microalgae has been carried out using the life cycle assessment (LCA) methodology [75]. This study has allowed to identify the obstacles and limitations which should receive specific research efforts to make this process environmentally sustainable. This study has been updated and the effects of technological improvements (leading to higher productivities) have been compared to the source of electricity. It turns out that the overall environmental balance can much more easily be improved when renewable electricity is produced on the plant [47], [46]. As a consequence, a new paradigm to transform solar energy (in the large) into transportation biofuel is proposed, including a simultaneous energy production stage.

A LCA has been carried out to assess the environmental impact of methane production by coupling microalgae and anaerobic digestion. The study highlights the limitation derived by the low biodegradability of the considered microalgae [15] which induces a large digester design and thus more energy to mix and heat it.

6.2.5. Models of ecosystems

6.2.5.1. Adaptive behaviour in seasonal consumer-resource dynamics

Participants: Frédéric Grognard, Ludovic Mailleret, Pierre Bernhard, Andrei Akhmetzhanov.

In this work we studied the evolution of a consumer-resource (or predator-prey) system with seasonal character of the dynamics. We specified two main parts of the process. First, we considered the system during one season with a fixed length: the prey lay eggs continuously and the predators lay eggs or hunt the preys (choose their behaviour) according to the solution of an optimal control problem [12]. Secondly, we studied the long-scale discrete dynamics over seasons. We investigated the qualitative behaviour of the dynamics with respect to the parameters of the problem and showed that, depending on the parameters of the model, extinction or co-existence of the predators and preys can be evidenced [12].

We then examined how (resident) predators adopting this behaviour would fare when faced with a small population of selfish mutants that would be identical to the resident but would have the freedom to choose a different behaviour. We studied the resulting optimal control problem where the mutants maximize their own number of offspring using the knowledge of the resident’s behaviour, and showed that, in most situations, mutants can take advantage of their low frequency and fare better than the residents. Over the course of a large number of seasons, the mutants replace the residents, only to find themselves applying the original resident behaviour [52]. We have then proposed a strategy for the predator in which it would prevent the invasion by the mutant instead of maximizing its number of offspring, which corresponds to the computation of evolutionarily stable life history strategies.

We have then considered that the resource itself could adapt its behaviour over time to limit the damage caused by the consumer, and maximize its own offspring. This problem requires the solution of a non zero-sum differential game, the consumer and the resource being the two players. We showed that the patterns of the strategies of the consumers and the resources are identical to the ones that can be obtained if the opposing player adopts a constant behaviour; the timing of the switchings varies however [42].

6.2.5.2. Including phytoplankton photoadaptation into biogeochemical models

Participant: Olivier Bernard.
The complexity of the marine ecosystem models and the representation of biological processes, such as photoadaptation, remain open questions. We compared several marine ecosystem models with increasing complexity in the phytoplankton physiology representation in order to assess the consequences of photoadaptation model complexity in biogeochemical model predictions. Three models of increasing complexity were considered, and the models were calibrated to reproduce ocean data acquired at the Bermuda Atlantic Time-series Study (BATS) from in situ JGOFS data. It turns out that the more complex model are trickier to calibrate and that intermediate complexity models, with an adapted calibration procedure, have a better prediction capability [43].

6.2.5.3. Growth models of zooplankton

Participants: Jean-Luc Gouzé, Jonathan Rault, Eric Benoît.

The model built to describe a zooplankton community is some variant of the McKendrick-Von Foerster Equation. The model includes cannibalism within zooplankton and predation on phytoplankton. Dynamic mass budget theory is used in order to describe individual behaviour and allows mass conservation. Also we have added phytoplankton dynamics, and we use environmental data as an input for the model. The aim is to compare simulations with data provided by the Laboratoire d'Océanographie de Villefranche. Since the model incorporates lots of parameters, which are not always known in the literature, we have to use optimization techniques to find them. Further, equilibria of such models and their local stability is studied in using strongly continuous semigroup approach [50].

We have also built a discrete size-structured model. Discrete models are less numerically demanding and so can be more easily incorporated into bigger models. Moreover the study of discrete models are often easier than that of continuous ones. We focus our study on the impact of cannibalism within zooplankton community and show that under some hypotheses, cannibalism can stabilize the equilibrium of the model [86].

6.3. Software design

Participants: Olivier Bernard, Florian Guenn, Mélanie Gautier.

Over the years, BIOCORE has been developing a software framework for bioprocess control and supervision called ODIN [63]. This C++ application (working under Windows and Linux) enables researchers and industrials to easily develop and deploy advanced control algorithms through the use of a Scilab interpreter. It also contains a Scilab-based process simulator which can be harnessed for experimentation and training purposes. ODIN is primarily developed in the C++ programming language and uses CORBA to define component interfaces and provide component isolation. ODIN is a distributed platform, enabling remote monitoring of the controlled processes as well as remote data acquisition. Recently, a software development effort has been directed to the graphical user interface, a synoptic view component, new drivers for the experimental hardware and integration of the PlantML data exchange format. ODIN has been tested on four different processes and currently supervises the 66m² high rate pond at the LBE, INRA Narbonne.
BIPOP Project-Team

6. New Results

6.1. Modeling

6.1.1. Simulation of electrical circuits as nonsmooth dynamical systems

Participants: Vincent Acary, Olivier Bonnefon, Bernard Brogliato.

DC-DC converters are usually difficult to simulate with classical tools like SPICE because of the highly nonlinear behaviour of some components and the frequent occurrence of intrinsically generated switching events.

The simulation of such circuits modelled as nonsmooth systems has been successfully achieved with a clear advantage over several SPICE simulators and a simulator belonging to the hybrid modelling approach [1][48].

6.1.2. Spiking neuronal networks dynamics

Participant: Arnaud Tonnelier.

Precise spatiotemporal sequences of spikes are observed in many neural systems and are thought to be involved in the neural processing of sensory stimuli. In [58] we examine the capability of spiking neural networks to propagate stably spatiotemporal sequences of spikes. We derive some analytical results for the wave speed and show that the stability of simple waves is determined by the Schur criteria. The transmission of a sequence of several spikes is related to the existence of stable composite waves, i.e. the existence of stable spatiotemporal periodic traveling waves. We show that the stability of composite waves is related to the roots of a system of multivariate polynomials.

A fundamental aspect that shapes the properties of traveling waves in networks is the underlying lattice-structure of the space. Discreteness has a strong effect on propagating activity patterns and, for instance, anisotropy or propagation failure can be observed. Numerical simulations and analytical calculations have been carried out to characterize more precisely these properties [47].

6.1.3. Computational Toxicology

Participant: Arnaud Tonnelier.

It is now well recognized that toxicology has entered a new era. Previously mainly based on animal testing, toxicology is now turning to in vitro and in silico experiments. To assess the risk of chemicals but also to gather and to interpret the massive amounts of experimental data generated by modern toxicology, the development of mathematical and computational tools are essential. An important element in risk assessment of chemicals is the human bioaccumulative potential. We developed a predictive tool for human bioaccumulation assessment using a physiologically based toxicokinetic model [28].

6.1.4. High-order models of mechanical rods

Participants: Florence Bertails-Descoubes, Romain Casati.

Reduced-coordinates models for rods such as the articulated rigid body model or the super-helix model [50] are able to capture the bending and twisting deformations of thin elastic rods while strictly and robustly avoiding stretching deformations. In this work we are exploring new reduced-coordinates models based on a higher-order geometry. Typically, elements are defined by a polynomial curvature function of the arc length, of degree $d \geq 1$. The main difficulty compared to the super-helix model (where $d = 0$) is that the kinematics has no longer a closed form. We have already investigated the clothoidal case ($d = 1$) in the 2d case [51], relying on Romberg numerical integration, and a general approach in 3d based on power series expansion was formulated in the master thesis of R. Casati, for a single element. R. Casati is currently extending the method to a chain of linked elements as well as to an arbitrary degree $d$ of the curvature function.
6.1.5. **Inverse modeling of mechanical rods**  
**Participants:** Florence Bertails-Descoubes, Alexandre Derouet-Jourdan.

Controlling the input shape of slender structures such as rods is desirable in many design applications (such as hairstyling, reverse engineering, etc.), but solving the corresponding inverse problem is not straightforward. In [29] we started to extend to 3d our 2d method introduced in [8] for automatically converting a smooth sketched curve into a dynamic curve at stable equilibrium under gravity. The main challenge in 3d amounts to converting an input curve into a continuous piecewise helix. Using a least-squares optimization approach is a natural option, however it may suffer from both robustness and computational issues due to the presence of multiple local minima in the objective function. To overcome these issues, we have recently proposed to reformulate the problem as a geometric interpolation problem. In this new method, only tangents are strictly interpolated while points are displaced in an optimal way so as to lie in a feasible configuration, i.e., a configuration that is compatible with the interpolation by a helix. Our method proves to be much more robust and faster compared to the global optimization approach. We plan to publish these results in 2012.

6.1.6. **Multiple impacts modelling**  
**Participants:** Bernard Brogliato, Hongjian Zhang, Ngoc-Son Nguyen.

The work consists of studying two systems: the rocking block and tapered chains of balls, using the Darboux-Keller model of multiple impacts previously developed. The objectives are threefold: 1) show that the model predicts well the motion by careful comparisons with experimental data found in the literature, 2) study the system’s dynamics and extract critical kinetic angles that allow the engineer to predict the system’s gross motion, 3) develop numerical code inside the SICONOS platform that incorporates the model of multiple impact. Results are in [42].

6.1.7. **Simulating contact with Coulomb friction in fiber assemblies**  
**Participants:** Florence Bertails-Descoubes, Gilles Daviet.

We have developed a new frictional contact solver in [21] which is able to robustly and efficiently handle large fiber problems composed of thousands self-contacting rods with exact Coulomb friction. The solver relies on a Gauss-Seidel iterative approach, where each local one-contact solver is based on a hybrid strategy. The solution to the one-contact problem is first searched for using a nonsmooth Newton method based upon a generalized Fischer-Burmeister formulation. This primary solver manages to solve the local problem in 99.9% of the cases. When the solver fails to converge to an acceptable solution, the method switches to a more costly but exact solver, based on the $\alpha$-formulation introduced in [39]. This hybrid strategy experimentally allows us to always find a solution to the local problem, which greatly contributes to improve the robustness of the global solver. We have compared our new solver against other solvers of the literature (e.g., damped Newton solvers relying on the Alart-Curnier function) and observed a noticeable gain, both in terms of robustness and computational efficiency.

6.2. **Optimization**

6.2.1. **Nonsmooth analysis and optimization on matrix manifolds**  
**Participant:** Jérôme Malick.

Optimization on matrix manifolds is an emerging fields of research in optimization, driven by applications in robotics. We have contributed on two different projects.

- **Numerical efficiency of optimization methods.** Newton method on manifolds would require to compute a geodesic (that is to solve a ODE). It is clear that replacing classical differential-geometric objects with certain approximations, resulting in faster and possibly more robust algorithms. With our colleague P.-A. Absil from the Department of Mathematical Engineering of the École Polytechnique de Louvain (Belgique), we propose in [16] a way to construct “retractions” (a key step when applying optimization algorithms on matrix manifolds) by projecting onto the submanifold. We show
that the operation remains a retraction if the projection is generalized to a projection-like procedure that consists of coming back to the submanifold along “admissible” directions. This theory offers a framework in which previously-proposed retractions can be analyzed, as well as a toolbox for constructing new ones. Illustrations are given for projection-like procedures on some specific manifolds for which we have an explicit, easy-to-compute expression.

- **Towards the application of matrix optimization techniques to spectral manifolds.** Spectral sets are sets of matrices that depend only on the constraints on the eigenvalues: $S = \lambda^{-1}(C)$ with $C$ a subset of $\mathbb{R}^n$. A spectral set $S$ inherits from properties of the underlying set $C$, such as convexity. We prove in [46] that the spectral sets associated to smooth manifolds in $\mathbb{R}^n$ (having some local symmetry) are themselves manifolds in the space of matrices. This result looks simple but generalizes several useful particular cases, and was extremely difficult to prove: we brace together tools from nonsmooth analysis, differential geometry, group theory and spectral analysis.

### 6.2.2. Semidefinite programming and combinatorial optimization

**Participants:** Nathan Krislock, Jérôme Malick.

We have worked with Frederic Roupin (Prof. at Paris XIII) on the use of semidefinite programming to solve combinatorial optimization problems to optimality. Within exact resolution schemes (branch-and-bound), “good” bounds are those with a “good” balance between tightness and computing times.

We proposed a new family of semidefinite bounds for 0-1 quadratic problems with linear or quadratic constraints [26], [54]. An interesting feature is that the final accuracy level is controlled by a real parameter acting like a cursor. This gives ways to trade computing time for a (small) deterioration of the quality of the usual semidefinite bounds, in view of enhancing this efficiency in exact resolution schemes. Extensive numerical comparisons and tests showed the superior quality of our bounds on standard test-problems (unconstrained 0-1 quadratic problems, heaviest k-subgraph problems, and graph bisection problems).

We have embedded the new bounds within branch-and-bound algorithms to solve 2 standard combinatorial optimization problems to optimality.

- **Heaviest k-subgraph problems.** Our algorithm [26] takes advantage of the new bounds to prune very well in the search tree. Its performances are then comparable with the best method (based on convex quadratic relaxation using CPLEX as an engine). In practice, our method works particularly fine on the most difficult instances (with a large number of vertices, small density and small k).

- **Max-cut.** We are working on extending our algorithm to max-cut problems [53]. It dynamically manages polyedral and semidefinite relaxations to outperform the state-of-the-art solver ([56]) on the large test-problems.

### 6.2.3. Marginal prices in electricity production

**Participants:** Claude Lemaréchal, Jérôme Malick, Welington Oliveira, Sofia Zaourar.

Two subjects were involved this year in our ongoing collaboration with EdF.

- **Stabilizing prices.** Unit-commitment optimization problems in electricity production are large-scale, nonconvex and heterogeneous, but they are decomposable by Lagrangian duality. Realistic modeling of technical production constraints makes the dual objective function computed inexactly though. An inexact version of the bundle method has been dedicated to tackle this difficulty [52]. However, the computed optimal dual variables show a noisy and unstable behaviour, that could prevent their use as price indicator. We propose a simple and controllable way to stabilize the dual optimal solutions, by penalizing the total variation of the prices [59]. Our illustrations on the daily electricity production optimization of EDF show a striking stabilization at a negligible cost.

- **Accelerating** the solution phase by the so-called disaggregation technique [49], using the fact that (see Activity Report of 2010) the dual objective function is the sum of two terms: one coming from primal cost, one coming from valorization of constraints (plus possibly a third term when price stabilization is present). The resulting CPU time is drastically improved, sometimes divided by 10.
6.3. Control

6.3.1. Digital sliding mode control

**Participants:** Vincent Acary, Bernard Brogliato.

The problem of digital sliding mode controllers is a long-standing issue not yet satisfactorily solved. We propose ideas which are inspired from the numerical methods of contact mechanics [2] and which permit a) to suppress the numerical chattering, b) to obtain a smooth stabilization on the sliding surfaces. The work is continued together with Yury Orlov in more general cases where the system is acted upon by disturbances and a disturbance estimation is added [19].

6.3.2. Discrete-time discontinuous systems

**Participants:** Vincent Acary, Bernard Brogliato, Carmina Georgescu, Scott Greenhalg, Thorsten Schindler.

We focus on some classes of discontinuous dynamical systems like relay systems, linear complementarity systems. The objectives are to show that the time-stepping numerical schemes like Moreau’s algorithm can be used to successfully simulate such systems (like in the case of biological systems like gene networks), and also to study the properties of these schemes for finite nonzero time steps (like preservation of dissipativity properties). Results are in [23], [35]. Further work deals with timestepping schemes for nonsmooth dynamical systems. So far, these schemes are locally of order one both in smooth and nonsmooth segments. This is inefficient for applications with few events like circuit breakers. To consistently improve the behavior during smooth episodes, the traditional schemes are being embedded in time discontinuous Galerkin methods. After establishing the correct mathematical setting, a Petrov-Galerkin distributional differential inclusion is outlined. The bouncing ball example illustrates its capabilities.

6.4. Locomotion analysis

6.4.1. Synchronous imitation of human motion by a humanoid robot

**Participants:** Mehdi Benallegue, Pierre-Brice Wieber.

Interactions between humans and robots require that each one is able to understand and interpret each other’s actions. From the point of view of the robot, this means: (i) to move in a way that can be naturally interpreted by humans and (ii) to be able to understand the humans’ actions. Studies in Neuroscience in the case of interactions between humans indicate that these two abilities might be tightly linked in the human’s brain: we understand actions when we map the observed action onto our motor representation of the same action [57]. In this work, we consider that the “motor representation” of a task is the control law, and “mapping an observed action” means finding the corresponding control parameter, in an observer-based approach.

Considering a correspondence between two different control laws can be seen a modeling error. This modeling error can be seen as an unknown arbitrary perturbation on the modeled system, or an unknown input sent to the observed system. We developed an observer that can cancel the effects of unknown inputs on the dynamics of discrete time linear systems with unknown inputs. To do so, the observer has to satisfy a delayed invertibility condition and use delayed outputs. In other words, the observer has to wait for several measurement after a given instant to collect enough data to reconstruct the state at that instant.

6.4.2. Hierarchic QP solver

**Participant:** Pierre-Brice Wieber.
We are working in collaboration with the LAAS-CNRS and the CEA-LIST on solving multi-objective Quadratic Programs with Lexicographic ordering: Hierarchic QPs \cite{25}. The focus this year has been on the regularization of the problem when the Quadratic Program approaches singularities. There is indeed a problem of discontinuity of the solution when reaching such singularities, what’s not a rare event in robotic applications. This discontinuity has been related to the fact that Lexicographically ordered QPs correspond to the limit of weighed multi-objective QPs when weights go singular, and that the regularization is itself a weighting of objectives which goes to a limit when approaching singularities, and those two limit processes interfere. The solution we found so far is to cancel the first limiting process and move back from strict Hierarchic QPs to weighted QPs staying at a small distance from singularity \cite{33}. But this solution is not really satisfying and we have to find a better one.

6.4.3. Numerical modeling of muscle contraction under FES

**Participant:** Pierre-Brice Wieber.

We have been working in collaboration with the EPI DEMAR in Montpellier on modeling muscle contraction under Functional Electric Stimulation (FES). With respect to the literature in the domain, our contributions are mostly linked to the model of the contractile element, through the introduction of the recruitment at the fibre scale, formalizing the link between FES parameters, recruitment and Calcium signal paths. The resulting controlled model is able to reproduce both short term (twitch) and long term (tetanus) responses. It also matches some of the main properties of the dynamic behaviour of muscles, such as the Hill force-velocity relationship or the instantaneous stiffness of the Mirsky-Parmley model. The specific contribution of the BIPOP team has been on the numerical implementation of the contraction model as a Linear Complementarity Problem (LCP) allowing fast and precise numerical simulations \cite{22}.

6.4.4. Modeling of human balance in public transports

**Participants:** Pierre-Brice Wieber, Zohaib Aftab.

In our ongoing collaboration with the IFSTTAR (previously INRETS) on modeling human balance in public transports, we have aggregated biomechanical studies and numerical models proposed in robotics, and compared how they match or mismatch in situations of strong perturbations requiring a step to recover balance. We began developing a specific Model Predictive Control scheme for the prediction of recovery step locations with adaptive step timings, reproducing various balance recovery strategies as observed in humans. Initial results for stepping predictions have been validated against a balance recovery scenario found in the literature \cite{45}.

6.4.5. Model Predictive Control for Biped Walking

**Participants:** Pierre-Brice Wieber, Andrei Herdt, Jory Lafaye, François Keith.

We improved our Linear MPC-based walking motion generator by incorporating explicitly the robot’s kinematic constraints: polyhedral constraints on the position of the CoM ensure the kinematic feasibility of the generated walking motions for arbitrary vertical motions of the CoM. This more precise kinematic model within the LMPC allowed considering toe rotations in a safer way, considerably improving energy efficiency, naturalness of the motion, and maximal speed.

We proposed a formulation of dynamic constraints for 3D motion through simple bounds on the variables, leading to faster resolution of the corresponding optimization problem. This allowed generating three-dimensional walking on non-planar ground in real-time. Thanks to specifically enforcing leg compliance, this scheme managed additionally to reproduce the natural profiles of the CoM and the contact forces observed in human walking.

We finally refined our numerical scheme for solving Linear MPC problems in walking motion generation. We switched the underlying QP solver to enable reductions of the number of iterations through warmstart, non-empty initial active sets, and obtaining feasible solutions at each iterations, what considerably reduced the computation time, allowing 1 ms feedback loops \cite{30}, \cite{32}.
6.5. Software development

6.5.1. MECHE toolbox

Participants: Florence Bertails-Descoubes, Gilles Daviet.

The main tool developed in 2011 in the MECHE software was the hybrid iterative solver for Coulomb friction, published in [21]. In 2011, the MECHE software was extensively used to validate this new solver on large data consisting of thousands interacting fibers (subject to tens of thousands frictional contacts). Code parallelization and optimization were performed so as to speed up computations.

6.5.2. Platform development: Siconos

Participants: Vincent Acary, Olivier Bonnefon, Maurice Brémond, Franck Pérignon.

The main achievements for the SICONOS platform are

1. Automatic serialization of the whole set of classes in SICONOS
2. Improvements and development of a full auto-generated Python wrapper in the SICONOS/Front-End
3. Development of the Siconos/Multi-body library and validation on industrial examples (C60 circuit breaker of Schneider Electric)
4. New algorithms for the resolution of the discrete frictional contact problem
5. Development of \((\theta/\gamma)\)-schemes for first order dynamical systems
6. Development of routines for sliding mode control

6.5.3. AMELIF framework

Participants: Pierre-Brice Wieber, François Keith, Jory Lafaye.

The main improvements to the AMELIF framework developed this year are:

- A new package specific to torque control has been developed, that contains the algorithms required to realize a given motion with a humanoid robot: estimation of contact forces and torque computation (feedforward), feedback methods ensuring the contact force convergence. These algorithms have been tested for two humanoid platforms: the robot Romeo and the robot HRP-2.
- The dynamics algorithm has been improved, based on the expertise coming from the HuMAnS toolbox. Besides, inverse dynamic algorithms and Runge Kutta integration methods have been added.
- Finally, the bridge with the stack-of-tasks framework [55], that computes the inverse kinematics and the inverse dynamics of humanoid systems, has been enhanced to handle the binding with Python. With this framework, it is possible to use the Model Predictive Control algorithm aforementioned and to simulate the behaviour of a humanoid in a dynamic simulation realized by AMELIF. Tests are still in progress.
6. New Results

6.1. High-throughput sequence processing

- We published a book chapter on bioinformatics algorithms for GPU/manycore processors [16].
- Within the PhD of T. T. Tran, we proposed a new bit-parallel algorithm, extension of [39], as well as a new indexing structure adapted to GPUs [13].
- We proposed a new index structure specifically designed for reads produced by high throughput sequencers. It can deal both with variable or fixed length reads and can index reads in usually less memory than other classical solutions. This index has been implemented and is available online [10].
- We characterised the number of elements to be reordered when updating a full-text index such as a suffix array. We finally concluded that this number tends to be poly-logarithmic in the input length for DNA sequences [5].

6.2. Noncoding RNAs

- A. Saffarian defended her thesis on November 16. Within her thesis, we obtained two results:
  - We designed a new algorithm to produce all locally optimal secondary structures of an RNA Sequence. Locally optimal secondary structures are thermodynamically stable RNA structures that are maximal for inclusion: they cannot be extended without producing a conflict between base pairs in the secondary structure, or increasing the free energy. A journal article is in revision to *Journal of Computational Biology*.
  - We also proposed an algorithm to match a multi-structure of RNA against a sequence. A multi-structure gather several RNA structures, as real or putative structures on a same sequence, or as similar structures in a family of RNAs. A journal article was submitted to *Algorithms for Molecular Biology*.
- We published an algorithm for the comparison RNA secondary structures represented as nested arc-annotated sequences [7].
- The non-coding RNA collaborative annotation platform RNAspace is made available to the community, and published in *RNA* [3].

6.3. Genome rearrangements

- A. Thomas has started his PhD on September 2011. We already obtained two results:
  - We designed an algorithm for finding the minimal number of block interchanges required to transform a duplicated linear genome into a tandem duplicated linear genome. We provide a formula for the distance as well as a polynomial time algorithm for the sorting problem. This work has been accepted in Bioinformatics 2012.
  - We also introduced and study a new combinatorial problem, a biological phenomenon that apparently associates a significant proportion of segmental duplications in mammalians, drosophilas and bacterias to breakpoints in rearrangement events. called the Genome Dedoubling Problem. It consists in finding a minimum length rearrangement scenario required to transform a genome with duplicated segments into a non-duplicated genome such that duplications are caused by rearrangement breakpoints. We introduced new graph data structures to solve these problems. This work was presented at RECOMB’CG 2011 [11].
• We designed and applied new algorithms for inferring ultra-perfect evolution scenarios for Drosophila and mammals species [6].

• We implemented and applied the algorithm of [32] for the reconstruction of species tree from gene trees of Fungal and eukaryotes species [8].

• We proposed a new reconstruction of the architecture of the ancestral amniote genome based on the detection and assembly of ancestral genomic features conserved in extant species [9].

6.4. Non-ribosomal peptides

• A new database, called Doris (for Database Of non-Ribosomal Synthetases), has been created to extend the information we provide about non-ribosomal peptides to their producing enzymes, the non-ribosomal peptide synthetases. For the moment, a first version of the web interface has been developed by Louise Ott, an engineer from Lille1 University. More than 400 enzymes have been automatically extracted from general databases.

• A collaboration started with members of Orpailleur EPI to design a semi-automatic process to collect non-ribosomal synthetases (NRPSs). We already start adapting MODIM, a generic tool developed by Orpailleur EPI to collect and integrate data extracted from various web sources, to the specific needs of NRPSs.

• As mentioned in the software section, the source code has been reorganised by Laurie Tonon, a SED engineer, to use model view controller software architecture, implemented with Struts2.
4. New Results

4.1. Iterative Optimization for the Data Center (Alchemy-related research)

This result corresponds to research started within Alchemy, and it is less related to the objectives of ByMoore itself.

Iterative optimization is a simple but powerful approach that searches for the best possible combination of compiler optimizations for a given workload. However, each program, if not each data set, potentially favors a different combination. As a result, iterative optimization is plagued by several practical issues that prevent it from being widely used in practice: a large number of runs are required for finding the best combination; the process is inherently data set sensitive; and the exploration process incurs significant overhead that needs to be compensated for by performance benefits. Therefore, while iterative optimization has been shown to have significant performance potential, it is seldomly used in production compilers.

We propose [4] Iterative Optimization for the Data Center (IODC): we show that servers and data centers offer a context in which all of the above hurdles can be overcome. The basic idea is to spawn different combinations across workers and recollect performance statistics at the master, which then evolves to the optimum combination of compiler optimizations. IODC carefully manages costs and benefits, and is transparent to the end user.

We evaluate IODC using both MapReduce and throughput server applications. In order to reflect the large number of users interacting with the system, we gather a very large collection of data sets (at least 1000 and up to several million unique data sets per program), for a total storage of 10.7TB, and 568 days of CPU time. We report an average performance improvement of 1.48×, and up to 2.08×, for the MapReduce applications, and 1.14×, and up to 1.39×, for the throughput server applications.

4.2. Statistical Performance Comparisons of Computers (Alchemy-related research)

This result corresponds to research started within Alchemy, and it is less related to the objectives of ByMoore itself.

As a fundamental task in computer architecture research, performance comparison has been continuously hampered by the variability of computer performance. In traditional performance comparisons, the impact of performance variability is usually ignored (i.e., the means of performance measurements are compared regardless of the variability), or in the few cases where it is factored in using parametric confidence techniques, the confidence is either erroneously computed based on the distribution of performance measurements, instead of the distribution of sample mean of performance measurements, or too few measurements are considered for the distribution of sample mean to be normal. We first illustrate how such erroneous practices can lead to incorrect comparisons.

Then, we propose [3] a non-parametric Hierarchical Performance Testing (HPT) framework for performance comparison, which is significantly more practical than standard parametric confidence tests because it does not require to collect a large number of measurements in order to achieve a normal distribution of the sample mean. This HPT framework has been implemented as an open-source software.
4.3. Implementation of Signal Processing Tasks on Neuromorphic Hardware

Because of power and reliability issues, computer architects are forced to explore new types of architectures, such as heterogeneous systems embedding hardware accelerators. Neuromorphic systems are good candidate accelerators that can perform efficient and robust computing for certain classes of applications. We propose[9] a spiking neurons based accelerator, with its hardware and software, that can be easily programmed to execute a wide range of signal processing applications. A library of operators is built to facilitate implementation of various types of applications. Automated placement and routing software tools are used to map these applications onto the hardware. Altogether, this system aims at providing the user a simple way to implement signal processing tasks on neuromorphic hardware.

4.4. Automatic Abstraction and Fault Tolerance in Cortical Microarchitectures

Recent advances in the neuroscientific understanding of the brain are bringing about a tantalizing opportunity for building synthetic machines that perform computation in ways that differ radically from traditional Von Neumann machines. These brain-like architectures, which are premised on our understanding of how the human neocortex computes, are highly fault-tolerant, averaging results over large numbers of potentially faulty components, yet manage to solve very difficult problems more reliably than traditional algorithms. A key principle of operation for these architectures is that of automatic abstraction: independent features are extracted from highly disordered inputs and are used to create abstract invariant representations of the external entities. This feature extraction is applied hierarchically, leading to increasing levels of abstraction at higher levels in the hierarchy. This work[6] describes and evaluates a biologically plausible computational model for this process, and highlights the inherent fault tolerance of the biologically-inspired algorithm. We introduce a stuck-at fault model for such cortical networks, and describe how this model maps to hardware faults that can occur on commodity GPGPU cores that used to realize the model in software. We show experimentally that the model software implementation can intrinsically preserve its functionality in the presence of faulty hardware, without requiring any reprogramming or recompilation. This model is a first step towards developing a comprehensive and biologically-plausible understanding of the computational algorithms and microarchitecture of computing systems that mimic the human cortex, and to applying them to the robust implementation of computational tasks on future computing systems built of faulty components.
6. New Results

6.1. Robustness and Tolerance

6.1.1. Cubic B-spline approximation by curve unclamping

Participants: Xiao-Diao Chen, Weiyin Ma, Jean-Claude Paul.

A new approach for cubic B-spline curve approximation is presented. The method produces an approximation cubic B-spline curve tangent to a given curve at a set of selected positions, called tangent points, in a piecewise manner starting from a seed segment. A heuristic method is provided to select the tangent points. The first segment of the approximation cubic B-spline curve can be obtained using an inner point interpolation method, least-squares method or geometric Hermite method as a seed segment. The approximation curve is further extended to other tangent points one by one by curve unclamping. New tangent points can also be added, if necessary, by using the concept of the minimum shape deformation angle of an inner point for better approximation. Numerical examples show that the new method is effective in approximating a given curve and is efficient in computation [2].

6.1.2. Computing the Hausdorff distance between two B-spline curves

Participants: Xiao-Diao Chen, Weiyin Ma, Gang Xu, Jean-Claude Paul.

This paper presents a geometric pruning method for computing the Hausdorff distance between two B-spline curves. It presents a heuristic method for obtaining the one-sided Hausdorff distance in some interval as a lower bound of the Hausdorff distance, which is also possibly the exact Hausdorff distance. Then, an estimation of the upper bound of the Hausdorff distance in an sub-interval is given, which is used to eliminate the sub-intervals whose upper bounds are smaller than the present lower bound. The conditions whether the Hausdorff distance occurs at an end point of the two curves are also provided. These conditions are used to turn the Hausdorff distance computation problem between two curves into a minimum or maximum distance computation problem between a point and a curve, which can be solved well. A pruning technique based on several other elimination criteria is utilized to improve the efficiency of the new method. Numerical examples illustrate the efficiency and the robustness of the new method [3].

6.1.3. Surface area estimation of digitized 3D objects using quasi-Monte Carlo methods

Participants: Yu-Shen Liu, Jing Yi, Hu Zhang, Guo-Qin Zheng, Jean-Claude Paul.

A novel and efficient quasi-Monte Carlo method for estimating the surface area of digitized 3D objects in the volumetric representation is presented. It operates directly on the original digitized objects without any surface reconstruction procedure. Based on the Cauchy-Crofton formula from integral geometry, the method estimates the surface area of a volumetric object by counting the number of intersection points between the object’s boundary surface and a set of uniformly distributed lines generated with low-discrepancy sequences. Using a clustering technique, we also propose an effective algorithm for computing the intersection of a line with the boundary surface of volumetric objects. A number of digitized objects are used to evaluate the performance of the new method for surface area measurement [5].

6.1.4. Reverse Engineering for NC Machining Simulation

Participants: Nabil Anwer, Yi-Jun Yang, Haibi Zhao, Olivier Coma, Jean-Claude Paul.
Reverse engineering for NC Machining simulation is becoming an important component of NC simulation and verification. Design engineers need more accurate and complete CAD model of the simulated machined part for finite element analysis or parametric feature-based modeling for design modification or update. The as-cut or in process geometry should be correctly accessed in the CAD/CAM environment at any stage of the machining process. Few commercial software are addressing the reverse engineering issue and provide robust solutions. Until now, in process CAD models for NC simulation have been created with many drawbacks and inaccurate methods are proposed. Reverse engineering for NC machining simulation based on polyhedral in-process geometry is addressed. Two complementary approaches are presented here. An enriched representation embedded in ”Spring technologies Reverse engineering” or SRE file format enables to convert the polyhedral model to STEP file and a discrete shape recognition and segmentation approach provides a promising issue thanks to discrete differential geometry [43].

6.1.5. Projection of curves on B-spline surfaces using quadratic reparameterization

Participants: Yi-Jun Yang, Wei Zeng, Hui Zhang, Jun-Hai Yong, Jean-Claude Paul.

Curves on surfaces play an important role in computer aided geometric design. In this paper, we present a hyperbola approximation method based on the quadratic reparameterization of Bezier surfaces, which generates reasonable low degree curves lying completely on the surfaces by using iso-parameter curves of the reparameterized surfaces. The Hausdorff distance between the projected curve and the original curve is controlled under the user-specified distance tolerance. The projected curve is \( G^1 \) continuous, where \( T \) is the user-specified angle tolerance. Examples are given to show the performance of our algorithm [64].

6.1.6. A kind of parametric transform for trimmed surfaces

Participants: Sheng Yang, Jun-Hai Yong.

An approach for a kind of parametric transform is presented for trimmed parametric surfaces. Firstly, the characteristics of trimmed surface before and after parametric transform are evaluated. Then, an algorithm is proposed to adjust the geometric and topological data of a trimmed surface in order to achieve consistency. At last, the trimmed sphere surface is taken as example to further illustrate the algorithm [63].

6.1.7. A cell-based algorithm for evaluating directional distances in GIS

Participants: Sheng Yang, Jun-Hai Yong, Jia-Guang Sun, He-Jin Gu, Jean-Claude Paul.

Directional distance is commonly used in geographical information systems as a measure of openness. In previous works, the sweep line method and the interval tree method have been employed to evaluate the directional distances on vector maps. Both methods require rotating original maps and study points in every direction of interest. In this article, we propose a cell-based algorithm that pre-processes a map only once; that is, it subdivides the map into a group of uniform-sized cells and records each borderline of the map into the cells traversed by its corresponding line segment. Based on the pre-processing result, the neighbouring borderlines of a study point can be directly obtained through the neighbouring cells of the point, and the borderlines in a definite direction can be simply acquired through the cells traversed by the half line as well. As a result, the processing step does not need to enumerate all the borderlines of the map when determining whether a point is on a borderline or finding the nearest intersection between a half line and the borderlines. Furthermore, we implement the algorithm for determining fetch length in coastal environment. Once the pre-processing is done, the algorithm can work in a complex archipelago environment such as to calculate the fetch lengths in multiple directions, to determine the inclusion property of a point, and to deal with the singularity of a study point on a borderline [61].

6.1.8. A point-in-polygon method based on a quasi-closest point

Participants: Sheng Yang, Jun-Hai Yong, Jia-Guang Sun, He-Jin Gu, Jean-Claude Paul.
This paper presents a numerically stable solution to a point-in-polygon problem by combining the orientation method and the uniform subdivision technique. We define first a quasi-closest point that can be locally found through the uniform subdivision cells, and then we provide the criteria for determining whether a point lies inside a polygon according to the quasi-closest point. For a large number of points to be tested against the same polygon, the criteria are employed to determine the inclusion property of an empty cell as well as a test point. The experimental tests show that the new method resolves the singularity of a test point on an edge without loss of efficiency. The GIS case study also demonstrates the capability of the method to identify which region contains a test point in a map [62].

6.1.9. Using diffusion distances for flexible molecular shape comparison

Participants: Yu-Shen Liu, Qi Li, Guo-Qin Zheng, Karthik Ramani, William Benjamin.

Background: Many molecules are flexible and undergo significant shape deformation as part of their function, and yet most existing molecular shape comparison (MSC) methods treat them as rigid bodies, which may lead to incorrect shape recognition. In this paper, we present a new shape descriptor, named Diffusion Distance Shape Descriptor (DDSD), for comparing 3D shapes of flexible molecules. The diffusion distance in our work is considered as an average length of paths connecting two landmark points on the molecular shape in a sense of inner distances. The diffusion distance is robust to flexible shape deformation, in particular to topological changes, and it reflects well the molecular structure and deformation without explicit decomposition. Our DDSD is stored as a histogram which is a probability distribution of diffusion distances between all sample point pairs on the molecular surface. Finally, the problem of flexible MSC is reduced to comparison of DDSD histograms [50].

6.1.10. A fast sweeping method for computing geodesics on triangular manifolds

Participants: Song-Gang Xu, Yun-Xiang Zhang.

A wide range of applications in computer intelligence and computer graphics require computing geodesics accurately and efficiently. The fast marching method (FMM) is widely used to solve this problem, of which the complexity is $O(N \log N)$, where $N$ is the total number of nodes on the manifold. A fast sweeping method (FSM) is proposed and applied on arbitrary triangular manifolds of which the complexity is reduced to $O(N)$. By traversing the undigraph, four orderings are built to produce two groups of interfering waves, which cover all directions of characteristics. The correctness of this method is proved by analyzing the coverage of characteristics. The convergence and error estimation are also presented.

6.1.11. A torus patch approximation approach for point projection on implicit surface

Participants: Xiao-Ming Liu, Lei Yang.

Point projection on an implicit surface is essential for the geometric modeling and graphics applications of it. This paper presents a method for computing the principle curvatures and principle directions of an implicit surface. Using the principle curvatures and principle directions, we construct a torus patch to approximate the implicit surface locally. The torus patch is second order osculating to the implicit surface. By taking advantage of the approximation torus patch, this paper develops a second order geometric iterative algorithm for point projection on the implicit surface. Experiments illustrate the efficiency and less dependency on initial values of our algorithm [52].

6.1.12. Shape similarity assessment approach for CAD models based on graph edit distance

Participants: Bin Wang, Dong Li.

This paper proposes a new shape similarity assessment approach for CAD models in Boundary Representation (Brep) based on graph edit distance. A suboptimal computational procedure is performed to find the best alignment between local structures sets of attributed graphs derived from models. Assuming that only a minority of local structures characterize the functionality, we figure out the weight of every local structure in the query model through a training phase, and then evaluate the similarity between two models by calculating the weighted graph edit distance of corresponding attributed graphs. Experiment results show that our method provides solid retrieval performance on a real-world CAD model database [56].
6.1.13. Reconstructing 3D objects from 2D sectional views of engineering drawings using volume-based method

Participants: Yamei Wen, Hui Zhang, Zhongmian Yu, Jia-Guang Sun, Jean-Claude Paul.

Sectional views are widely used in engineering practice due to their clear and concise expression. However, it is difficult for computers to understand because of the large numbers of omitted entities and their diversified representations. This paper aims at reconstructing 3D models from 2D sectional views by improving the traditional volume based method. First, we present a two-stage loop searching algorithm to extract desired loops from sectional views. Then, sub-objects are identified by the hint-based feature identification algorithm with an intuitive loop-matching criterion. After that, a model-directed algorithm is proposed to guide the generation of sub-objects which are assembled together to form the final objects. The algorithm can handle full sections, partial sections and offset sections, as well as orthographic views. Multiple sectional views are supported in our algorithm. Moreover, the domain of objects is extended to inclined quadric surfaces and intersecting quadric surfaces with higher order curves. Experiment results show its practicability [60].

Participants: Wen-Ke Wang, Hui Zhang, Xiao-Ming Liu, Jean-Claude Paul.

This paper presents a necessary and sufficient condition to judge whether two cubic Beziér curves are coincident. For two cubic Beziér curves whose control points are not collinear, they are coincident if and only if their corresponding control points are coincident or one curve is the reversal of another curve. However, this is not true for the degree that is higher than 3. This paper provides a set of counterexamples of degree 4 [28].

6.1.15. Registration of point clouds using sample-sphere and adaptive distance restriction

Participants: Yu Meng, Hui Zhang.

Registration of point clouds is a fundamental problem in shape acquisition and shape modeling. In this paper, a novel technique, the sample-sphere method, is proposed to register a pair of point clouds in arbitrary initial positions. This method roughly aligns point clouds by matching pairs of triplets of points, which are approximately congruent under rigid transformation. For a given triplet of points, this method can find all its approximately congruent triplets in $O(kn \log n)$ time, where $n$ is the number of points in the point cloud, and $k$ is a constant depending only on a given tolerance to the rotation error. By employing the techniques of wide bases and largest common point set (LCP), our method is resilient to noise and outliers. Another contribution of this paper is proposing an adaptive distance restriction to improve ICP (iterative closest point) algorithm, which is a classical method to refine rough alignments. With this restriction, the improved ICP is able to reject unreasonable corresponding point pairs during each iteration, so it can precisely align the point clouds which have large non-overlapping regions [24].

6.1.16. Torus/torus intersection

Participants: Xiao-Ming Liu, Chang-Yuan Liu, Jun-Hai Yong, Jean-Claude Paul.

This paper presents a new algorithm for torus/torus intersection. The pre-image of the intersection in the parametric space of one torus is represented by an implicit equation. The pre-image is divided into one-valued function curve segments by characteristic points. The topological feature of these characteristic points is analyzed to obtain the structure of the pre-image. Intersection curves satisfying required precision are found by a self-adaptive refinement method. Experiment results are presented to illustrate the stability and efficiency of the method [21].

6.1.17. Polyline approach for approximating Hausdorff distance between planar free-form curves

Participants: Yan-Bing Bai, Jun-Hai Yong, Jean-Claude Paul, Xiao-Ming Liu.
This paper presents a practical polyline approach for approximating Hausdorff distance between planar free-form curves. After the input curves are approximated with polylines using recursively splitting method, the precise Hausdorff distance between polylines is computed as approximation of Hausdorff distance between free-form curves, and the error of approximation is controllable. The computation of Hausdorff distance between polylines is based on an incremental algorithm that computes directed Hausdorff distance from a line segment to a polyline. Furthermore, not every segment on polylines contributes to the final Hausdorff distance. Based on the bound properties of Hausdorff distance and continuity of polylines, two pruning strategies are applied in order to prune useless segments. R-Tree structure is employed as well to accelerate the pruning process. We experimented our algorithm on sets of Bezier, B-Spline and NURBS curves respectively, and there are 95% segments pruned on approximating polylines in average. Two comparisons are also presented: One is with an algorithm computing directed Hausdorff distance on polylines by building Voronoi diagram of segments, the other is with equation solving method for computing Hausdorff distance between free-form curves [1].

6.1.18. Algorithm for orthogonal projection of parametric curves onto B-spline surfaces

Participants: Hai-Chuan Song, Xiao-Ming Liu, Jean-Claude Paul.

This paper proposes an algorithm for calculating the orthogonal projection of parametric curves onto B-spline surfaces. It consists of a second order tracing method with which we construct a polyline to approximate the pre-image curve of the orthogonal projection curve in the parametric domain of the base surface. The final 3D approximate curve is obtained by mapping the approximate polyline onto the base surface. The Hausdorff distance between the exact orthogonal projection curve and the approximate curve is controlled under the user-specified distance tolerance. And the continuity of the approximate curve is $\epsilon_T^{-G^1}$, where $\epsilon_T$ is the user-specified angle tolerance. Experiments demonstrate that our algorithm is faster than the existing first order algorithms [8].

6.1.19. Converting sectional views to three orthographic views to reconstruct 3D models

Participants: Fengqing Ding, Hui Zhang, Yamei Wen.

Compared with the CSG-based approach, the Brep-based approach has several advantages to construct 3D models from 2D engineering drawings, such as the structure is simpler and the domain of objects that can be handled is wider. However, this approach cannot handle sectional views directly. In this paper, a new method of converting sectional views to three orthographic views is presented. Firstly, the views which have the same projection direction are merged into one view. If the number of views is two, then a new view will be added according to the coordinate relations. Secondly, elements which have been omitted in sectional views are recovered according to the matching information of the existing edges. Finally, the existing Brep-based approach is used to reconstruct the 3D models. The algorithm can handle full sections, broken-out sections, offset sections as well as two orthographic views. The algorithm has been validated by experiments [15].

6.1.20. Computing the Minimum Distance between Two Tori

Participants: Xiao-Ming Liu, Chang-Yuan Liu, Qiang Hu, Jun-Hai Yong.

The minimal distance computing between two tori is the basis of their collision detection and intersection. A method is proposed for discriminating three types of position relationship (i.e., inclusion, disjunction and intersection) between two tori, and for computing their minimal distance. This paper proves that the Hausdorff distance between two circles in three-dimensional space can be obtained by computing their collinear normal points, which can be calculated by solving an equation of degree 8. With classification and comparison of the collinear normal points, the minimum distance and the Hausdorff distance between these two circles are obtained. In addition, this paper proves that the position relationship between two tori relates to not only the minimum distance but also the directed Hausdorff distance between their central circles. And then the minimum distance between two tori is calculated. Numerical results are presented to illustrate the stability and efficiency of the method [20].
6.1.21. Computing the Inner Distances of Volumetric Models for Articulated Shape Description with a Visibility Graph

Participants: Yu-Shen Liu, Karthik Ramani, Min Liu.

A new visibility graph based algorithm is presented for computing the inner distances of a 3D shape represented by a volumetric model. The inner distance is defined as the length of the shortest path between landmark points within the shape. The inner distance is robust to articulation and can reflect well the deformation of a shape structure without an explicit decomposition. Our method is based on the visibility graph approach. To check the visibility between pairwise points, we propose a novel, fast, and robust visibility checking algorithm based on a clustering technique which operates directly on the volumetric model without any surface reconstruction procedure, where an octree is used for accelerating the computation. The inner distance can be used as a replacement for other distance measures to build a more accurate description for complex shapes, especially for those with articulated parts [22].

6.1.22. An extended schema and its production rule-based algorithms for assembly data exchange using IGES

Participants: Kai-Mo Hu, Bin Wang, Yong Liu, Jing Huang, Jun-Hai Yong.

Assembly data exchange and reuse play an important role in CAD and CAM in shortening the product development cycle. However, current CAD systems cannot transfer mating conditions via neutral file format, and their exported IGES files are heterogeneous. In this paper, a schema for the full data exchange of assemblies is presented based on IGES. We first design algorithms for the pre-and-post processors of parts based on solid model, in which the topologies are explicitly specified and will be referred by mating conditions, and then extend the IGES schema by introducing the Associativity Definition Entity and Associativity Instance Entity defined in IGES standard, so as to represent mating conditions. Finally, a production rule-based method is proposed to analyze and design the data exchange algorithms for assemblies. Within this schema, the heterogeneous representations of assemblies exported from different CAD systems can be processed appropriately, and the mating conditions can be properly exchanged. Experiments on the prototype system verify the robustness, correctness, and flexibility of our schema [49].

6.1.23. Robust shape normalization of 3D articulated, volumetric models

Participants: Chao Wang, Yu-Shen Liu, Min Liu, Jun-Hai Yong, Jean-Claude Paul.

3D shape normalization is a common task in various computer graphics and pattern recognition applications. It aims to normalize different objects into a canonical coordinate frame with respect to rigid transformations containing translation, rotation and scaling in order to guarantee a unique representation. However, the conventional normalization approaches do not perform well when dealing with 3D articulated objects. To address this issue, we introduce a new method for normalizing a 3D articulated object in the volumetric form. We use techniques from robust statistics to guide the classical normalization computation. The key idea is to estimate the initial normalization by using implicit shape representation, which produces a novel articulation insensitive weight function to reduce the influence of articulated deformation. We also propose and prove the articulation insensitivity of implicit shape representation. The final solution is found by means of iteratively reweighted least squares. Our method is robust to articulated deformation without any explicit shape decomposition. The experimental results and some applications are presented for demonstrating the effectiveness of our method [27].

Participants: Zhi Chen, Bin Wang, Norbert Muller, Hui Zhang, Jun-Hai Yong.
The summation of floating-point numbers is ubiquitous in computer systems, while computation implemented in fixed length floating-point arithmetic may lead to inaccurate result due to rounding error. This paper presents an efficient algorithm which produces a faithful result by combining splitting the mantissa and error-free accumulation. Each summand is split into several parts with limited significant bits, which ensures these parts can be accumulated without rounding error under certain conditions. In the implementation, we discuss how to get exponent of floating-point number quickly, which is key to decide how to split summand. Our method works on computers complying with IEEE 754 standard. The running time of our algorithm is proportional to the size of the input data, according to both analysis and numerical tests [12].

6.1.25. 3DMolNavi: A navigation system for flexible molecular shape retrieval based on histogram and dimensionality reduction

Participants: Yu-Shen Liu, Meng Wang, Jean-Claude Paul.

3DMolNavi is a web-based visualized navigation system developed for intuitively exploring flexible molecular shape retrieval. This system is based on the histogram of Inner Distance Shape Signature (IDSS) for fast retrieving molecules that are similar to a query molecule, and uses dimensionality reduction to navigate the retrieved results in 2D and 3D spaces [23].

Participants: Hui Kong, Hehua Zhang, Xiaoyu Song, Ming Gu, Jiaguang Sun.

Geometric algorithms are widely used in many scientific fields like computer vision, computer graphics. To guarantee the correctness of these algorithms, it’s important to apply formal method to them. In this paper, we propose an approach to proving the correctness of geometric algorithms. The main contribution of the paper is that a set of proof decomposition rules is proposed which can help improve the automation of the proof of geometric algorithms. We choose TLA+2, a structural specification and proof language, as our experiment environment. The case study on a classical convex hull algorithm shows the usability of the method [36].

6.1.27. Multi-resolution mesh fitting by B-spline surfaces for reverse engineering

Participants: Sen Zhang, Zhigang Li, Hui Zhang.

This paper presents a new multi-resolution mesh fitting algorithm, extending the adaptive patch-based fitting scheme where each underlying quadrilateral is recursively subdivided into four sub-patches. In this paper, the $G^3$ continuity constraints, which mainly consist of perpendicular constraints and twist compatibility constraints, are deduced for B-spline patches. In order to construct a unique B-spline patch for each quadrilateral, the mesh vertices are applied in a least-square approximation, and the energy functions associated with a patch are minimized. In contrast to the original algorithm, this paper fits the mesh into B-spline patches instead of Bézier patches with $G^1$ continuity. The B-spline patches make the algorithm have more free control points to be used for optimizing the shape of the quadrilateral patches to achieve higher flexible patch control and less recursive times [42].

6.1.28. An example-driven symbol recognition approach based on key features in engineering drawings

Participants: Tiantian Guo, Hui Zhang, Yamei Wen.

In this paper, we present an example-driven symbol recognition algorithm based on its key features in CAD engineering drawings. When user provides an example of a specific symbol, the input symbol is analyzed and its features are extracted automatically. Based on the relation representation, the constrained tree with key feature priority can be established for this type of symbol. By this means, the symbol library can be built and expanded automatically in order to handle variety engineering drawings. In the next stage of the recognition processes, we first locate the key feature nodes in drawings, and then find other elements around which satisfy the topology structure of constrained tree. If all the elements and constrains in the tree are found, the symbol object will be recognized. Because of the accurate position, unnecessary matching calculations are greatly reduced. Experimental results validate that our approach is effective [33].
6.1.29. Automatic generation of canonical views for CAD models

Participants: Kaimo Hu, Bin Wang, Bin Yuan, Junhai Yong.

Selecting the best views for 3D objects is useful for many applications. However, with the existing methods applied in CAD models, the results neither exhibit the 3D structures of the models fairly nor conform to human’s browsing habits. In this paper, we present a robust method to generate the canonical views of CAD models, and the above problem is solved by considering the geometry and visual salient features simultaneously. We first demonstrate that for a CAD model, the three coordinate axes can be approximately determined by the scaled normals of its faces, such that the pose can be robustly normalized. A graph-based algorithm is also designed to accelerate the searching process. Then, a convex hull based method is applied to infer the upright orientation. Finally, four isometric views are selected as candidates, and the one whose depth image owns the most visual features is selected. Experiments on the Engineering Shape Benchmark (ESB) show that the views generated by our method are pleasant, informative and representative. We also apply our method in the calculation of model rectilinearity, and the results demonstrate its high performance [34].

6.2. Geometric Uncertainties

6.2.1. G^n blending multiple surfaces in polar coordinates

This paper proposes a method of $G^n$ blending multiple parametric surfaces in polar coordinates. It models the geometric continuity conditions of parametric surfaces in polar coordinates and presents a mechanism of converting a Cartesian parametric surface into its polar coordinate form. The basic idea is first to re-parameterize the parametric blendees into the form of polar coordinates. Then they are blended simultaneously by a basis function in the complex domain. To extend its compatibility, we also propose a method of converting polar coordinate blending surface into N NURBS patches. One application of this technique is to fill N-sided holes. Examples are presented to show its feasibility and practicability [6].

6.2.2. Filling n-sided regions with $G^1$ triangular Coons B-spline patches

Filling n-sided regions is an essential operation in shape and surface modeling. Positional and tangential continuities are highly required in designing and manufacturing. We propose a method for filling n-sided regions with untrimmed triangular Coons B-spline patches, preserving $G^1$ continuity exactly. The algorithm first computes a central point, a central normal, the central, and the corner derivative vectors. Then the region is split into n triangular areas by connecting the central point to each corner of the boundary. These inner curves and all cross-boundary derivatives are computed fulfilling $G^1$ compatibility conditions. And finally, the triangular patches are generated in the Coons B-spline form, one boundary of which is regressed to the central vertex. Neither positional nor tangential error is introduced by this method. And only one-degree elevation is needed [54].

6.2.3. G^n Filling orbicular N-sided holes using periodic B-spline surfaces

The orbicular N-sided hole filling problem is usually introduced by filleting an end-point of a part with large radius. The existing methods based on quadrilateral partition or constrained-optimization can rarely generate high-order continuous blending surfaces under these circumstances. This paper first reparameterizes the boundary of the specified orbicular N-sided hole to ensure the compatibility of neighboring cross-boundary derivatives on the connecting points, preserving their $G^n$ continuity. Then we compute the control points of the periodic B-spline surface using the sufficient $G^n$ continuity condition on the pole and the algorithm of extending parametric surfaces. This method generates single blending surface, which can be converted into standard B spline surface by adding knots without introducing errors. It only elevates the degree of the boundary by n. The construction method is simple and efficient, without iteration nor large-scale matrix solving. It achieves $G^n$ continuity under compatible conditions. The blending examples underline its feasibility and practicability [55].
6.2.4. A Thin-plate CAD Mesh Model Splitting Approach Based on Fitting Primitives

**Participants:** Chun Geng, Hiromasa Suzuki, Dong-Ming Yan, Takasi Michikawa, Yuichi Sato, Masayoshi Hashima, Eiji Ohta.

Extracting structural information from mesh models is crucial for Simulation Driven Design (SDD) in industrial applications. Focusing on thin plate CAD mesh models (the most commonly used parts in electronic products such as PCs, mobile phones and so on), we present an algorithm based on primitive fitting for segmenting thin plate CAD mesh models into parts of three different types, two of which are extruding surfaces and the other is a lateral surface. This method can be used for solid model reconstruction in the SDD process. Our approach involves two steps. First, a completely automatic method for accurate primitive fitting on CAD meshes is proposed based on the hierarchical primitive fitting framework. In the second step, a novel procedure is proposed for splitting thin plate CAD mesh models by detecting parallel extruding surfaces and lateral surfaces. The method presented here has been proved to work smoothly in applications of real product design [46].

6.2.5. A face-based shape matching method for IGES surface model

**Participants:** Kaimo Hu, Bin Wang, Yi Gao, Qiming Yuan, Junhai Yong.

IGES is a widely used standard for mechanical data exchange. In this paper, we present a new method for the retrieval task of IGES surface model. Based on this method, a novel distinctive face selection strategy is proposed and evaluated. In the training database, each model is treated as a set of disordered faces, and their features are extracted and stored respectively. The Discounted Cumulative Gain (DCG) value of each face is then calculated and stored for later utilization. To retrieve models in the testing database, we first forecast each face’s DCG value by searching its most similar face’s DCG value in training database, and then the top k faces with highest forecasted DCGs are selected as query input. A greedy algorithm is finally applied to get the total similarity. Experimental results show that our algorithm is superior or at least comparable to some of the most powerful methods in finding parts with similar functionality in most cases [48].

6.2.6. Generating B-spline curves based on control-point interpolation

**Participants:** Jing Liu, Kan-Le Shi, Jun-Hai Yong, He-Jin Gu.

Generating smooth B-spline curves is a fundamental operation of computer aided geometric design. This paper presents a method to calculate unknown control points using specified control points and knots to generate a smooth B-spline curve. It is based on the basis-function-maximum-value parameterization introduced in this paper. This method first parameterizes all control points; then regards given control points as data points to create a fit curve by interpolation; and finally obtains the unknown control points by evaluating the corresponding parameters directly, which ensures the continuity and smoothness of the generated B-spline curve. The examples in the last section illustrate the feasibility of this method [51].

6.2.7. A new functionality-based benchmark for basic CAD Model retrieval

**Participants:** Kaimo Hu, Bin Wang, Yi Gao, Dong Li, Junhai Yong.

In this paper, we propose a new functionality-based benchmark for CAD model retrieval. Our benchmark contains 1968 frequently-used CAD models which are divided into training set and test set. The models are carefully classified by their functionalities in industry. Eight different shape descriptors are then compared using four famous evaluation measurements. The results show that models having the same functionalities do not necessarily share the same or similar shapes, hence the functionality-based retrieval methods are encouraged, which we believe will be of great help for the improvements of design reusability. Some possible future work for 3D model retrieval in mechanical domain are also proposed based on the observation of our experiments [47].

6.2.8. Shape similarity assessment approach for CAD models based on graph edit distance

**Participants:** Bin Wang, Dong Li, Kaimo Hu, Hui Zhang.
This paper proposes a new shape similarity assessment approach for CAD models in Boundary Representation (Brep) based on graph edit distance. A suboptimal computational procedure is performed to find the best alignment between local structures sets of attributed graphs derived from models. Assuming that only a minority of local structures characterize the functionality, we figure out the weight of every local structure in the query model through a training phase, and then evaluate the similarity between two models by calculating the weighted graph edit distance of corresponding attributed graphs. Experiment results show that our method provides solid retrieval performance on a real-world CAD model database [57].

6.2.9. The transition between sharp and rounded features and the manipulation of incompatible boundary in filling n-sided holes

Participants: Kan-Le Shi, Jun-Hai Yong, Peng Liu, Jia-Guang Sun, Jean-Claude Paul.

N-sided hole filling plays an important role in vertex blending. Piegl and Tiller presented an algorithm to interpolate the given boundary and cross-boundary derivatives in B-spline form. To deal with the incompatible cases that their algorithm cannot handle, we propose an extension method to manipulate the transition between sharp and rounded features. The algorithm first patches n crescent-shaped extended surfaces to the boundary with $G^2$ continuity to handle incompatibility problem in the corners. Then, we compute the inner curves and the corresponding cross-boundary derivatives fulfilling tangent and twist compatibilities. The generated B-spline Coons patches are $G^1$-continuously connected exactly, and have $\varepsilon - G^1$ continuity with the extended surfaces. Our method improves the continuity-quality of the shape and reduces the count of the inserted knots. It can be applied to all $G^0$-continuous boundary conditions without any restrictions imposed on the boundary or cross-boundary derivatives. It generates better shapes than some popular industrial modeling systems on these incompatible occasions. Some examples underline its feasibility [53].

6.2.10. Epsilon-G2 B-spline surface interpolation

Participants: Kan-Le Shi, Jun-Hai Yong, Jia-Guang Sun, Jean-Claude Paul.

This paper proposes a method to construct a B-spline surface that interpolates the specified four groups of boundary derivative curves in the B-spline form. The discontinuity can be bounded by an arbitrary geometric invariant as the tolerance. The method first handles the six types of the compatibility problems by continuity-preserving reparameterization, knot-insertion and local control-point tuning. The transformed boundary conditions are then parametrically compatible, so the Coons strategy can be applied to construct the final interpolant. Not only can it be used in the reliable geometric modeling, but the approach also can be applied to many other algorithms that require compatibility guarantee [26].

6.2.11. G2 B-spline interpolation to a closed mesh

This paper focuses on interpolating vertices and normal vectors of a closed quad-dominant mesh $1G^2$-continuously using regular Coons B-spline surfaces, which are popular in industrial CAD/CAM systems. We first decompose all non-quadrangular facets into quadrilaterals. The tangential and second-order derivative vectors are then estimated on each vertex of the quads. A least-square adjustment algorithm based on the homogeneous form of $G^2$ continuity condition is applied to achieve curvature continuity. Afterwards, the boundary curves, the first- and the second-order cross-boundary derivative curves are constructed fulfilling $G^2$ continuity and compatibility conditions. Coons B-spline patches are finally generated using these curves as boundary conditions. In this paper, the upper bound of the rank of $G^2$ continuity condition matrices is also strictly proved to be $2n-3$, and the method of tangent-vector estimation is improved to avoid petal-shaped patches in interpolating solids of revolution [7].

6.2.12. A new method for identifying and validating features from 2D sectional views

Participants: Yamei Wen, Hui Zhang, Jiaguang Sun, Jean-Claude Paul.
Feature identification is one of the key steps for 3D solids reconstruction from 2D vector engineering drawings using the volume-based method. In this paper, we propose a novel method to identify and validate features from sectional views. First, features are classified as explicit features (EPFs) and implicit features (IPFs), which are then identified in an order of priority using heuristic hints. We show that the problem of constructing EPFs can be formulated as a 0-1 integer linear program (ILP), and the IPFs are generated based on the understanding of semantic information of omitted projections in sectional views. Then, the Loop-Relation Graph (LRG) is introduced as a multi-connected-subgraph representation for describing the relations between loops and features. According to the LRG, a reasoning technique based on confidence is implemented to interactively validate features. This method can recover features without complete projections, and the level of understanding sectional views is improved. Full sections, partial sections, offset sections as well as revolved sections can be handled by our method. Several examples are provided to demonstrate the practicability of our approach [29].

6.2.13. Ridge extraction of a smooth 2-manifold surface based on vector field
Participants: Wujun Che, Xiaopeng Zhang, Yi-Kuan Zhang, Jean-Claude Paul.

This paper presents a general scheme to compute ridges on a smooth 2-manifold surface from the standpoint of a vector field. A ridge field is introduced. Starting with an initial ridge, which may or may not be umbilical, a ridge line is then traced by calculating an associated integral curve of this field in conjunction with a new projection procedure to prevent it from diverging. This projection is the first that can optimize a ridge guess to lie on a ridge line uniquely and accurately. In order to follow this scheme, we not only develop practical ridge formulae but also address their corresponding computational procedures for an analytical surface patch, especially for an implicit surface. In contrast to other existing methods, our new approach is mathematically sound and characterized by considering the full geometric structures and topological patterns of ridges on a generic smooth surface. The resulting ridges are accurate in the numerical sense and meet the requirement of high accuracy with complete topology. Although the objective of this paper is to develop a mathematically sound framework for ridges on a smooth surface, we give a comprehensive review of relevant works on both meshes and smooth surfaces for readers [11].

6.2.14. Manifold-ranking based retrieval using $k$-regular nearest neighbor graph
Participants: Bin Wang, Feng Pan, Kaimo Hu, Jean-Claude Paul.

Manifold-ranking is a powerful method in semi-supervised learning, and its performance heavily depends on the quality of the constructed graph. In this paper, we propose a novel graph structure named $k$-regular nearest neighbor ($k$-RNN) graph as well as its constructing algorithm, and apply the new graph structure in the framework of manifold-ranking based retrieval. We show that the manifold-ranking algorithm based on our proposed graph structure performs better than that of the existing graph structures such as $k$-nearest neighbor ($k$-NN) graph and connected graph in image retrieval, 2D data clustering as well as 3D model retrieval. In addition, the automatic sample reweighting and graph updating algorithms are presented for the relevance feedback of our algorithm. Experiments demonstrate that the proposed algorithm outperforms the state-of-the-art algorithms [9].

6.2.15. Efficient computation of clipped Voronoi diagram for mesh generation
Participants: Dong-Ming Yan, Wenping Wang, Bruno Lévy, Yang Liu.

The Voronoi diagram is a fundamental geometric structure widely used in various fields, especially in computer graphics and geometry computing. For a set of points in a compact domain (i.e. a bounded and closed 2D region or 3D volume), some Voronoi cells of their Voronoi diagram are infinite or partially outside of the domain, but in practice only the parts of the cells inside the domain are needed, as when computing the centroidal Voronoi tessellation. Such a Voronoi diagram confined to a compact domain is called a clipped Voronoi diagram. We present an efficient algorithm for computing the clipped Voronoi diagram for a set of sites with respect to a compact 2D region or a 3D volume. We also apply the proposed method to optimal mesh generation based on the centroidal Voronoi tessellation [30].
6.2.16. Automatic Generation of Canonical Views for CAD Models  
**Participants:** Kaimo Hu, Bin Wang, Bin Yuan, Junhai Yong.

Selecting the best views for 3D objects is useful for many applications. However, with the existing methods applied in CAD models, the results neither exhibit the 3D structures of the models fairly nor conform to human’s browsing habits. In this paper, we present a robust method to generate the canonical views of CAD models, and the above problem is solved by considering the geometry and visual salient features simultaneously. We first demonstrate that for a CAD model, the three coordinate axes can be approximately determined by the scaled normals of its faces, such that the pose can be robustly normalized. A graph-based algorithm is also designed to accelerate the searching process. Then, a convex hull based method is applied to infer the upright orientation. Finally, four isometric views are selected as candidates, and the one whose depth image owns the most visual features is selected. Experiments on the Engineering Shape Benchmark (ESB) show that the views generated by our method are pleasant, informative and representative. We also apply our method in the calculation of model rectilinearity, and the results demonstrate its high performance [35].

6.2.17. Mechanical Parts Retrieval Based on Typical Face Matching  
**Participants:** Yi Gao, Bin Wang, Kaimo Hu, Junhai Yong.

This paper presents a face-based retrieval algorithm to search mechanical parts with similar partial features. The method makes it easier to retrieve models with partial features so as to support early stage reusability. In the training phase, all the faces in the database are trained and assigned with a value indicating their distinction. Trivial faces and atypical ones are removed in this phase to improve online retrieval efficiency. In the query phase, we evaluate the distinction of the input faces by aligning them with faces in the database. A greedy algorithm is finally applied to match the input faces and the faces in the database according to their similarity order. Experimental results show that our method can provide a favorable performance when applied to retrieve the models with common partial features comparing to some other mesh-based methods [18].

6.2.18. Continuity Transition with a Single Regular Curved-Knot B-Spline Surface  
**Participants:** Kan-Le Shi, Jun-Hai Yong, Jean-Claude Paul, Jia-Guang Sun.

We propose a canonical form of the curved-knot B-spline surface called the regular curved-knot B-spline. On one hand it allows the transition of the knot vectors so that the continuity configurations of the two opposite boundaries can be different. On the other hand, the regular form achieves the simplicity in storage, evaluation and the construction algorithms, and that makes it possible to be applied in the industrial geometric modeling systems. The applications: bridging, multi-sided hole filling and irregular feature modeling, show that it is well suited for modeling complicated objects, such as a transition between sharp and rounded features. Compared with patching numbers of B-splines, it not only increases the inter-surface continuity of the shape, but also reduces the complexity of algorithms [25].

6.2.19. Meshless quadrangulation by global parameterization  
**Participants:** Er Li, Bruno Lévy, Xiaopeng Zhang, Wu-Jun Che, Weiming Dong, Jean-Claude Paul.

Point cloud is a basic description of discrete shape information. Parameterization of unorganized points is important for shape analysis and shape reconstruction of natural objects. In this paper we present a new algorithm for global parameterization of an unorganized point cloud and its application to the meshing of the cloud. Our method is guided by principal directions so as to preserve the intrinsic geometric properties. After initial estimation of principal directions, we develop a kNN(k-nearest neighbor) graph-based method to get a smooth direction field. Then the point cloud is cut to be topologically equivalent to a disk. The global parameterization is computed and its gradients align well with the guided direction field. A mixed integer solver is used to guarantee a seamless parameterization across the cut lines. The resultant parameterization can be used to triangulate and quadrangulate the point cloud simultaneously in a fully automatic manner, where the shape of the data is of any genus [19].
6.3. Computer Graphics

6.3.1. Multi-Image Based Photon Tracing for Interactive Global Illumination of Dynamic Scenes

Participants: Chunhui Yao, Bin Wang, Bin Chan, Junhai Yong, Jean-Claude Paul.

Image space photon mapping has the advantage of simple implementation on GPU without pre-computation of complex acceleration structures. However, existing approaches use only a single image for tracing caustic photons, so they are limited to computing only a part of the global illumination effects for very simple scenes. In this paper we fully extend the image space approach by using multiple environment maps for photon mapping computation to achieve interactive global illumination of dynamic complex scenes. The two key problems due to the introduction of multiple images are 1) selecting the images to ensure adequate scene coverage; and 2) reliably computing raygeometry intersections with multiple images. We present effective solutions to these problems and show that, with multiple environment maps, the image-space photon mapping approach can achieve interactive global illumination of dynamic complex scenes. The advantages of the method are demonstrated by comparison with other existing interactive global illumination methods [10].

6.3.2. Quality Solid Texture Synthesis using Position and Index Histogram Matching

Participants: Jiating Chen, Bin Wang.

The synthesis quality is one of the most important aspects in solid texture synthesis algorithms. In recent years several methods are proposed to generate high quality solid textures. However, these existing methods often suffer from the synthesis artifacts such as blurring, missing texture structures, introducing aberrant voxel colors, and so on. In this paper, we introduce a novel algorithm for synthesizing high quality solid textures from 2D exemplars. We first analyze the relevant factors for further improvements of the synthesis quality, and then adopt an optimization framework with the k-coherence search and the discrete solver for solid texture synthesis. The texture optimization approach is integrated with two new kinds of histogram matching methods, position and index histogram matching, which effectively cause the global statistics of the synthesized solid textures to match those of the exemplars. Experimental results show that our algorithm outperforms or at least is comparable to the previous solid texture synthesis algorithms in terms of the synthesis quality [44].

6.3.3. Real-time rendering of heterogeneous translucent objects with arbitrary shapes

Participants: Yajun Wang, Jiaping Wang, Nicolas Holzschuch, Kartic Subr, Jun-Hai Yong, Baining Guo.

We present a real-time algorithm for rendering translucent objects of arbitrary shapes. We approximate the scattering of light inside the objects using the diffusion equation, which we solve on-the-fly using the GPU. Our algorithm is general enough to handle arbitrary geometry, heterogeneous materials, deformable objects and modifications of lighting, all in real-time. In a pre-processing step, we discretize the object into a regular 4-connected structure (QuadGraph). Due to its regular connectivity, this structure is easily packed into a texture and stored on the GPU. At runtime, we use the QuadGraph stored on the GPU to solve the diffusion equation, in real-time, taking into account the varying input conditions: Incoming light, object material and geometry. We handle deformable objects, provided the deformation does not change the topological structure of the objects [58].

6.3.4. Fast Local Color Transfer via Dominant Colors Mapping

Participants: Weiming Dong, Guanbo Bao, Xiaopeng Zhang, Jean-Claude Paul.

We present a novel algorithm to address the above issues. Our method establishes a tight connection between the local color statistics of the source and target images. All the obvious color features can be presented in the result [45].

6.3.5. Real-time watercolor illustrations and animation on GPU

This paper presents a real-time approach to render 3D scenes with the effects of watercolor on GPU. Most processes of the approach are implemented with image-space techniques. Our algorithm renders detail layer, ambient layer and stroke layer separately, and then combines them into final result. During the rendering processes, we use screen space ambient occlusion and shadow mapping to compute shadow in much shorter time, and we use image filter approach to simulate important effects of watercolor. Because our approach is mainly implemented with image-space techniques, it is convenient to use GPU to accelerate the rendering processes and finally our approach achieves real-time speed [59].

6.3.6. A Hierarchical Grid Based Framework for Fast Collision Detection

We present a novel hierarchical grid based method for fast collision detection (CD) for deformable models on GPU architecture. A two-level grid is employed to accommodate the non-uniform distribution of practical scene geometry. A bottom-to-top method is implemented to assign the triangles into the hierarchical grid without any iteration while a deferred scheme is introduced to efficiently update the data structure. To address the issue of load balancing, which greatly influences the performance in SIMD parallelism, a propagation scheme which utilizes a parallel scan and a segmented scan is presented, distributing workloads evenly across all concurrent threads. The proposed method supports both discrete collision detection (DCD) and continuous collision detection (CCD) with self-collision. Some typical benchmarks are tested to verify the effectiveness of our method. The results highlight our speedups over prior algorithms on different commodity GPUs [17].

6.3.7. Improved Stochastic Progressive Photon Mapping with Metropolis Sampling

Participants: Jiating Chen, Bin Wang, Junhai Yong.

This paper presents an improvement to the stochastic progressive photon mapping (SPPM), a method for robustly simulating complex global illumination with distributed ray tracing effects. Normally, similar to photon mapping and other particle tracing algorithms, SPPM would become inefficient when the photons are poorly distributed. An inordinate amount of photons are required to reduce the error caused by noise and bias to acceptable levels. In order to optimize the distribution of photons, we propose an extension of SPPM with a Metropolis-Hastings algorithm, effectively exploiting local coherence among the light paths that contribute to the rendered image. A well-designed scalar contribution function is introduced as our Metropolis sampling strategy, targeting at specific parts of image areas with large error to improve the efficiency of the radiance estimator. Experimental results demonstrate that the new Metropolis sampling based approach maintains the robustness of the standard SPPM method, while significantly improving the rendering efficiency for a wide range of scenes with complex lighting [14].

6.3.8. Efficient Depth-of-Field Rendering with Adaptive Sampling and Multiscale Reconstruction

Depth-of-field is one of the most crucial rendering effects for synthesizing photorealistic images. Unfortunately, this effect is also extremely costly. It can take hundreds to thousands of samples to achieve noise-free results using Monte Carlo integration. This paper introduces an efficient adaptive depth-of-field rendering algorithm that achieves noise-free results using significantly fewer samples. Our algorithm consists of two main phases: adaptive sampling and image reconstruction. In the adaptive sampling phase, the adaptive sample density is determined by a ‘blur-size’ map and ‘pixel-variance’ map computed in the initialization. In the image reconstruction phase, based on the blur-size map, we use a novel multiscale reconstruction filter to dramatically reduce the noise in the defocused areas where the sampled radiance has high variance. Because of the efficiency of this new filter, only a few samples are required. With the combination of the adaptive sampler and the multiscale filter, our algorithm renders near-reference quality depth-of-field images with significantly fewer samples than previous techniques [13].

6.3.9. Real-Time Illumination of Complex Lights Using Divided Sampling

Participants: Chunhui Yao, Bin Wang, Junhai Yong.
Existing methods for real-time illumination of complex lights, either require long time pre-computation, or only focus on some special types of illumination. Because computing different kinds of illumination requires different sampling strategies, this paper introduces a novel efficient framework for rendering illumination of complex light sources, in which the pre-computation is not necessary. We divide the rendering equation into three parts: high-frequency term, low-frequency term and occlusion term. Each term is computed by a proper sampling strategy. High-frequency term is solved by importance sampling the BRDF, while low-frequency term is computed by importance sampling the light sources. Occlusion term is computed with depth information in screen-space, and the required number of samples is greatly reduced by interleaved sampling. Our framework is easy to implement on GPU and can solve many real-time rendering problems. We take real-time environment-map-lighting as an example for demonstrating applications of this framework. The results show that our technique can handle complete light effects with higher quality than previous works [31].

6.3.10. Fast Multi-Operator Image Resizing and Evaluation

Participants: Weiming Dong, Guanbo Bao, Xiaopeng Zhang, Jean-Claude Paul.

Current multi-operator image resizing methods succeed in generating impressive results by using image similarity measure to guide the resizing process. An optimal operation path is found in the resizing space. However, their slow resizing speed caused by inefficient computation strategy of the bidirectional patch matching becomes a drawback for practical use. In this paper, we present a novel method to address this problem. By combining seam carving with scaling and cropping, our method can realize content-aware image resizing very fast. We define cost functions combing image energy and dominant color descriptor for all the operators to evaluate the damage to both local image content and global visual effect. Therefore our algorithm can automatically find an optimal sequence of operations to resize the image by dynamic programming or greedy algorithm. We also extend our algorithm to indirect image resizing which can protect the aspect ratio of the dominant object in an image [16].

6.3.11. Real-time Volume Caustics with Image-based Photon Tracing

Participants: Yuxiang Wang, Bin Wang, Li Chen.

Rendering of volume caustics in participating media is often expensive, even with different acceleration approaches. Basic volume photon tracing is used to render such effects, but rather slow due to its massive quantity of photons to be traced. In this paper we present an image-based volume photon tracing method for rendering volume caustics at real-time frame rates. Motivated by multi-image based photon tracing, our technique uses multiple depth maps to accelerate the intersection test procedure, achieving a plausible and fast rendering of volume caustics. Each photon dynamically selects the depth map layer for intersection test, and the test converges to an approximate solution using image space methods in a few recursions. This allows us to compute photon distribution in participating media while avoiding massive computation on accurate intersection tests with scene geometry. We demonstrate that our technique, combined with photon splatting techniques, is able to render volume caustics caused by multiple refractions [39].

6.3.12. Parallel Spatial Hashing for Collision Detection of Deformable Surfaces

We present a fast collision detection method for deformable surfaces with parallel spatial hashing on GPU architecture. The efficient update and access of the uniform grid are exploited to accelerate the performance in our method. To deal with the inflexible memory system, which makes the building of stream data a challenging task on GPU, we propose to subdivide the whole workload into irregular segments and design an efficient evaluation algorithm, which employs parallel scan and stream compaction, to build the stream data in parallel. The load balancing is a key aspect that needs to be considered in the SIMD parallelism. We break the heavy and irregular collision computation down into lightweight part and heavyweight part, ensuring the later perfectly run in load balancing manner with each concurrent thread processes just a single collision. In practice, our approach can perform collision detection in tens of milliseconds on a PC with NVIDIA GTX 260 graphics card on benchmarks composed of millions of triangles. The results highlight our speedups over prior CPU-based and GPU-based algorithms [32].
6.3.13. Distribution-Aware Image Color Transfer  
**Participants:** Fuzhang Wu, Weiming Dong, Xing Mei, Xiaopeng Zhang, Xiaohong Jia, Jean-Claude Paul.

Color transfer is a practical image editing technology which is useful in various applications. An ideal color transfer algorithm should keep the scene in the source image and apply the color styles of the reference image. All the dominant color styles of the reference image should be presented in the result especially when there are similar contents in the source and reference images. We propose a robust color transfer framework to address the above issues. Our method can establish a soft connections between the local color statistics of the source and reference images. All the obvious color features can be presented in the result image, as well as the spatial distribution of the reference color pattern [40].

6.3.14. Translucent Material Transfer Based on Single Images  
**Participants:** Chao Li, Weiming Dong, Ning Zhou, Xiaopeng Zhang, Jean-Claude Paul.

Extraction and re-rendering of real materials give large contributions to various image-based applications. As one of the key properties of modeling the appearance of an object, materials mainly focus on the effects caused by light transportation. Therefore, understanding the characteristics of a complex material from a single photograph and transferring it to an object in another image becomes a very challenging problem. In this paper, we present a novel framework to transfer real translucent materials such as fruits and flowers between single images. We define a group of information which can model the attributes during the extraction and transfer process. Once we extract this information from both the source and target images, we can easily produce a realistic photograph of an object with target-like materials and suitable shading effects in the environment of sources [37].

6.3.15. Multicage Image Deformation On GPU  
**Participants:** Weiliang Meng, Xiaopeng Zhang, Weiming Dong, Jean-Claude Paul.

As a linear blending method, cage-based deformation is widely used in various applications of image and geometry processing. In most cases especially in the interactive mode, deformation based on embedded cages does not work well as some of the coefficients are not continual and make the deformation discontinuous, which means existing “spring up” phenomenon. However, it’s common for us to deform the ROI(Region of Interest) while keeping local part untouched or with only small adjustments. In this paper, we design a scheme to solve the above problem. A multicage can be generated manually or automatically, and the image deformation can be adjusted intelligently according to the local cage shape to preserve important details. On the other hand, we don’t need to care about the pixels’ position relative to the multicage. All the pixels go through the same process, and this will save a lot of time. We also design a packing method for cage coordinates to pack all the necessary coefficients into one texture. A vertex shader can be used to accelerate the deformation process, leading to realtime deformation even for large images [38].

6.3.16. Real-time volume caustics with image-based photon tracing  
**Participants:** Yuxiang Wang, Bin Wang, Li Chen.

Rendering of volume caustics in participating media is often expensive, even with different acceleration approaches. Basic volume photon tracing is used to render such effects, but rather slow due to its massive quantity of photons to be traced. In this paper we present an image-based volume photon tracing method for rendering volume caustics at real-time frame rates. Motivated by multi-image based photon tracing, our technique uses multiple depth maps to accelerate the intersection test procedure, achieving a plausible and fast rendering of volume caustics. Each photon dynamically selects the depth map layer for intersection test, and the test converges to an approximate solution using image space methods in a few recursions. This allows us to compute photon distribution in participating media while avoiding massive computation on accurate intersection tests with scene geometry. We demonstrate that our technique, combined with photon splatting techniques, is able to render volume caustics caused by multiple refractions [39].

6.3.17. Interactive Visual Simulation of Dynamic Ink Diffusion Effects  
**Participants:** Shibiao Xu, Xing Mei, Weiming Dong, Zhiyi Zhang, Xiaopeng Zhang.
This paper presents an effective method that simulates the ink diffusion process with visual plausible effects and real-time performance. Our algorithm updates the dynamic ink volume with a hybrid grid-particle representation: the fluid velocity field is calculated with a low-resolution grid structure, while the highly detailed ink effects are controlled and visualized with the particles. We propose an improved ink rendering method with particle sprites and motion blur techniques. The simulation and the rendering processes are efficiently implemented on graphics hardware for interactive frame rates. Compared to traditional simulation methods that treat water and ink as two mixable fluids, our method is simple but effective: it captures various ink effects such as pinned boundary [Chu and Tai 2005] and filament pattern [Shiny et al. 2010] with real-time performance; it allows easy interaction with the artists; it includes basic solid-fluid interaction. We believe that our method is attractive for industrial animation and art design [41].
6. New Results

6.1. Low Mach number flows simulations issue

Participants: Pascal Bruel, Tarik Kousksou.

Since the targeted flows simulations (DNS) are by essence unsteady and at low Mach number, the use of a compressible solve has to be considered with great care. As a preliminary step towards the use of a fully implicit DG approach, we have joined the group of E. Dick at the Ghent University (Belgium) to help studying different aspects linked with low Mach number flow simulations [8], [7], [3]. The question of time consistency of the hyperbolic fluxes schemes for unsteady calculations has been dealt with and some pathological behavior of schemes such as the ones belonging to the AUSM family have been evidenced. A modification of AUSM+-up that satisfies the time-step dependency as well as the suitable scaling property of the pressure-velocity coupling evidenced has been proposed and tested [6].

6.2. Simulations of jets in crossflow

Participants: Pascal Bruel, Tarik Kousksou.

In order to prepare our benchmarking activity, we have been using the LES computer code AVBP (from Cerfacs and IFP) in order to simulate a multijet in crossflow configuration corresponding to the MAVERIC flow configuration. These simulations have been done in partnership with Turbomeca. The comparisons between LES and experiments is quite encouraging. An acoustic forcing technique has been used to establish a stationary acoustic wave inside the crossflow. The mass flow rate through the different holes proved to be significantly altered by the presence of the planar acoustic wave [4].

6.3. Discontinuous Galerkin methods for compressible multiphase flows

Participants: Vincent Perrier, Erwin Franquet.

We developed discontinuous Galerkin methods for compressible multiphase flows. This method is based on the method developed in [12] concerning the modelling of multiphase flows, and on the method developed in [36] concerning multiphase flows. In the method developed in [12], the exact expression of the continuous system is unclear, and as a consequence, the cell integral that naturally appear in the discontinuous Galerkin formulation is not clearly defined. In [2], [11], we developed an original analysis of the scheme [12] by mean of a stochastic process, which gave a unified framework for defining both the numerical scheme and the continuous limit. This was then applied to multiphase flows with phase transition in [10], [1]. Our method is currently being extended to interface flows with the maximum preserving limiter developed by [38].
6. New Results

6.1. Dynamically and Heterogeneous Reconfigurable Platforms

6.1.1. New Reconfigurable Architectures

6.1.1.1. Power models of reconfigurable architectures

Participants: Robin Bonamy, Daniel Chillet, Olivier Sentieys.

Including a reconfigurable area in complex systems-on-chip is now considered as an interesting solution to reduce the area of the global system and to support high performances. But the key challenge in the context of embedded systems is currently the power budget of the system, and the designer needs some early estimations of the power consumption of its system. Power estimation for reconfigurable systems is a difficult problem because several parameters need to be taken into account to define an accurate model.

Hardware implementation of an algorithm provides different choices to the designer compared to software implementation. It is possible to vary the parallelism level or loop unrolling index, which has a direct impact on area and execution time and therefore on power and energy consumption. First we evaluated delay, area, power and energy impacts of loop transformations using High Level Synthesis tools. We have made several power measurements on a real FPGA platform and for different task implementations in order to build a model of energy consumption versus execution time. Work is in progress to also characterize energy consumption of tasks through extracting the number of elementary operators used in the hardware implemented task.

Furthermore, we also consider the opportunity of the dynamic reconfiguration, which makes possible to partially reconfigure a specific part of the circuit while the rest of the system is running. This opportunity has two main effects on power consumption. First, thanks to the area sharing ability, the global size of the device can be reduced and the static (leakage) power consumption can thus be reduced. Secondly, it is possible to delete the configuration of a part of the device which reduces the dynamic power consumption when a task is no longer used. Although the cost of the reconfiguration is still important, in some cases this technique can be interesting to reduce the power of the system. To evaluate the potential gain of the dynamic reconfiguration, we have made some measurements on a Virtex 5 board. We have defined a first model of the power consumption of the reconfiguration. This model shows that the power consumption not only depends on the bitstream file size but also on the content of the reconfiguration region [41], [42].

These experiments allow us to define energy and delay models that will be used by the operating system including a power management strategy to decide on-line which task instances must be executed to efficiently manage the available power using dynamic partial reconfiguration [82].

6.1.1.2. High-level modeling of reconfigurable architectures

Participants: Robin Bonamy, Daniel Chillet, Sébastien Pillement.

To help System-on-Chip designers to explore the large design space, high-level methodologies and tools are more and more often required. The exploration phase is particularly difficult when the system must satisfy a large number of constraints, like performance, real time and power consumption. If the classical multiprocessor system-on-chips can be modeled without any difficulty, dynamically reconfigurable embedded accelerators are not correctly covered by the usual modeling languages.

In this context, we have extended the AADL (Architecture Analysis and Design Language) language to include the reconfiguration aspect included in nowadays’ MPSoC [19], [40]. This work is part of a more general project, Open-People, which proposes complete methodology for power and energy consumption analysis. The proposal is based on AADL property extensions which are applied on component models. A three-level model has been defined for every targeted FPGA. The first level defines a generic FPGA which allows to model every possible FPGA. The second level allows the specialization of the FPGA for a specific family. Finally, the third level provides the support to describe the deployment of an application on a specific FPGA circuit.
To complete these levels of description, we started the development of techniques for constraint verifications. These developments are based on the OCL language, which allows to extract characteristics on the AADL model, compute mathematical expressions and finally verify mathematical constraints. These verifications have been developed for power and energy consumption, they include static and dynamic power estimation and soon the power consumption during the dynamic reconfiguration process.

6.1.1.3. Reconfiguration controller
Participants: Manh Pham, Daniel Chillet, Sébastien Pillement.

Dynamically reconfigurable architectures, which can offer high performance, are increasingly used in different domains. Unfortunately, lots of applications cannot benefit from this new paradigm due to large timing overhead. Even for partial reconfiguration, modifying a small region of an FPGA takes few ms. To cope with this problem we have developed an ultra-fast power-aware reconfiguration controller (UPaRC) to boost the reconfiguration throughput up to 1.433 GB/s. UPaRC not only enhance the system performance, but also auto-adapt to various performance and consumption conditions. This could enlarge the range of supported applications and can optimize power-timing trade-off of reconfiguration phase for each selected application during run-time. The energy-efficiency of UPaRC over state-of-the-art reconfiguration controllers is up to 45 times more efficient. This work has been accepted for publication in DATE’2012 [56].

6.1.2. Management of Dynamically Reconfigurable Systems

6.1.2.1. Spatio-Temporal Scheduling based on Artificial Neural Networks
Participants: Antoine Eiche, Daniel Chillet, Sébastien Pillement, Olivier Sentieys.

Management of task execution on dynamically reconfigurable accelerators is known to be a difficult problem due to the large number of possibilities of task instantiations. The problem to solve can be defined as the “spatio-temporal task scheduling”. The problem becomes even more difficult to solve when the solutions must be produced during the execution of the application, i.e. on-line. In this context, new algorithms must be defined and, to solve this problem, we propose to define a neural network based on the Hopfield model. We are therefore able to address heterogeneous multiprocessor systems and to manage the reconfigurable resources embedded within MPSoC [23]. Our latest works on this topic focused on two different issues. First we demonstrated that neural network structures used for task scheduling can continue to produce valid solutions even if one or several neurons are in fault [70]. This characteristic is very important for present and future technologies for which the fabrication process variability can lead to increase the number of defaults in the circuit. The second focus concerned the optimization of the neural network convergence by using parallel evaluation of neurons. We have shown how to define several neuron packets (from the neural network) that can be evaluated in parallel without modifying the convergence property [44], [76].

6.1.2.2. Flexible Communication OS Service
Participants: Daniel Chillet, Sébastien Pillement, Ludovic Devaux.

In a multiprocessor system, to gain the advantages of parallelism, efficient communication and memory management are highly required. Recent developments in the partial and dynamic reconfigurable computing domain demand better ways to manage simultaneous task execution. But, the requirements are slightly different from the traditional software based systems. In this context, Operating System (OS) services like scheduling, placement, inter-task communication have been developed to make such platforms flexible and self-sufficient. For task communications within flexible architectures, we defined a specific network-on-chip adapted to dynamically and partially reconfigurable resources included into modern SoC. The characterization of the DRAFT network was completed and its integration inside reconfigurable systems on chip was realized [14]. We then focused on the run-time communication service [50] and dynamic memory management [49] in reconfigurable System-on-Chips (RSoCs). We first developed a hardware communication block and the communication schemes supported by this new OS service. The originality relies on the implementation of this services directly inside the FPGA. We then demonstrated the requirements and advantages of having a local memory task or a dynamically configurable memory task, in order to improve effectiveness and efficiency of the proposed schemes.
6.1.3. Fault-Tolerant Reconfigurable Architectures

Participants: Sébastien Pillement, Manh Pham, Stanislaw Piestrak.

In terms of complex systems implementation, reconfigurable FPGA circuits are now part of the mainstream thanks to their flexibility, performances and high number of integrated resources. FPGAs enter new fields of applications such as aeronautics, military, automotive or confined control thanks to their ability to be remotely updated. However, these fields of applications correspond to harsh environments (cosmic radiation, ionizing, electromagnetic noise) and with high fault-tolerance requirements. We then propose a complete framework to design reconfigurable architecture supporting fault-tolerance mitigation scheme [58]. The proposed framework allows simulation, validation of mitigation operations, but also to size architecture resources. The physical implementation of the fault-tolerant reconfigurable platform permits to validate the proposed model and the effectiveness of the framework. This implementation shows the potential of dynamically reconfigurable architectures for supporting fault-tolerance in embedded systems. We also worked on new approach in order to include dependability in the DRAFT coarse-grained reconfigurable architecture [37].

6.1.4. Low-Power Architectures

6.1.4.1. Ultra Low-Power Architecture for Control-Oriented Applications in Wireless Sensor Nodes

Participants: Olivier Sentieys, Steven Derrien, Vivek D. Tovinakere, Philippe Quémerais, Romain Fontaine.

This research work aims at developing ultra low-power SoC for wireless sensor nodes, as an alternative to existing approaches based low-power micro-controllers. The proposed approach reduces the power consumption by using a combination of hardware specialization and power gating techniques. In particular, we use the fact that typical WSN applications are generally modeled as a set of small to medium grain tasks that are implemented on low power microcontroller using light weight thread-like OS constructs.

Rather than implementing these tasks in software, we instead propose to map each of these tasks to their own specialized hardware structures that we call a hardware micro-task. Such hardware task consists of a minimalistic (and customized) data-path controlled by a finite state machine (FSM). By customizing each of these hardware implementations to their corresponding task, we expect to significantly reduce the dynamic power dissipated by the whole system. Besides, to circumvent the increase in static power caused by the possibly numerous hardware tasks implemented in the chip, we also propose to combine our approach with power gating, so as to supply power to a hardware task only when it needs to be executed [28].

As a prof of concept, a chip has been designed and fabricated in a 65nm CMOS from STMicroelectonics using the CMP facilities. The area is about 1mm² in a QFN52 package. The circuit is a controller part of a wireless sensor network node. It embeds an OpenMSP microcontroller core with SRAM memories for data and programs and some dedicated hardware tasks to control an external radio transceiver such as the TI CC2420 commonly used in the industry.

To reduce energy consumption, low power design techniques such as power gating were used. Two power domains are implemented: one is dedicated to microcontroller and memories, while the goal of the second is to measure the efficiency of our hardware micro-task concept.

The input-output ring around the core is divided into three parts: two parts are digital I/O pads corresponding to a power domain and the third contains analog pads to control the power gating for monitoring. Our goal is to analyze the power benefits of our approach and to compare it with classical microprocessor architectures.

6.1.4.2. Wakeup Time and Wakeup Energy Estimation in Power-Gated Logic Clusters

Participants: Olivier Sentieys, Vivek D. Tovinakere.

Run-time power gating for aggressive leakage reduction has brought into focus the cost of mode transition overheads due to frequent switching between sleep and active modes of circuit operation. In order to design circuits for effective power gating, logic circuits must be characterized for overheads they present during mode transitions. We have proposed a method to determine steady-state virtual-supply voltage in active mode and hence present a model for virtual-supply voltage in terms of basic circuit parameters. Further, we derived
expressions for estimation of two mode transition overheads: wakeup time and wakeup energy for a power-gated logic cluster using the proposed model. Experimental results of application of the model to ISCAS85 benchmark circuits show that wakeup time may be estimated within an average error of 16.3% across 22× variation in sleep transistor sizes and 13× variation in circuit sizes with significant speedup in computation time compared to SPICE level circuit simulations [30], [63].

6.1.5. Arithmetic Operators for Cryptography

Participants: Arnaud Tisserand, Thomas Chabrier, Danuta Pamula.

6.1.5.1. ECC Processor with Protections Against SCA

A dedicated processor for elliptic curve cryptography (ECC) is under development. Functional units for arithmetic operations in \( \mathbb{F}_{2^m} \) and \( \mathbb{F}_p \) finite fields and 160–600-bit operands have been developed for FPGA implementation. Several protection methods against side channel attacks (SCA) have been studied. The use of some number systems, especially very redundant ones, allows to change the way some computations are performed and then their effects on side channel traces.

We propose in [83] hardware implementation of the double base number system (DBNS) random recoding of secret keys. This recoding is performed on-the-fly during the elliptic curve cryptography (ECC) scalar multiplication \( [k]P \). This leads random behavior of the point operations at the side channel level.

We started a collaboration with the University of Sfax in Tunisia on the use of ECC processor for secure communications in low-cost wireless applications. A first FPGA implementation is under development and we expect to submit our first results in 2012.

6.1.5.2. Arithmetic Operators for High-Performance Cryptography

In [32], we published an extended version of the work started in 2010 on fast algorithms and implementations of \( \mathbb{F}_{2^m} \) finite field multiplication units in FPGA. The proposed and compared methods are based on separated multiplication and reduction steps and analyzed various area and time dependency/efficiency/complexity tradeoffs.

With Mark Hamilton, PhD student in the Code and Crypto group from the University College Cork (UCC), we worked on fast algorithms and implementations of \( \mathbb{F}_p \) finite field multipliers for some specific values of \( p \). The corresponding results have been published in [46].

6.1.6. SoC Modeling and Prototyping on FPGA-based Systems

Participants: François Charot, Kevin Martin, Laurent Perraud, Charles Wagner.
SoCLib and MutekH are two software development projects to which we contribute. SoCLib (http://www.soclib.fr) is an open platform for modeling and simulation of multiprocessors system-on-chip (MP-SoC). MutekH (http://www.mutekh.org) is a free and portable operating system for embedded platforms, ranging from micro-controller to multiprocessor systems. The use of the configurable and extensible simulation model of the Altera NIOSII processor of the SoCLib library and of the MutekH operating system allows us to easily deploy software applications such as codes from MediaBench, MiBench and Cryptographic Library benchmark sets or multithreaded applications on monoprocessor and multiprocessor simulation platforms. These platforms are used on the one hand for the validation of the processor extensions automatically generated by our compilation tools and on the other hand for the measurement of the speedup achieved using these new extensions.

6.2. Compilation and Synthesis for Reconfigurable Platform

Participants: Steven Derrien, Emmanuel Casseau, Daniel Menard, François Charot, Christophe Wolinski, Olivier Sentieys, Patrice Quinton.

6.2.1. Polyhedral based loop transformations for High-Level synthesis

Participants: Steven Derrien, Antoine Morvan, Patrice Quinton.

After almost two decades of research effort, there now exists a large choice of robust and mature C to hardware tools that are used as production tools by world-class chip vendor companies. Although these tools dramatically slash design time, their ability to generate efficient accelerators is still limited, and they rely on the designer to expose parallelism and to use appropriate data layout in the source program. We believe this can be overcome by tackling the problem directly at the source level, using source-to-source optimizing compilers. More precisely, our aim is to study how polyhedral based program analysis and transformation can be used to address this problem.

In the context of the PhD of Antoine Morvan, we have studied how it was possible to improve the efficiency and applicability of nested loop pipelining (also known as nested software pipelining) in C to hardware tools. Loop pipelining is a key transformation in high-level synthesis tools as it helps maximizing both computational throughput and hardware utilization. Nevertheless, it somewhat loses its efficiency when dealing with small trip-count inner loops, as the pipeline latency overhead quickly limits its efficiency.

Even if it is possible to overcome this limitation by pipelining the execution of a whole loop nest, the applicability of nested loop pipelining has so far been limited to a very narrow subset of loops, namely perfectly nested loops with constant bounds. In this work, we have extended the applicability of nested-loop pipelining to imperfectly nested loops with affine dependencies. We have shown how such loop nest can be analyzed and, under certain conditions, how one can modify the source code in order to allow nested loop pipeline to be applied using a method called polyhedral bubble insertion. Our approach shown encouraging results and led to a publication to the IEEE International Conference on Field Programmable Technology [48] in December 2011.

6.2.2. Reconfigurable Processor Extensions Generation

Participants: Christophe Wolinski, François Charot, Erwan Raffin, Kevin Martin, Antoine Floch.

During this year, we have continued our work on the generation of reconfigurable processor extension using the constraint programming approach. Previously, we showed how all the problems ranging from instruction identification, scheduling and binding to optimized architecture synthesis can be defined and solved using the constraint programming approach. This year, a new pattern scheduling approach has been defined. It enables concurrent match selection and parallel match scheduling on the processor and extension assuming that the execution on an extension is not atomic. It means that the data produced by an extension must not necessarily be sent to the processor just after the end of processing. Thanks to that, a better scheduling can be obtained [71]. The efficient FPGA implementation of processing units require optimization of hardware resources, such as registers and multiplexers. The extension synthesis defined previously has been revisited. For applications from MediaBench, MiBench and MiCrypt benchmark sets, an improvement of 35%, after placement and routing on the Stratix2 Altera FPGA, is observed.
6.2.3. Run-time Reconfigurable Architecture Modeling

Participants: Christophe Wolinski, François Charot, Emmanuel Casseau, Daniel Menard, Antoine Floch, Erwan Raffin, Steven Derrien.

We have continued to work on the modeling problem of the run-time reconfigurable, operator-based, ROMA multimedia architecture. The ROMA processor is composed of a set of $M$ coarse-grained reconfigurable operators, $N$ data memories, a configuration memory, two interconnection networks (between operators and between operators and memories), and dedicated controllers designed for each module of the datapath. A centralized controller manages the configuration and the execution steps. The ROMA processor has three different interfaces: a data interface connected to the operator network, a control interface and a debug interface connected to the main controller. The number of operators, the number of memories and their size can be decided according to application requirements. The compilation flow of our framework rests on the use of an architecture abstract model of the targeted ROMA architecture.

During this year we have focused on the definition of the constraint model to deploy an application graph on the pipeline architecture model. The goal is here to minimize the latency of the pipeline. The main changes are at the operator and memory levels. The operators are pipelined and the dual port memories behave like circular buffers. Recall that in the case of the non pipelined model, the goal is to optimize the execution time of the application under resource constraints. We have carried out experiments to evaluate the quality of our method using different pattern libraries (patterns supported by the ROMA SWP coarse-grained reconfigurable operator, patterns extracted from the MediaBench set) [47]. In these experiments the model has no limitation in terms of number of operators and number of memories. The optimality of the solutions were proven in 93% of cases. More details can be found in [29] and in the Ph.D. thesis of Erwan Raffin [17].

In the context of the RecMotifs project, we have continued to work on a specific design flow integrating STMicroelectronics’ compiler flow. This project also allowed us to bring significant evolution to our pattern analysis software tools. The RecMotifs flow consists in a pattern analysis flow for STMicroelectronics graphml files generated by ST compiler. This flow allows pattern description (description of graphml pattern that can be used in the covering pass), type extraction, pattern generation (pattern generation on a graphml file), covering (covering of a graphml file with minimization of the parallel execution time without any resource constraints). Once the pattern analysis has been applied to the graphml files, C code regeneration can be performed using GeCos.

6.2.4. Floating-Point to Fixed-Point Conversion

Participants: Daniel Menard, Karthick Parashar, Olivier Sentieys, Romuald Rocher, Hai-Nam Nguyen.

For the fixed-point conversion process, different optimization algorithms have been tested. The aim is to minimize the implementation cost under accuracy constraint. In [54], two new algorithms for the word-length optimization procedure, based on the Greedy Randomized Adaptive Search Procedure (GRASP), are proposed. Compared to existing methods, our proposition yields better results and has a complexity between deterministic methods and stochastic methods.

6.3. Algorithm Architecture Interaction

6.3.1. Flexible hardware accelerators for biocomputing applications

Participants: Steven Derrien, Naeem Abbas, Patrice Quinton.

It is widely acknowledged that FPGA-based hardware acceleration of compute intensive bioinformatics applications can be a viable alternative to cluster (or grid) based approach as they offer very interesting MIPS/watt figure of merits. One of the issues with this technology is that it remains somewhat difficult to use and to maintain (one is rather designing a circuit rather than programming a machine).
Even though there exists C-to-hardware compilation tools (Catapult-C, Impulse-C, etc.), a common belief is that they do not generally offer good enough performance to justify the use of such reconfigurable technology. As a matter of fact, successful hardware implementations of bio-computing algorithms are manually designed at RTL level and are usually targeted to a specific system, with little if any performance portability among reconfigurable platforms.

This research work, which is part of the ANR BioWic project, aims at providing a framework for helping semi-automatic generation of high-performance hardware accelerators. In particular we expect to widen the scope of common design constraints by focusing on system-level criterions that involve both the host machine and the accelerator (workload balancing, communications and data reuse optimisations, hardware utilization rate, etc.). This research work builds upon the CAIRN research group expertise on automatic parallelization for application specific hardware accelerators and has been targeting mainstream bioinformatics applications (HMMER, ClustalW and BLAST).

Our work in 2011 extended the experiment results obtained in 2010 and led to the submission of a paper to IEEE Trans. in Parallel and Distributed Computing (the article being in revision). We also investigated another case study based on a more classical sequence comparison algorithm for which we investigated different style of architectural partitioning. This work led to a paper published in the proceedings of the ARC International Symposium [43].

6.3.2. Range Estimation and Computation Accuracy Optimization

**Participants:** Daniel Menard, Karthick Parashar, Olivier Sentieys, Romuald Rocher, Pascal Scalart, Aymen Chakhari, Jean-Charles Naud, Emmanuel Casseau, Andrei Banciu.

6.3.2.1. Range Estimation

Efficient range estimation methods are required to optimize the integer part word-length. Our previous works based on the Karhunen-Loève Expansion (KLE) have been extended in [38]. The impulse response between the input and a variable is used to propagate the KLE parameters of the inputs. Range estimation has proven to be a difficult problem for non-linear operations especially when the input data is correlated. A stochastic approach can significantly improve the results compared to the classical methods like the interval and affine arithmetic. The aim is to obtain tight intervals by adapting the bounds to a desired probability of overflows. An approach for the analysis of range uncertainties based on the Polynomial Chaos Expansion (PCE) has been developed. The PCE representation is obtained for every input variable and an analytical description of the variability of the output is determined. Furthermore, the correlation of the inputs is captured using the Nataf transform. The range is computed using a probabilistic analysis from the probability density function (PDF).

6.3.2.2. Accuracy and performance evaluation

The automation of fixed-point conversion requires generic methods to study accuracy degradation. In [51], [73] a new approach using analytical noise power propagation considering conditional structures. These structures are generated from programming language statements such as if-then-else or Switch. The proposed model takes into account two key points in fixed-point design: first, an alternative processing of noise depending on the condition; second, decision errors generated by quantization noise affecting the condition. This method is integrated in the fixed-point conversion process and uses path probabilities of execution alternatives obtained from profiling. This work extends existing analytical approaches for fixed-point conversion. Experimentations of our analytical method show that it has a fairly accurate noise power estimation compared to the real accuracy degradation. An analytical approach is studied to determine accuracy of systems including unsmooth operators. An unsmooth operator represents a function which is not derivable in all its definition interval (for example the sign operator). The classical model is no valid yet since these operators introduce errors that do not respect the Widrow assumption (their values are often higher than signal power). So an approach based on the distribution of the signal and the noise is proposed. It is applied to the sphere decoding algorithm. We also focus on recursive structure where an error influences future decision. So, the Decision Feedback Equalizer is also considered.

6.3.3. Reconfigurable Video Coding

**Participants:** Emmanuel Casseau, Olivier Sentieys, Arnaud Carer, Cécile Beaumin, Hervé Yviquel.
In the field of multimedia coding, standardization recommendations are always evolving. To reduce design time, Reconfigurable Video Coding (RVC) standard allows defining new codec algorithms based on a modular library of components. RVC dataflow-based specification formalism expressly targets multiprocessors platforms. However, software processor cannot cope with high performance and low power requirements. Hence, the mapping of RVC specifications on hardware accelerators is investigated in this work, as well as the scheduling of the functional units (FU) of the specification. Dataflow programming, such as RVC applications, express explicit parallelism within an application. Although multi-core processors are now available everywhere, few applications are able to truly exploit their multiprocessing capabilities. We describe in [69] a scheduling strategy for executing a dataflow program on multi-core architectures using distributed schedulers and lock-free communications. Actually, our goal is to design an RVC-dedicated reconfigurable architecture with various resources. Our previous results lead to the definition of a reconfigurable FIFO for optimizing cost and performance of RVC dataflow specifications by taking advantage of their dynamic behavior. We are currently working with Mickael Raulet from IETR INSA Rennes and Dr. Jani Boutellier from the University of Oulu (Finland), concerning the execution of an RVC decoder on a network of Transport Triggered Architecture (TTA) processors (proposed by the Tampere University of Technology). Thanks to its modular structure, TTA can be seen as a nice kind of CPU design to develop Application-Specific Processor. TTA processor network is connected by hardware channels so it has many similarities with RVC network. Hervé Yviquel, is expected to have a 4-month stay in 2012 in TUT to provide a functional automated flow to design TTA-based platform and compile RVC application for this platform.

6.3.4. Multi-Antenna Systems

Participants: Olivier Berder, Pascal Scalart, Quoc-Tuong Ngo.

Considering the possibility for the transmitter to get some Channel State Information (CSI) from the receiver, antenna power allocation strategies can be performed thanks to the joint optimization of linear precoder (at the transmitter) and decoder (at the receiver) according to various criteria.

A new exact solution of the maximization of the minimum Euclidean distance between received symbols has been proposed for two 16-QAM modulated symbols. This precoder shows an important enhancement of this minimum distance compared to diagonal precoders, which leads to a significant BER performance improvement. This new strategy selects the best precoding matrix among eight different expressions, depending on the value of the channel angle. Selecting only two of these expressions, this precoder was then generalized to any rectangular QAM modulation [26].

Not only the minimum Euclidean distance but also the number of neighbors providing it has an important role in reducing the error probability when a Maximum Likelihood detection is considered at the receiver. Aiming at reducing this number of neighbors, a new precoder in which the rotation parameter has no influence is proposed for two independent data streams transmitted. The expression of the new precoding strategy is less complex and the space of solution is, therefore, smaller [53], [74]. In the paper [52], we proposed the general neighbor-dmin precoder for three independent data-streams and the simulation results also confirm a significant bit-error-rate improvement of the new precoder in comparison with other traditional precoding strategies.

6.3.5. Cooperative Strategies for Low-Energy Wireless Networks

Participants: Olivier Berder, Le Quang Vinh Tran, Olivier Sentieys.

During the last decade, many works were devoted to improving the performance of relaying techniques in ad hoc networks. One promising approach consists in allowing the relay nodes to cooperate, thus using spatial diversity to increase the capacity of the system. In wireless distributed networks where multiple antennas can not be installed in one wireless node, cooperative relay and cooperative Multi-Input Multi-Output (MIMO) techniques can indeed be used to exploit spatial and temporal diversity gain in order to reduce energy consumption.
Considering a system having a two-antenna source, two one-antenna relays and a one-antenna destination, MIMO simple cooperative relay model (MSCR) and MIMO full cooperative relay model (MFCR) are proposed in comparison with MIMO normal cooperative relay model (MNCR) where the relays forward signals consecutively to destination. The energy efficiency of these models is investigated by using a realistic power consumption model where the parameters are extracted from the characteristics of CC2420, a wireless sensor transceiver widely used and commercially available. For each transmission range, the optimal cooperative scheme in terms of energy efficiency is provided by simulation results [65], [78].

A fair analytical investigation on these cooperative protocols was also performed. A lower bound for the average symbol error probability (ASEP) of full DSTC cooperative relaying system in a Rayleigh fading environment is provided. In the case when the Signal to Noise Ratio (SNR) of the relay-relay link is much greater than that of the source-relay link, the upper bound on ASEP of this system is also derived. The effect of the distance between the relays shows that the performance does not degrade so much as the distance between relays is lower than a half of the source-destination distance. Moreover, we also show that, when the error synchronization range is lower than 0.5, the impact of the transmission synchronization error of the relay-destination link on the performance is not considerable [64].

The energy efficiency of cooperative MIMO and relay techniques is also very useful for the Infrastructure to Vehicle (I2V) and Infrastructure to Infrastructure (I2I) communications in Intelligent Transport Systems (ITS) networks where the energy consumption of wireless nodes embedded on road infrastructure is constrained. Applications of cooperation between nodes to ITS networks are proposed and the performance and the energy consumption of cooperative relay and cooperative MIMO are investigated in comparison with the traditional multi-hop technique. The comparison between these cooperative techniques helps us to choose the optimal cooperative strategy in terms of energy consumption for energy constrained road infrastructure networks in ITS applications [27].

6.3.6. Opportunistic Routing

Participants: Olivier Berder, Olivier Sentieys, Ruifeng Zhang, Jean-Marie Gorce [Insa Lyon, INRIA Swing].

However, the aforementioned approaches introduce an overhead in terms of information exchange, increasing the complexity of the receivers. A simpler way of exploiting spatial diversity is referred to as opportunistic routing. In this scheme, a cluster of nodes still serves as relay candidates but only a single node in the cluster forwards the packet. This paper proposes a thorough analysis of opportunistic routing efficiency under different realistic radio channel conditions. The study aims at finding the best trade-off between two objectives: energy and latency minimizations, under a hard reliability constraint. We derive an optimal bound, namely, the Pareto front of the related optimization problem, which offers a good insight into the benefits of opportunistic routings compared with classical multi-hop routing schemes [31]. We then provided a closed-form expression of the lower bound of the energy-delay tradeoff and of energy efficiency for different channel models (additive white Gaussian noise, Rayleigh fast fading and Rayleigh block-fading) in a linear network. These analytical results are also verified in 2-dimensional Poisson networks using simulations. The closed-form expression provides a framework to evaluate the energy-delay performance and to optimize the parameters in physical layer, MAC layer and routing layer from the viewpoint of cross-layer design during the planning phase of a network.

6.3.7. Adaptive techniques for WSN power optimization

Participants: Olivier Berder, Daniel Menard, Olivier Sentieys, Mahtab Alam, Trong-Nhan Le.

Wireless sensor networks (WSNs) have obtained a great relevancy in civil as well as military applications such as environment sensing, real-time surveillance and habitat monitoring. It is difficult to design a node that is efficient for all of these different applications. The ideal sensor node would have to dynamically adapt its behavior to various parameters such as the data traffic, the channel conditions, the amount of harvested energy, its battery level, etc. Including the capability to scavenge energy from its environment, the design of an efficient power manager able to address both hardware and software processing seems very promising.
Energy modeling is an important issue for designing and dimensioning low power wireless sensor networks (WSN). In order to help the developers to optimize the energy spent by WSN nodes, a pragmatic and precise hybrid energy model is proposed. This model considers different scenarios that occur during the communication and evaluates their energy consumption based on software profiling as well as the hardware components power profiles. The proposed model is a combination of analytical derivations and real time measurements. These experiments are particularly useful to understand the medium access control (MAC) layer mechanisms, such as wake up or data collisions for the preamble sampling category, and the energy wasted by collisions can be evaluated [18], [35].

An adaptive wake-up-interval scheme for preamble sampling MAC protocols for variable traffic in WSN is then proposed. The wake-up-interval is updated based on the traffic status register (whose content depends on the presence of messages for a particular node). The results show that the sensor node adapts and converges its wake-up-interval to the best trade-off value for fixed and variable traffic patterns. Two optimization parameters (length of traffic status register and initial wake-up-interval value) are also tuned to achieve fast convergence speed for different traffic rates and variations.

A wireless body area sensor network (WBASN) demands ultra-low power and energy-efficient protocols. MAC layer plays a pivotal role for energy management in WBASN, moreover, idle listening is the dominant energy waste in most of the MAC protocols. WBASN exhibits wide range of traffic variations based on different physiological data emanating from the monitored patient. In this context, we proposed a novel energy efficient traffic-aware dynamic (TAD) MAC protocol for WBASN [36]. A comparison with other protocols for three different widely used radio chips, i.e., cc2420, cc1000 and amis52100, is presented. The results show that TAD-MAC outperforms all the other protocols under fixed and variable traffic rates.
6. New Results

6.1. Mathematical analysis of kinetic models

Participants: Aurore Back, Nicolas Besse, Emmanuel Frénod, Mathieu Lutz.

6.1.1. Asymptotic analysis of gyrokinetic models

Proceeding [52] presents the method that allows us to get the gyrokinetic Approximation of the Dynamical System satisfied by the trajectory of a particle submitted to a Strong Magnetic Field. The goal of the method is to build a change of coordinates in order to make the fast dynamics of two components of the trajectory to disappear. This change of coordinates is based on a Darboux mathematical Algorithm and on a Lie Transform. It is the first work of a forthcoming series of papers which goal is to make the Geometrical gyrokinetic Approximation a mathematically affordable theory. Review paper [51] presents the results of Two-Scale Convergence Theory and an application to Homogenization of linear Singularly Perturbed Hyperbolic Partial Differential Equations. It consists in the theoretical basis of the Two-Scale Numerical Methods.

6.1.2. Two-scale convergence with differential form

In the framework of the thesis of Aurore Back [11], we developed at two-scale convergence theory using the tools of exterior calculus and differential forms. A geometric formulation of the Vlasov-Maxwell equations was introduced and some geometric conservation properties were proved.

6.1.3. Analysis of multi-water-bag models

In the case of toroidal geometry, thanks to the strong anisotropy between parallel (to the magnetic field) and transverse direction, we could perform an asymptotic analysis of the eigenvalue problem for the integro-differential gyrowaterbag operator with two independent dimensions, the third being represented by Fourier toroidal modes. This analysis enabled us to reduce the two-dimensional integro-differential operator to a series of one-dimensional integro-differential operators the solution of which enables to obtain as well the poloidal as the radial envelope of the global eigenmodes as well as their local frequency. Note that the terms of the series can be computed numerically independently from each other as the differential variables decouple, which leads to an embarrassingly parallel algorithm. The global dispersion relation for the global eigenfrequency appears as an integral quantification relation involving the local frequency due to the property of conservation of the action. On the other hand the mathematical analysis, in particular the spectral properties, of the obtained operators has been performed. Several mathematical results on the well-posedness of gyrowaterbag models have been obtained as an exact geometric reduction of the Vlasov equation, the notion of solution differing depending on the nature of the problem being considered [14], [15], [16].

6.2. Numerical analysis

Participants: Martin Campos Pinto, Nicolas Crouseilles, Michel Mehrenberger, Eric Sonnendrücker.

6.2.1. Analysis of numerical methods for the Vlasov-Poisson system

In [47], we derive the order conditions for fourth order time splitting schemes in the case of the 1D Vlasov-Poisson system. Computations to obtain such conditions are motivated by the specific Poisson structure of the Vlasov-Poisson system: this structure is similar to Runge-Kutta-Nyström systems. The obtained conditions are proved to be the same as RKN conditions derived for ODE up to the fourth order. Numerical tests are performed and show the benefit of using high order splitting schemes in that context.
In [37], we prove enhanced error estimates for high order semi-lagrangian discretizations of the Vlasov-Poisson equation. It provides new insights into optimal numerical strategies for the numerical solution of this problem. The new error estimate $O(\min(\frac{\Delta t}{\Delta x}, 1)\Delta x^p + \Delta t^2)$ is based on advanced error estimates for semi-lagrangian schemes, also equal to shifted Strang schemes, for the discretization of the advection equation.

6.2.2. Analysis of a new particle method with deformable shapes

Particle methods are known to be simple and efficient in most practical cases, however they suffer from weak convergence properties: they only converge in a strong sense when the particles present an extended overlapping (i.e., when the number of overlapping particles tends to infinity as the mesh size $h$ of their initialization grid tends to 0), and additional constraints such as vanishing moments. In practice, extended particle overlapping can be expensive and it involves an additional parameter to be optimized, such as the overlapping exponent $q < 1$ for which the particles radius behaves like $h^q$. In PIC codes for instance, extended overlapping requires increasing the number of particles per cell together with the number of cells, which determine the radius of the particles. In many practical cases such conditions are not met, which leads to strong oscillations in the solutions. To smooth out the oscillations some methods (like the Denavit redeposition scheme, recently revisited as a Forward semi-Lagrangian scheme) use periodic remappings, but frequent remappings introduce unwanted numerical diffusion which seems to contradict the benefit of using low-diffusion particle schemes. Moreover, the vanishing moment condition prevents high orders to be achieved with positive particles.

In [44] we present a new class of particle methods with deformable shapes for transport problems that converge in the supremum norm without requiring remappings, extended overlapping or vanishing moments for the particles. Unlike the classical error analysis based on a smoothing kernel argument, our estimates hold for any particle collection with Lipschitz smoothness and compact supports that have the same scale than their initialization grid. Our results are threefold. On the theoretical side we first show that for arbitrarily smooth characteristic flow, high order convergence rates are obtained by deforming the particles with local polynomial mappings. On the practical side we provide an explicit implementation of the first order case: the resulting linearly-transformed particle (LTP) scheme consists of transporting the particle centers along the numerical flow, together with finite difference approximations of the local Jacobian matrices of the flow. For the fully discrete scheme we establish rigorous a priori error estimates and demonstrate the uniform boundedness of the particle overlapping. Finally, we describe an adaptive multilevel version of the LTP scheme that includes a local correction filter for positivity-preserving approximations.

In [45] we apply the LTP method to the 1+1d Vlasov-Poisson problem with a simple deposition scheme and show that deforming the particles helps removing the noise traditionally observed with standard PIC schemes.

6.2.3. Two-Scale Asymptotic-Preserving issues

In the submitted paper [48], we build a Two-Scale Macro-Micro decomposition of the Vlasov equation with a strong magnetic field. This consists in writing the solution of this equation as a sum of two oscillating functions with circumscribed oscillations. The first of these functions has a shape which is close to the shape of the Two-Scale limit of the solution and the second one is a correction built to offset this imposed shape. The aim of such a decomposition is to be the starting point for the construction of Two-Scale Asymptotic-Preserving Schemes. The aim of using Two-Scale Asymptotic-Preserving Schemes is first, to deal efficiently with long time scales with solutions having high frequency oscillations and second, to manage the transition between different regimes, in a unified framework.

The aim of a new starting project is to test on a simplified model the Two-Scale Asymptotic-Preserving Schemes. The model, a two dimensional in phase space Vlasov-Poisson equation with small parameter, is used for a long time simulation of a beam in a focusing channel. This work was already done in [71] in the case where the solution is approximated by the two scale limit. The goals are first to improve this approximation, by going further, to the first order one, and secondly, to replace this approximation by an exact decomposition, using the macro-micro framework. This last approach will permit to treat the case of a not necessary small parameter.
In order to accomplish the first task we started to write a PIC code which is to be integrated in SeLaLib.

6.3. Development of numerical methods

6.3.1. Application of isogeometric analysis to plasma physics simulations

Mainly around the PhD thesis of Ahmed Ratnani [13] which has been defended in October 2011, we have been using the concept of isogeometric analysis introduced by Hughes and co-workers [77] which consists in representing the computational domain as well as the numerical solution of the equations with NURBS (Non Uniform Rational B-Splines).

In [26] we introduced a time-domain conforming Finite Element solver using arbitrary order B-Splines as basis functions. The discrete function spaces used in the Finite Element formulation form a De Rham sequence, which has proved to be an important property for numerical Maxwell solvers. In particular, they allow to have a simple relation between spline coefficients of the magnetic and electric field that is independent on order and geometry for one of Ampère’s or Faraday’s law. The other then necessarily involves a discrete Hodge operator which depends on order and geometry. High-order energy conserving leap-frog schemes have been validated with this solver.

In [21], we developed an arbitrary order B-Spline Finite Element solver for the quasi-neutrality equation that is generally coupled to gyrokinetic Vlasov-solvers. Compared to the previous solver used in GYSELA which was spectral in the angular variable and second order Finite Differences in the radial variable this solver can be of high-order in both direction. This enables us for a given accuracy to decrease the number of grid points. Moreover, thanks to the periodicity in the angular variable and the tensor product structure of the problem, we could introduce a fast diagonalization method using a FFT such that the cost of the new solver only marginally depends on the order and is only slightly higher than the cost of the previously used method. Another important new algorithm introduced in this work is the decoupling of the parallel and transverse parts of the equation, by solving successively for the average value along the parallel direction and the remaining part.

In [28] we present an axisymmetric PIC code based on isogeometric analysis, which was initially the IsoPIC project (supported by CEA Gramat) of CEMRACS 2010. The goal of this study is to use it for solving the system of Vlasov-Maxwell equations. The idea is to develop an axisymmetric Finite Element PIC (Particle-In-Cell) code in which specific spline Finite Elements are used to solve the Maxwell equations (in 2D transverse electric mode) and the same spline functions serve as shape function for the particles. The computational domain itself is defined using splines or NURBS. We are in particular interested in the emission of electrons in a diode with hemispherical cathode (thanks to symmetry in \( \theta \) direction, we can consider the 2D axisymmetric geometry).

6.3.2. Spline discrete differential forms

In [11], [36] we have developed the concept of spline discrete differential forms which can be used to discretized equations defined using the notions of exterior calculus. These have been applied for the numerical solution of the Maxwell and the Vlasov equations. Hodge operators either using a dual grid or a weak formulation are developed and commuting diagram properties are proved.

6.3.3. Drift-kinetic simulations

We implemented the conservative semi-Lagrangian method in the GYSELA code which is based on the classical backward semi-Lagrangian method which is not exactly conservative. We noticed that for the conservative method it is essential that the advection field remains numerically exactly divergence free in order to avoid numerical instabilities. In addition specific limiters for the conservative method were developed and comparison between the backward semi-Lagrangian method, the conservative semi-Lagrangian method with 1D splitting and the same method with an unsplit Finite Volume like formulation in the \((r, \theta)\) plane which provides a better conservation of volume [43].
6.3.4. Waterbag simulations

In [31] we apply the multi-water-bag model and the method of moments to the Vlasov-Poisson system in a case where the solution becomes multivalued. The motivation of this study is that the kinetic Vlasov-Poisson model is very expensive to solve numerically. It can be approximated by a multi-water-bag model in order to reduce the complexity. This model amounts to solve a set of Burgers equations, which can be done easily by finite volume methods. However, the physical solution can become multivalued (filamentation appears). In this case, shocks appear in the simulation and we lose information about the filaments. To catch them, we can use a moment method. We describe here the two models and present several numerical experiments.

A linear analysis code CYLGYR based on the gyrowaterbag model in cylindrical geometry has been developed. It enables, starting from a given equilibrium configuration, to obtain the whole set of modes that can exist. It was used to validate the linear phase of the previously developed non linear semi-lagrangian gyrowaterbag code in cylindrical geometry GMWB3D-SL [61]. Excellent agreement for the growth rates (eigenvalues) and the radial envelopes (eigenfunctions) has been obtained for global eigenmodes. On the other hand the linear code CYLGYR gives results in excellent agreement with those given by the linear kinetic code KINEZERO. We are now using as well the linear gyrowaterbag code CYLGYR and the non linear code GMWB3D-SL to compare the quasi-linear and non-linear fluxes and thus measure the validity of the quasi-linear approach for gyrokinetic turbulence. Such comparisons will also be performed with the gyrokinetic code GYSELA in cylindrical geometry.

6.3.5. Validation of the quasi-linear theory

We have developed and optimized a parallel semi-Lagrangian code for the numerical resolution of the Hamiltonian Vlasov-wave model in two phase-space dimensions. Using this code to perform a statistical study on a large number of runs of the system we have showed that the quasi-linear theory, whose aim is to justify the approximation of a self-coherent hamiltonian system like the Vlasov-Poisson model by diffusive self-coherent model of Fokker-Planck type, was valid in the strongly chaotic non linear regime of 1D electrostatic turbulence provided it is regarded from a statistical point of view [17].

6.4. Plasma-wall interactions - application to ELM modes on JET

Participants: Sever Hirstoaga, Giovanni Manfredi.

The aim of [24] was to model the effect of energetic charged particles (generated during violent events known as edge-localized modes) on the divertor plates of a tokamak. We thus have developed a 1D Vlasov-Poisson code with open boundaries for both ions and electrons. This work was already described in last year’s report. In the proceedings [33] we compare the numerical results previously obtained with the Eulerian code (in [24]) to those obtained with two different aproaches: a PIC code (developed at the University of Innsbruck) and a fluid code (developed at Culham, UK) which is based on a set of Branginski-type equations. These comparisons show a very good agreement between Eulerian and PIC codes when computing the energy fluxes of both species, while the fluid code overestimates these fluxes. We also note that both the Eulerian and PIC codes yield similar results for the early burst of electrons, whereas the fluid code is not able to reproduce this effect, thus confirming its kinetic origin.

6.5. Full wave modeling of lower hybrid current drive in tokamaks

Participants: Pierre Bertrand, Simon Labrunie, Takashi Hattori, Jean Rodolphe Roche.

This work is performed in collaboration with Yves Peysson (DRFC, CEA Cadarrache). The aim of this project is to develop a finite element numerical method for the full-wave simulation of electromagnetic wave propagation in plasma. Full-wave calculations of the LH wave propagation is a challenging issue because of the short wave length with respect to the machine size. In the continuation of the works previously led in cylindrical geometry, a full toroidal description for an arbitrary poloidal cross-section of the plasma has been developed.
Since its wavelength $\lambda$ at the LH frequency is very small compared to the machine size $R$, a conventional full wave description represents a considerable numerical effort. Therefore, the problem is addressed by an appropriate mathematical finite element technique, which incorporates naturally parallel processing capabilities. This is particularly important aspect when simulations for plasmas of large size must be considered. It is based on a mixed augmented variational (weak) formulation taking account of the divergence constraint and essential boundary conditions, which provides an original and efficient scheme to describe in a global manner both propagation and absorption of electromagnetic waves in plasmas.

With such a description, usual limitations of the conventional ray tracing related to the approximation $\lambda \ll \phi_B \ll R$, where $\phi_B$ is the size of the beam transverse to the rf power flow direction, may be overcome. Since conditions are corresponding to $\lambda \ll \phi_B \sim R$, the code under development may be considered as a WKB full wave, dielectric properties being local.

The domain considered is as near as possible of the cavity filled by a tokomak plasma. Toroidal coordinates are introduced. In our approach we consider Fourier decomposition in the angular coordinate to obtain stationary Maxwell equations in a cross-section of the tokomak cavity.

A finite element method is proposed for the simulation of time-harmonic electromagnetic waves in a plasma, which is an anisotropic medium. The approach chosen here is sometimes referred to as full-wave modeling in the literature: the original Maxwell’s equations are used to obtain a second order equation for the time-harmonic electric field. These are written in a weak form using an augmented variational formulation (AVF), which takes into account the divergence. The variational formulation is then discretized using modified Taylor-Hood (nodal) elements.

During 2011 we introduced a new boundary condition in order to take account of the antenna and essential condition are considered in the code "FullWaveFEM" and new real case was considered.

### 6.6. Domain decomposition for the resolution of nonlinear equations

**Participant:** Jean Rodolphe Roche.

This a joint work with Noureddine Alaa, Professor at the Marrakech Cadi Ayyad University.

Strongly problems of parabolic equations have received considerable attentions, and various forms of this problems have been proposed in the literature, especially in the area of reaction-diffusion equations with cross-diffusion, such problems arise from biological, chemical and physical systems. Various methods have been proposed in the mathematical literature to study the existence, uniqueness and compute numerical approximation of solutions for quasi-linear partial differential equation problems. This year our we develop a numerical method to solve periodic non linear parabolic equations based on domain decomposition and optimization interior points method, see [34].

### 6.7. Inverse problem governed by Maxwell equations

**Participant:** Jean Rodolphe Roche.

This work is performed in collaboration with Jose Herskovits Norman of UFRJ, Rio de Janeiro, Antonio André Novotny from the LNCC, Petropolis, both from Brazil and Alfredo Canelas from the University of the Republic, Montevideo, Uruguay.

The industrial technique of electromagnetic casting allows for contactless heating, shaping and controlling of chemical aggressive, hot melts. The main advantage over the conventional crucible shape forming is that the liquid metal does not come into contact with the crucible wall, so there is no danger of contamination. This is very important in the preparation of very pure specimens in metallurgical experiments, as even small traces of impurities, such as carbon and sulphur, can affect the physical properties of the sample. Industrial applications are, for example, electromagnetic shaping of aluminum ingots using soft-contact confinement of the liquid metal, electromagnetic shaping of components of aeronautical engines made of superalloy materials (Ni,Ti, ...), control of the structure solidification.
The electromagnetic casting is based on the repulsive forces that an electromagnetic field produces on the surface of a mass of liquid metal. In the presence of an induced electromagnetic field, the liquid metal changes its shape until an equilibrium relation between the electromagnetic pressure and the surface tension is satisfied. The direct problem in electromagnetic casting consists in determining the equilibrium shape of the liquid metal. In general, this problem can be solved either directly studying the equilibrium equation defined on the surface of the liquid metal, or minimizing an appropriate energy functional. The main advantage of this last method is that the resulting shapes are mechanically stable.

The inverse problem consists in determining the electric currents and the induced exterior field for which the liquid metal takes on a given desired shape. This is a very important problem that one needs to solve in order to define a process of electromagnetic liquid metal forming.

In a previous work we studied the inverse electromagnetic casting problem considering the case where the inductors are made of single solid-core wires with a negligible area of the cross-section. In a second paper we considered the more realistic case where each inductor is a set of bundled insulated strands. In both cases the number of inductors was fixed in advance. This year we aim to overcome this constraint, and look for configurations of inductors considering different topologies with the purpose of obtaining better results. In order to manage this new situation we introduce a new formulation for the inverse problem using a shape functional based on the Kohn-Vogelius criterion. A topology optimization procedure is defined by means of topological derivatives, see [18] and [30]. To take account the free boundary evolution we consider a new level set method adapted to topological first and second order asymptotic topological analysis.

6.8. Diffusion of knowledge and methods towards other fields

Participant: Emmanuel Frénod.

Methods, results and more generally knowledge produced within Calvi team have been applied to environmental sciences. In [22] and [50] asymptotic methods initially designed for tokamak plasmas are applied to coastal ocean waters linked phenomena.

[38] deals with the concept of confinement of paralic ecosystems. It improves an existing model in order to account for tide oscillations in any kind of geometry such as a non-rectangular lagoons with a non-flat bottom. The model, that relies on PDEs is then implemented thanks to the finite element method. Numerical results confirm the feasibility of confinement studies thanks to the introduced model.

Methods for mass transfer modeling was applied in the haulage context in [49].
6. New Results

6.1. VMAD and LLVM

The goal is to provide a set of annotations (pragmas) that the user can insert in the source code to perform low level analyses (profiling) or optimizations (dynamic parallelization for example).

We are developing a virtual machine handling advanced dynamic analyses and transformations of programs. VMAD is organized as a sequence of basic operations, where external modules associated to specific strategies are dynamically loaded when required. The program binary files handled by VMAD are previously instrumented at compile time to include necessary data, instrumentation instructions and callbacks to the virtual machine. Dynamic information, such as memory locations of launched modules, are patched at startup in the binary file. The LLVM compiler has been extended to automatically instrument programs to meet the requirements both of VMAD and of the handled/chosen analysis and transformation strategies.

VMAD uses sampling and multi-versioning to limit the instrumentations time overhead. At runtime, targeted codes are launched by successive chunks that can be either original, instrumented or optimized/parallelized versions. After each chunk execution, decisions can be taken relatively to the current optimization strategy. At this time, VMAD is handling advanced memory access profiling through linear interpolation of the addresses, dynamic dependency analysis and version selection. The last developments are focusing on speculative polyhedral parallelization.

The profiling strategy interpolating the memory addresses accessed in a loop nest has been run on some of the SPEC2006 and Pointer Intensive benchmark suites, showing a very low time overhead, in most cases. More details are available in the research reports [46] and [47], and publications [15] and [16].

6.2. Dynamic version selector

Adaptive version selection between different parallel versions of code is necessary when the execution context of a program is not known. The execution contexts includes all or some of these possibly variable parameters: the target architecture, the load of the computer at execution time, and the input data.

We have developed a framework handling loops in the polyhedral model, that is able to take a runtime decision about which version to execute. It is based on:

- the generation of different code versions of a loop nest;
- an install-time profiling to take into account the architecture parameters, that builds a parametric ranking table between the versions;
- a runtime selection, predicting the load balance and the execution time of each code version, before executing the best one.

We showed that different versions of a code are required on several polyhedral loop nest benchmarks, depending on both the target architecture and the input data. And we showed speedups compared to any statically chosen version in all execution contexts. More details are available in publication [19].

6.3. Binary parallelization

Our work on parallelizing binary programs has continued in 2011, with several new results. The general principle is to analyze the binary code and extract a model of the most intense loops. The model has to include everything that is related to memory access, and also some part of the computations done in registers. Once a suitable model is extracted, it can be used to derive a new scheduling for each targeted loops, optimizing various criteria: this is where polyhedral techniques are used, providing algorithms to optimize
locality, parallelism, or both at the same time. After a new scheduling is computed, the transformed code is generated by a polyhedron-scanning algorithm. Our approach relies on an intermediate representation whose emphasis is on memory accesses, hiding, i.e., outlining all low-level details and retaining only what is needed by the parallelization component: we use raw C constructs, and macros to denote outlined code. Starting with the executable program, a first phase raises the code into our intermediate representation. The second phase uses a stock parallelizing component, producing a transformed C programs. The last phase lowers this intermediate representation into a new binary executable. The system then uses a run-time monitoring component (generated automatically at the same time as the parallel version) that redirects execution to the transformed loops whenever appropriate.

This year’s activity on this topic in our team has started by finalizing and presenting a paper at the IMPACT workshop [20], held during CGO’2011, in Chamonix (France). This workshop focuses on tools and techniques based on the polyhedral model. It has been interesting to hear the various reactions and remarks of researchers attending our presentation: the general position is that our work opens new perspectives on the use of the polyhedral model, and avoids to need to have a complete polyhedral tool-chain. Another major aspect is the fact that our 3-phase strategy clearly separates the polyhedral part of the whole process, in essence providing a basis for a polyhedral programming language that is slightly more general that what was considered before.

The work on this topic has continued on two directions. The first was to effectively abstract the parallelizing phase. This has been done by demonstrating the use of two distinct parallelizers: the first is PLUTO, a polyhedral locality optimizer and parallelizer, and the second is CETUS, a ‘simple’ parallelizer. The second new direction was directed by the complexity of typical “real-world” executable programs. It has consisted in developing new dependence analysis and parallelization techniques, handling more general classes of programs. This current is currently submitted for publication.

These research results will be presented at the forthcoming HiPEAC conference, to be held in Paris in January 2012. A full-length paper has been accepted for publication in ACM Transactions on Architecture and Code Optimization some time in 2012.

6.4. Modeling the dynamic behavior of executable programs

Modeling the dynamic behavior of a given program is useful for several reasons. First, it is a particular way of profiling the program, targeting non trivial characteristics of the execution. As such, it helps programmers understand the behavior of the program, and hopefully helps them optimizing it. Second, the results can be used in a compiler, using run-time information to drive static optimizations. This path has seen considerable development when it comes, for example, to sequence basic blocks so as to leverage branch predictors and/or optimize the usage of instruction caches. We ambition to take it one step further, using run-time information to help a compiler in the task of auto-parallelization. Third, modeling can be used on-line, during the execution of the program, to drive the use of dynamic optimizations.

Our first achievement in 2011 has been the presentation of our paper at the International Symposium on Performance Analysis of Software and Systems [17]. The paper describes an approach that e have called program skeletonization. The basic idea is to perform a static analysis of the code under scrutiny, and locate a small number of register assignments that completely determine the set of memory addresses the program will access. By instrumenting these elementary value assignments and extracting the ensuing computations of addresses, the amount of instrumentation can be dramatically reduced, at the cost of offloading some computations to the profiler. On average, this provides a significant gain in the time needed to obtain a memory trace, and is independent on the particular application, e.g., cache simulation, data race detection, and so on.

Our second main research direction on this topic has been the characterization of semi-regular memory accesses. Semi-regular accesses are caused by the traversal of a data structure linking successive memory cells in no particular memory order, i.e., a linked list or a tree. We have developed a modeling algorithm that is able to detect that a set of instructions perform irregular accesses that are actually highly correlated, differing only by an affine function of the enclosing loop indices. This has several implications in terms of potential
optimizations. First it exhibits a kind of abstract iterator, that can later be handled, e.g., by inspector/executor techniques. Second, it reduces the number of potential dependencies that have to be tested.

The third, most recent, research project that we have started this year is the analysis of traces of parallel programs, currently MPI programs. Parallel traces offer new research challenges, because they contain events that are only partially ordered. We have extended our loop nest recognition algorithm [7] to handle parallel traces. Our preliminary results show that this algorithm is highly effective in extracting communication patterns. This has a number of potential applications that we plan to study in the coming months.

6.5. Dynamic dependence analysis

We have started a research project on dynamic dependence analysis. The principle is to observe an execution of a given program and collect dependence information. This form of profiling is similar to memory profiling, except that to goal is to directly produce data dependencies. During collection, data dependencies are abstracted into dependence graphs which, in turn, give enough information to decide whether a given code portion is parallel and, if the answer is positive, precisely constrain the set of applicable program transformations. Our implementation currently uses our own profiling infrastructure to obtain data from a running program, and models the sequence of run-time data dependencies in a unique framework. The system is of course sensitive to the fact that the input data is representative of typical inputs: the conclusion it draws cannot be applied without resorting to speculation. Currently, we restrict the system to a parallelization assistant, whose result is a set of suggestion that the programmer is free to follow or ignore.

A fundamental characteristic of a parallelization assistant is the class of parallel constructions that it is able to extract from run-time data. We have designed the profiling component and the analysis algorithm such as to be able to represent the dependencies with various abstractions, from simple boolean dependencies to full dependence polyhedra. However, even the simplest dependence model provides useful hints to parallelize a given program. In this case, our tool flags every loop in the program as either intrinsically sequential, or potentially parallel. To make this widely usable, we have decided to target common parallel programing constructions, namely OpenMP directives. In turns out that our design is flexible enough to let the system also target loops that become parallel after simple privatization transformations. The result of profiling is thus a set of complete OpenMP directives, making the loop parallel but also instructing the compiler to take special measure for local data that (falsely) renders loop iterations dependent.

Because the general design of our dynamic dependence analysis system is generic and modular, we plan to develop and distribute software implementing our approach. This project, called Parwiz, has received support from INRIA under the form of an ADT (*Action de Développement Technologique*). The funding should let us hire an engineer for two years. Unfortunately, we have not been able to find a suitable candidate in 2011, and plan to continue the recruitment process in 2012. In the meantime, we have supervised en Argentinian student, José Cacherosky, during 4 months (from July to October 2011), as an intern with funding from the INRIA *International Internships* program. The goal of the internship was to extend our framework (developed mainly to work from binary programs) to another execution environment, namely the Java Virtual Machine. Most of the time has been spent on developing an instrumentation infrastructure, but José Cacherosky has also started the implementation of some of the parallelism detection algorithms. We plan to continue this work soon, and provide a tool that could work in several, very distinct environments. Finally, Fabrice Rastello, research scientist at the École Normale Supérieure de Lyon (with the INRIA team COMPSYS), has expressed interest in collaborating with us on this research project.

6.6. Dealing with arithmetic overflows in the polyhedral model

**Participants:** Nicolas Magaud, Julien Narboux, Éric Violand.

Our goal in collaboration with Alexandre Pilkiewicz, PhD student, and François Pottier, senior researcher at INRIA, is to prove formally the correctness of a compiler based on the polyhedral model and to integrate it in the Compcert compiler.
But as the polyhedral transformations apply to affine loop nests in a mathematical framework where each loop variable is considered to be a mathematical integer, and not a machine integer, we must therefore warrant that no arithmetic overflow occurs when the considered loop nests are executed.

We proposed a solution to produce a compiler which does not ignore the problem of overflows. Our solution consists in generating a formula which captures the presence of overflows in the program, then asking to an external tool (i.e. the iscc calculator), for a sufficient condition about the parameters which implies the absence of overflows. Finally we check this condition dynamically. If the condition holds we can use the optimized version of the program. If it does not, in order to preserve the semantics of the program we keep the original version.

Figure 3 illustrates our solution for overcoming the problem of arithmetic overflows and for ensuring the correctness of polyhedral transformations. In addition to the polyhedral optimizer, our compiler uses an oracle and a validator.

The oracle returns a boolean expression \( b \) which denotes a sufficient condition to ensure that both the original program \( \text{org} \) and the optimized program \( \text{opt} \) do not produce any overflow. Our transformation then builds a program that we call the resulting program, of the shape If \( b \) then \( \text{opt} \) else \( \text{org} \). It dynamically evaluates the boolean expression \( b \) and executes \( \text{org} \), i.e. the original program, if the condition is not fulfilled or \( \text{opt} \), i.e. the optimized program, if the condition is true. The resulting program is then transmitted to the validator.

The validator is a function which takes the original program \( \text{org} \), the optimized program \( \text{opt} \) and the resulting program, and returns a boolean: if it returns true, then the resulting program is equivalent to the original one and our compiler therefore produces the resulting program.

We now have to formally prove the validator using the Coq proof assistant.

![Diagram](image.png)

*Figure 3. A solution for overcoming the problem of arithmetic overflows*
6. New Results

6.1. NFS-related results

Concerning the number field sieve algorithm for the discrete logarithm problem in prime fields, Răzvan Barbulescu improved the theoretical complexity of the step called “individual logarithm”, using, at a crucial point, a sequence of ECM steps with well-tuned, increasing parameters. He also proved that an approach similar to Coppersmith’s factoring factory was feasible as well for discrete logarithm, yielding an improved overall complexity if heavy precomputations are allowed [21].

In 2010, Thomas Prest and Paul Zimmermann developed a new algorithm for the polynomial selection in the Number Field Sieve (NFS). This algorithm produces two non-linear polynomials, extending Montgomery’s “two quadratics” method. For degree 3, it gives two skewed polynomials with resultant $O(N^{5/4})$, which improves on Williams $O(N^{4/3})$ recent result. The paper will appear in the Journal of Symbolic Computation [13] and its impact is assessed by the fact that two preprints extending and analyzing the algorithm have already been proposed.

6.2. Ballot stuffing in a postal voting system

In collaboration between many members of the CASSIS and CARAMEL teams, we have studied a postal voting system used by the CNRS for an election involving about 30,000 voters [16]. The structure of the material can be easily understood out of a few samples of voting material (distributed to the voters), without any prior knowledge of the system. Taking advantage of some flaws in the design of the system, we have shown how to perform major ballot stuffing, making possible to change the outcome of the election. Our attack has been tested and confirmed by the CNRS, and the system was quickly fixed for the next elections.

6.3. Symmetric cryptanalysis

Mohamed Ahmed Abdelraheem, Céline Blondeau, María Naya-Plasencia, Marion Videau, and Erik Zenner have proposed an attack against ARMADILLO2, the recommended variant of a multi-purpose cryptographic primitive dedicated to hardware which has been proposed by Badel et al. in 2010. The attack uses a meet-in-the-middle technique that allows us to invert the ARMADILLO2 core function. This makes it possible to perform a key recovery attack when used as a FIL-MAC. A variant of this attack has been applied to the stream cipher derived from the PRNG mode. A (second) preimage attack is also proposed against the hash function mode. All attacks have been validated by implementing cryptanalysis on scaled variants. The experimental results match the theoretical complexities.

The underlying idea of the attacks, the parallel matching algorithm, has also been generalized. The results are presented in the paper [14].

Thomas Fuhr, Henri Gilbert, Jean-René Reinhard, and Marion Videau have studied the security of the two most recent versions of the message authentication code 128-EIA3, which was considered for adoption (and has been adopted) as a third integrity algorithm in the emerging 3GPP standard LTE. An efficient existential forgery attack against the June 2010 version of the algorithm has been presented. This attack allows, given any message and the associated MAC value under an unknown integrity key and an initial vector, to predict the MAC value of a related message under the same key and the same initial vector with a success probability 1/2. The tweaked version of the algorithm that was introduced in January 2011 to circumvent this attack has also been analysed. While this new version offers a provable resistance against similar forgery attacks under the assumption that (key, IV) pairs are never reused by any legitimate sender or receiver, some evidence is given that some of its design features limit its resilience against IV reuse. The results are presented in the paper [18].
6.4. Implementation of cryptographic pairings

The extended version of a work on parallel architectures for the computation of the $\eta_T$ pairing over supersingular elliptic curves in characteristic 2 and 3, presented at CHES 2009 then accepted at IEEE Transaction on Computers in 2010, was finally published [3]. This paper was the result of a joint effort of Jérémie Detrey and Nicolas Estibals, in collaboration with Jean-Luc Beuchat and Eiji Okamoto (University of Tsukuba, Japan), Francisco Rodríguez-Henríquez (CINVESTAV-IPN, Mexico).

Also, the work on supersingular genus-2 pairings by Diego F. Aranha (UNICAMP, Brazil), Jean-Luc Beuchat (University of Tsukuba, Japan), Jérémie Detrey and Nicolas Estibals was accepted for publication at the Cryptographers’ Track of the RSA Conference (CT-RSA 2012) [15]. Since last year, where only the Eta pairing algorithm was described, several major revisions were undertaken to improve this paper, among which a careful and detailed analysis of the various distortion maps of the considered family of hyperelliptic curves.

This study also allowed us to exhibit a somewhat simple distortion map which would enable this curve to benefit from the shorter loop of the Ate pairing algorithm. Exploring this option is currently work in progress, and the results should eventually be submitted to a journal.

6.5. Multiple-precision arithmetic

In [25], Pascal Molin showed that the error function $\text{erf}$ can be computed very efficiently using a formula involving an integral of a form appropriate for fast evaluation using the trapezoidal scheme. A rigorous analysis of the scheme in this context allows to get precise bounds on the various errors terms, and therefore to give a proven complexity result for the multiple-precision evaluation of $\text{erf}$. The good theoretical behaviour is confirmed by an implementation in Pari.

Together with David Harvey (New York University), P. Zimmermann studied the short division of long integers, i.e., the division of a $2n$-bit integer by an $n$-bit integer where only the integer quotient is wanted, or an approximation of it. They gave detailed algorithms with rigorous errors bounds, and implemented them in GNU MPFR. Using Harvey’s integer middle product code, they obtain a speedup of up to 10% with respect to the best known implementation [20].

With Guillaume Melquiond (Proval project-team, INRIA Saclay), and Prof. W. Georg Nowak (Institute of Mathematics, Vienna), P. Zimmermann worked on the numerical approximation of the Masser-Gramain constant, following some work of Gramain and Weber in 1985. This work disproves a conjecture of Gramain, and enables one to determine the following approximation of that constant:

$$1.819776 < \delta < 1.819833.$$  

This work has been completed in 2011 [12].

The article “The Great Trinomial Hunt” has been published in the Notices of the AMS [7].

6.6. Proving the complexity of computing endomorphism rings

Subsequent to the work [6] that has been finally published this year, Gaëtan Bisson has been working on rigorously proving a subexponential running time bound for computing endomorphism rings of ordinary elliptic curves over finite fields. In the end, the proof rests on only one assumption, namely the extended Riemann hypothesis (ERH) [4].

In his thesis [1], he has also made substantial advances towards the extension of these algorithms to genus 2 curves.

In studying the above-mentioned algorithms, Gaëtan Bisson, in collaboration with Andrew V. Sutherland, has designed a low-memory, Pollard-rho type algorithm for finding relations in generic groups [5].
6.7. Point counting on curves with real multiplication

Pierrick Gaudry, David Kohel and Benjamin Smith have designed a new variant of the Schoof algorithm for point counting on hyperelliptic curves, that can take advantage of the presence of the knowledge of an explicit and efficient endomorphism coming from real multiplication. In that case, the overall complexity drops from $\tilde{O}(\log^8 q)$ to $\tilde{O}(\log^5 q)$. Using our algorithm we have computed a 256-bit prime-order Jacobian, suitable for cryptographic applications, and also the order of a 1024-bit Jacobian. The corresponding paper [19] obtained the Best Paper Award at the Asiacrypt 2011 conference.

6.8. Computation of isogenies between abelian varieties

Following the work [11] of David Lubicz and Damien Robert (that has just been accepted for publication in Compositio Mathematica) about the explicit computation of isogenies using theta coordinates, Romain Cosset and Damien Robert [24] have developed further nice features. In the original paper, only $(\ell^2, \ell^2)$-isogenies between abelian surfaces were available. It is now possible to handle $(\ell, \ell)$-isogenies between genus 2 curves, thus providing a more precise tool. Two key elements were necessary: Romain Cosset gave explicit methods to transfer points between the classical representation with Mumford’s coordinates and the theta functions. This is a generalisation of the work of Van Wamelen. And Romain Cosset and Damien Robert developed an explicit algorithm to change the level in the Theta coordinates that are used to represent the geometrical objects. Many details can be found in Cosset’s thesis [2].

Using the same kind of tools, Christophe Arène and Romain Cosset [23] have constructed the first complete addition law on abelian surfaces. Although they are not yet of any practical use, completeness is a feature that is in principal interesting for cryptographic applications.

The article by Faugère, Lubicz and Robert on computing modular correspondences with Theta constants has finally appeared in Journal of Algebra [9].
5. New Results

5.1. New result 1

In [5], we explain the links between the solutions of the bidomain and monodomain models using some analytical arguments. The result is partially based on the theory of the bidomain operator explained in [2]. We can imagine several consequences to this general results, like improving the preconditionner proposed by C. Pierre [7] or derive some intermediate models.

5.2. New result 2

We computed some bidomain solutions for use by M. Pop and M. Sermesant in the STACOM’11 challenge from the MICCAI 2011 conference. They are the only bidomain simulations presented within this collaborative challenge. A collaborative paper will be published, see [8].
CARTE Project-Team

6. New Results

6.1. Resource analysis by quasi-interpretation

Participants: Guillaume Bonfante, Jean-Yves Marion.

In [15], Guillaume Bonfante, Jean-Yves Marion and Jean-Yves Moyen show how quasi-interpretations can be used to deal with the resource analysis of first order functional programs. This work has been a root for several further development in implicit computational complexity.

6.2. Characterization of programs based on embedding

Participant: Guillaume Bonfante.

So far, in the implicit complexity characterizations based on the ordering MPO developed in the team, we were using the subterm relation to compare values. In [21], we have shown that the embedding relation is a generalization of these results.

6.3. Property proofs for adversary rewrite systems

Participant: Isabelle Gnaedig.

We have continued to work on rewriting property proofs in the adversary context. Our inductive proof technique, initially developed for proving termination of rewriting for systems that do not enjoy the strong termination property, was first proposed to establish termination proofs under particular strategies: the innermost, outermost, local strategies [58].

We then have tackled the proof problem of weak properties i.e., properties that do hold only on certain derivation branches. Weak property proofs are still marginal in the domain of rewriting, probably because classical proof techniques, especially for termination, work on the rules, so that the phenomena arising in the induced rewriting relation are hidden. Our technique, developing proof trees simulating rewriting trees by abstraction and narrowing, explicitly describes the behavior of the studied property on derivation branches, allowing to establish it on good branches. In addition, it is constructive, which is very useful in the programming context: the good branches are identified at compile time, when the proof is established. At run time, derivations are computed only on a good derivation branch, which avoids using the costly breadth-first strategy.

We then have proposed a procedure, based on our inductive principle, for weak termination and C-reducibility, which can be seen as a weak notion of sufficient completeness. The procedure principle is generic and can be instantiated by specific mechanisms related to both properties [20].

6.4. Computer virology: behavioral analysis

Participants: Isabelle Gnaedig, Jean-Yves Marion, Philippe Beaucamps.

Our study on behavioural malware detection has been continued. We have been developing an approach detecting suspicious schemes on an abstract representation of the behavior of a program, by abstracting program traces, rewriting given subtraces into abstract symbols representing their functionality. Considering abstract behaviors allows us to be implementation-independent and robust to variants and mutations of malware. Suspicious behaviors are then detected by comparing trace abstractions to reference malicious behaviors.
Last year, we had proposed to abstract trace automata by rewriting them with respect to a set of predefined behavior patterns defined as a regular language described by a string rewriting system [35]. We have increased the power of our approach on two aspects. We first have modified the abstraction mechanism, keeping the abstracted patterns in the rewritten traces, by just marking them. This now allows us to handle interleaved patterns. Second, we have extended the rewriting framework to express data constraints on action parameters by using term rewriting systems. An important consequence is that, unlike in [35], using the data-flow, we can now detect information leaks in order to prevent unauthorized disclosure or modifications of information [28].

The previous approach has also been extended to a probabilistic model of rewriting, in order to express uncertainty in the behavior pattern recognition. All these results on detection of malware by behavior abstraction have been given in the PhD thesis of Philippe Beaucamps, directed by Isabelle Gnaedig and Jean-Yves Marion, and defended 14 November, 2011 [11].

6.5. Randomness and ergodicity: compressibility
**Participant:** Mathieu Hoyrup.

In [25], we solve a problem that has been open for 15 years. It relates three notions of complexity and information: Shannon information and entropy, Kolmogorov algorithmic information and Martin-Löf randomness. We obtain that the limit rate of compressibility of a random sequence equals the entropy of the underlying ergodic measure. This result is the achievement of several years of development.

6.6. Randomness and ergodicity: decomposition
**Participant:** Mathieu Hoyrup.

Results about the forecasting of the long-term statistics in dynamical systems. In previous works we studied the computability of the limit-frequencies. We had proved in particular that in general they cannot be computed, we have turned to the following question: can they be computed, allowing the observation of the system as an oracle? In [24], we obtain several positive results, leaving the general problem open.

6.7. Computability and measure theory
**Participant:** Mathieu Hoyrup.

In [26], we study the constructive content of the Radon-Nikodym theorem, show that it is not computable in general and precisely locate its non-computability in the Weihrauch lattice.

6.8. Randomness and ergodicity: limit frequencies
**Participant:** Mathieu Hoyrup.

A new constructive proof of Birkhoff’s ergodic theorem, with as an application a strengthening of former results on random elements in ergodic systems, random elements eventually reach effective closed sets of positive measure (while it was only known for a more restricted class of sets). The paper [19] is in press and will appear soon in Information and Computation.

6.9. Randomness for a class of measures
**Participant:** Mathieu Hoyrup.

New results about randomness for a class of measures (and not only for one particular measure) are presented in [14].

6.10. Decidability in Perturbed Dynamical Systems
**Participant:** Emmanuel Hainry.
We have studied the link between undecidability and robustness in dynamical systems. Indeed, undecidability occurs very easily in dynamical systems. However, there exist good decision algorithms that work for most systems that are not pathological. We argue that this decidability trait may be related to their robustness to infinitesimal noise. We have proved that in smooth dynamical systems, robustness is equivalent to decidability of the reachability problem. This result relies on various hypotheses depending on the compactness of the domain and whether time is discrete or continuous [31].

6.11. Complexity in Recursive Analysis

**Participant:** Emmanuel Hainry.

In [30], we present a characterization of polytime computable functions in the Recursive Analysis setting. This paper in fact presents a generic framework for lifting characterizations of complexity or computability classes in the classical setting into analog characterizations in Recursive Analysis.

6.12. A soft linear logic characterization of polynomial space

**Participant:** Jean-Yves Marion.

Jean-Yves Marion has worked on light (soft) linear logics with Marco Gaboardi and Simona Ronchi Della Rocca in [16]. This work is based on an extension of a soft linear lambda calculus by means of a conditional construction. It provides a correspondence with the well-known result $\text{APTIME}=\text{PSPACE}$.

6.13. From control flow analysis to complexity

**Participant:** Jean-Yves Marion.

Jean-Yves Marion proposed a type system for an imperative programming language which certifies time bounds in [27]. It is based on secure flow information analysis as proposed for instance by Bell and La Padula. Thus, a link is done between computational complexity and security-typed languages.
CASCADE Project-Team (section vide)
6. New Results

6.1. Automated Deduction

We develop general techniques which allow us to re-use available tools in order to build a new generation of solvers offering a good trade-off between expressiveness, flexibility, and scalability. We focus on the careful integration of combination techniques and rewriting techniques to design decision procedures for a wide range of verification problems. In his habilitation, Laurent Vigneron presents his contributions to the application of automated deduction for designing decision procedures and for verifying infinite systems, with a particular focus on abstract congruence closure and on verification of security protocols [17].

6.1.1. Building and verifying decision procedures

Participants: Alain Giorgetti, Olga Kouchnarenko, Christophe Ringeissen, Elena Tushkanova.

We have developed a methodology to build decision procedures by using superposition calculi which are at the core of equational theorem provers. We are interested in developing automated deduction techniques to prove properties about these superposition-based decision procedures. To this aim, we plan to further investigate the use of meta-superposition, which has been already applied to check the termination and the combinability of superposition-based procedures [25]. We are working on the development of a framework for specifying and verifying superposition-based procedures. Since these procedures are defined as inference systems, we use the Maude system based on rewriting logic as a specification and prototyping language to implement superposition and meta-superposition.

6.1.2. Combining decision procedures

Participants: Christophe Ringeissen, Michaël Rusinowitch, Valerio Senni.

Modularity is a highly desirable property in the development of satisfiability procedures. In [59] we are interested in using a dedicated superposition calculus to develop satisfiability procedures for (unions of) theories sharing counter arithmetic. In the first place, we are concerned with the termination of this calculus for theories representing data structures and their extensions. To this purpose, we prove a modularity result for termination which allows us to use our superposition calculus as a satisfiability procedure for combinations of data structures. In addition, we present a general combinability result that permits us to use our satisfiability procedures into a non-disjoint combination method à la Nelson-Oppen without loss of completeness. This latter result is useful whenever data structures are combined with theories for which superposition is not applicable, like theories of arithmetic.

6.2. Security Protocol Verification

The design of cryptographic protocols is error-prone. Without a careful analysis, subtle flaws may be discovered several years after the publication of a protocol, yielding potential harmful attacks. In this context, formal methods have proved their interest for obtaining good security guarantees. Many analysis techniques have been proposed in the literature [79]. We have edited a book [64] where each chapter presents an important and now standard analysis technique. We develop new techniques for richer primitives, wider classes of protocols and higher security guarantees.

6.2.1. Modeling complex primitives

Participants: Mathilde Arnaud, Véronique Cortier, Michaël Rusinowitch, Mathieu Turuani.

Some attacks exploit in a clever way the interaction between protocol rules and algebraic properties of cryptographic operators. In [82], we provide a list of such properties and attacks as well as existing formal approaches for analyzing cryptographic protocols under algebraic properties.
Encryption “distributing over pairs” is employed in several cryptographic protocols. We have shown that unification is decidable for an equational theory HE specifying such an encryption [18]. We model block chaining in terms of a simple, convergent, rewrite system over a signature with two disjoint sorts: list and element. and present in [65] an algorithm for deciding the unification problem modulo this rewrite system. Potential applications of this unification procedure include flaw detection for protocols employing the CBC encryption mode. We have also proposed in [13] [28] an algorithm for solving general intruder constraints in the equational theory ACI. This last result is useful for handling set datastructures and also multiple intruders.

In their seminal work Dolev and Yao used string rewriting to check protocol security against an active intruder. The main technical result and algorithm were improved by Book and Otto who formulated the security check in terms of an extended word problem for cancellation rules. We extend in [66] their main decidability result to a larger class of string rewrite systems called opt-monadic systems.

Most current techniques do not apply to protocols that perform recursive computation e.g. on a list of messages received from the network. While considering general recursive input/output actions very quickly yields undecidability, we provide NPTIME decision procedures on protocols that perform recursive tests on received messages but output messages that depend on the inputs in a standard way [26]. This is in particular the case of secured routing protocols, distributed right delegation or PKI certification paths.

We have also shown [19] that deducibility and static equivalence are decidable for the equational theories modeling trapdoor commitment and re-encryption, that are particularly relevant in the context of e-voting protocols.

6.2.2. Voting and Advanced Classes of Protocols

Participants: Mathilde Arnaud, Stefan Ciobaca, Véronique Cortier, Steve Kremer, Mathieu Turuani, Laurent Vigneron, Cyrille Wiedling.

New classes of protocols are still emerging and not all can be analysed using existing techniques. We study how to cover the emergent families of security protocols with a special focus on voting protocols.

Voting Protocols. Voting is a cornerstone of democracy and many voting systems have been proposed so far, from old paper ballot systems to purely electronic voting schemes. Although many works have been dedicated to standard protocols, very few address the challenging class of voting protocols. One major issue is the fact that privacy-related properties are stated using equivalences, which are very difficult to prove. We have studied several protocols that are currently in use:

- Helios is an open-source web-based end-to-end verifiable electronic voting system, used e.g. by UCL and the IACR association in real elections. We have discovered a vulnerability which allows an adversary to compromise the privacy of voters and we have presented a fixed version, showed to satisfy a formal definition of ballot secrecy using the applied pi calculus [39]. The vulnerability we discovered apply to some other protocols of the literature [71]. Studying further the Helios protocol, we have provided a computational proof of ballot secrecy [30].

- Norway has used e-voting in its last political election in September 2011, with more than 25 000 voters using the e-voting option. Using formal models, we have analyzed the underlying protocol w.r.t. privacy, considering several corruption scenarios [69].

- We have reviewed a postal voting system used in spring 2011 by the French research institute CNRS and designed by a French company (Tagg Informatique). We have shown how to perform major ballot stuffing, making possible to change the outcome of the election [38]. Our attack has been tested (without any prior knowledge of the system except a few samples of voting material) and confirmed by the CNRS.

Securing routing Protocols. The goal of routing protocols is to construct valid routes between distant nodes in the network. If no security is used, it is possible for an attacker to disorganize the network by maliciously interacting with the routing protocols, yielding invalid routes to be built. That is why secure versions of routing protocols are now developed. In her PhD thesis [12], Mathilde Arnaud has proposed a new model and an
associated decision procedure to check whether a routing protocol can ensure that honest nodes only accept valid routes, even if one of the nodes of the network is compromised. This result has been obtained for a bounded number of sessions, adapting constraint solving techniques.

**Automated verification of indistinguishability properties.** New emerging classes of protocols often require to model less classical security properties, such as anonymity properties, strong versions of confidentiality and resistance to offline guessing attacks. Many of these properties can be modelled using the notion of indistinguishability by an adversary, which can be conveniently modeled using process equivalences. In [67] we present a novel procedure to verify equivalence properties for a bounded number of sessions which is able to handle a large class of equational theories. Although, we were unable to prove termination of the resolution procedure, the procedure has been implemented in a prototype tool and has been effectively tested on examples, some of which were outside the scope of existing tools, including fully automated checking of anonymity of an electronic voting protocol by Fujioka et al.

### 6.2.3. Securely Composing Protocols

**Participants:** Stefan Ciobaca, Véronique Cortier, Steve Kremer.

Protocols are often built in a modular way. For example, authentication protocols may assume pre-distributed keys or may assume secure channel. However, when an authentication protocol has been proved secure assuming pre-distributed keys, there is absolutely no guarantee that it remains secure when executing a real protocol for distributing the keys. How the security of these protocols can be combined is an important issue that is studied in the PhD thesis of Stefan Ciobaca [15]. More precisely, we show how protocols sharing data can be safely interleaved, provided that they use disjoint primitives or that each common primitive contains some tag identifying each protocol, like e.g. the name of the protocol. As a sub-result, we provide sufficient and simple conditions for composing key distribution protocols with any protocol using secure channels or pre-distributed keys.

Moreover, we studied [35] whether password protocols can be safely composed, even when a same password is reused. The hypothesis that users do not reuse the same password for different protocols seems indeed unreasonable. More precisely, we present a transformation which maps a password protocol that is secure for a single protocol session (a decidable problem) to a protocol that is secure for an unbounded number of sessions. Our result provides an effective strategy to design secure password protocols: (i) design a protocol intended to be secure for one protocol session; (ii) apply our transformation and obtain a protocol which is secure for an unbounded number of sessions. Our technique also applies to compose different password protocols allowing us to obtain both inter-protocol and inter-session composition.

### 6.2.4. Soundness of the Dolev-Yao Model

**Participants:** Véronique Cortier, Guillaume Scerri.

All the previous results rely on symbolic models of protocol executions in which cryptographic primitives are abstracted by symbolic expressions. This approach enables significantly simple and often automated proofs. However, the guarantees that it offers have been quite unclear compared to cryptographic models that consider issues of complexity and probability. Cryptographic models capture a strong notion of security, guaranteed against all probabilistic polynomial-time attacks. A recent line of research consists in identifying cases where it is possible to obtain the best of both cryptographic and formal worlds in the case of public encryption: fully automated proofs and strong, clear security guarantees. We have proposed a survey [22] of the results obtained so far.

Existing soundness results for symmetric encryption are not satisfactory. This is due to the fact that dishonest keys may introduce many behaviors that cannot be easily captured in symbolic models. We discuss the difficulties and limitations of the available results in [37]. In particular, we provide several examples of protocols that are symbolically correct but computationally flawed if assuming IND-CCA2. Based on these findings, Guillaume Scerri has started a PhD thesis on designing more flexible symbolic models for cryptographic proofs. His first result is a computationally sound symbolic model in the presence of dishonestly generated keys, allowing a symbolic adversary to generate new equalities between terms, on-the-fly.
A soundness result is usually established for some set of cryptographic primitives and extending the result to encompass new primitives typically requires redoing most of the work. In [41], [40], we propose a notion of computational soundness, amenable to modular extensions. Specifically, we prove that a deduction sound implementation of some arbitrary primitives can be extended to include asymmetric encryption and public data-structures (e.g. pairings or list), without repeating the original proof effort. Furthermore, our notion of soundness concerns cryptographic primitives in a way that is independent of any protocol specification language.

6.3. Model-based Verification

We have investigated extensions of regular model-checking to new classes of rewrite relations on trees. We have studied specification and proof of modular imperative programs.

6.3.1. Safety Verification Techniques with Regular Fixpoint Computations

Participants: Roméo Courbis, Pierre-Cyrille Héam, Olga Kouchnarenko.

Term rewriting systems are now commonly used as a modelling language for programs or systems. On those rewriting based models, reachability analysis, i.e. proving or disproving that a given term is reachable from a set of input terms, provides an efficient verification technique. Many recent works have shown the relevance of regular approximation techniques to tackle in practice undecidable reachability problems.

We propose in [42] to exploit rewriting approximations developed in [87] for analysing properties of CCS specifications (without renaming). The approach has been implemented and used to verify properties of the Alternating Bit Protocol and of hardware components specifications expressed as CCS processes.

6.3.2. Rewriting-based Mathematical Model Transformations

Participant: Alain Giorgetti.

We have initiated a collaboration with the Department “Temps-Fréquence” of the FEMTO-ST institute (Franche-Comté Electronique Mécanique Thermique et Optique - Sciences et Technologies, CNRS UMR 6174) on the formalization of multiscale methods for MEMS arrays. Multiscale methods provide a solution for the simulation of large MEMS arrays, by approximating their mathematical model. The resulting approximated model can be rigorously derived from the exact one through a sequence of formal transformations that differs for each case. A great challenge is to generalize these formal computations and to automate them, at least in part. This exploratory research has been supported in 2011 by the University of Franche-Comté with a BQR (Research Quality Bonus) of 5000 euros, and by the CASSIS project with a 6 months post-doctoral position. A first contribution is the design of a rule-based transformation language and its implementation as a Maple package [72]. A second contribution is the specification of lazy rewriting modulo associativity and commutativity [29].

For a more scalable treatment of linearity we plan in a near future to detect the scalar nature of mathematical terms by assigning a type to each expression and then to develop a type-checker. We also plan to guide computation by goals, i.e. to adapt reachability analysis to mathematical models.

6.3.3. Algorithms for Tree Walking Automata

Participants: Pierre-Cyrille Héam, Vincent Hugot, Olga Kouchnarenko.

Tree walking automata are widely used to tackle data base algorithmic problems, particularly to analyse queries over XML documents. The emptiness problem for tree walking automata is known to be EXPTIME-complete. The general algorithm to solve this problem consists in transforming the tree walking automaton into a classical top-down tree automaton. The best known algorithm in the literature works in time $O(s2^n^2)$ where $n$ is the number of states of the tree walking automaton, and $s$ is the size of the alphabet. In [52] we proposed a new algorithm based on an overloop concept and working in time $O(2^n^2n)$. Then we improved our approach for deterministic tree walking automata to have in this case a $O(2^n log n)$ time complexity. Finally, we also proposed a polynomial-time approximation based semi-algorithm for the emptiness problem, providing very promising experimentations.
6.3.4. Verification of Linear Temporal Patterns over Finite and Infinite Traces

Participants: Pierre-Cyrille Héam, Vincent Hugot, Olga Kouchnarenko.

In the regular model-checking framework, reachability analysis can be guided by temporal logic properties, for instance to achieve the counter example guided abstraction refinement (CEGAR) objectives. A way to perform this analysis is to translate a temporal logic formula expressed on maximal rewriting words into a "rewrite proposition" – a propositional formula whose atoms are language comparisons, and then to generate semi-decision procedures based on (approximations of) the rewrite proposition. In [73] we investigated suitable semantics for LTL on maximal rewriting words and their influence on the feasibility of a translation, and we proposed a general scheme providing exact results on a fragment of LTL corresponding mainly to safety formulae, and approximations on a larger fragment.

We study in collaboration with A. Lanoix (LINA, Nantes) infinite state models of component-based systems supporting dynamic reconfigurations. To validate such complex systems, there is a need to check model consistency and also to ensure that dynamic reconfigurations satisfy integrity constraints, invariants, and also temporal constraints over reconfiguration sequences. In [55], we proposed to check the model consistency through reconfigurations by combining proof and bounded model-checking techniques. Furthermore, in [46] we proposed to specify dynamic reconfigurations by using more complex architectural constraints and linear temporal logic patterns. As component-based systems evolve at runtime, there is a need to evaluate these properties at runtime, even if only a partial information is expected. For this purpose we introduced a new four-valued logic with potential true and potential false values; they are chosen whenever an observed behaviour has not yet led to a violation or acceptance of the property under consideration. We then implemented the runtime verification of linear temporal patterns by reusing the FPath and FScript tools [83].

6.3.5. Lower Bounds for Computing the pro-Group Closure of a Regular Language

Participant: Pierre-Cyrille Héam.

The profinite topology is used in rational languages classification. In particular, several important decidability problems, related to the Malcev product, reduce to the computation of the closure of a rational language in the profinite topology. It is known that given a rational language by a deterministic automaton, computing a deterministic automaton accepting its profinite closure can be done with an exponential upper bound. We prove in [23] that this upper bound is also a worst case lower bound if the alphabet contains at least three letters.

6.4. Model-based Testing

Our research in Model-Based Testing (MBT) aims to extend the coverage of tests. The coverage refers to several artefacts: model, test scenario/property, and code of the program under test [60]. The test generation uses various underlying techniques such as symbolic animation of models [61] or symbolic execution of programs by means of dedicated constraints or SMT solvers, or model-checkers.

6.4.1. Automated Test Generation from Behavioral Models

Participants: Fabrice Bouquet, Pierre-Christophe Bué, Kalou Cabrera, Jérome Cantenot, Frédéric Dadeau, Stéphane Debricon, Elizabeta Fournieret, Jonathan Lasalle.

We have introduced an original model-based testing approach that takes a behavioural view (modelled in UML) of the system under testing and automatically generates test cases and executable test scripts according to model coverage criteria. We have extended this result to SysML specifications for validating embedded systems [24], [57], [56].
In the context of software evolution, we have worked on exploiting the evolution of requirements in order to classify test sequences, and precisely target the parts of the system impacted by this evolution [49], [50]. We have proposed to define the life cycle of a test via three test classes: (i) Regression, used to validate that unimpacted parts of the system did not change, (ii) Evolution, used to validate that impacted parts of the system correctly evolved, and (iii) Stagnation, used to validate that impacted parts of the system did actually evolve. The associated algorithms are under implementation in a dedicated prototype to be used in the SecureChange European project [62]. A link with the security model proof has been started with partners of the project in [51] that allows to generate test needs associated to security properties verified on model.

6.4.2. Scenario-Based Verification and Validation

Participants: Fabrice Bouquet, Kalou Cabrera, Frédéric Dadeau, Elizabeta Fourneret.

Test scenarios represent an abstract test case specification that aims at guiding the model animation in order to produce relevant test cases. Contrary to the previous section, this technique is not fully automated since it requires the user to design the scenario, in addition to the model.

We have designed a scenario based testing language for UML/OCL that can be either connected to a model animation engine [31] or to a symbolic animation engine, based on a set-theoretical constraint solver [20]. In the context of the ANR TASCCC project, we are investigating the automation of test generation from Security Functional Requirements (SFR), as defined in the Common Criteria terminology. SFRs represent security functions that have to be assessed during the validation phase of security products (in the project, the Global Platform, an operating system for latest-generation smart cards). To achieve that, we are working on the definition of description patterns for security properties, to which a given set of SFRs can be related. These properties are used to automatically generate test scenarios that produce model based test cases. The traceability, ensured all along the testing process, makes it possible to provide evidences of the coverage of the SFR by the tests, required by the Common Criteria to reach the highest Evaluation Assurance Levels. We have proposed a dedicated formalism to express test properties [32]. A test property is first translated into a finite state automaton whose coverage by a given test suite is then measured. This makes it possible to evaluate the relevance of the test suite w.r.t. a given property.

In the context of the SecureChange project, we also investigate the evolution of test scenarios. As the system evolves, the model evolves, and the associated test scenarios may also evolve. We are currently extending the test generation and management of system evolutions to ensure the preservation of the security.

6.4.3. Mutation-based Testing of Security Protocols

Participants: Frédéric Dadeau, Pierre-Cyrille Héam.

Verification of security protocols models is an important issue. Nevertheless, the verification reasons on a model of the protocol, and does not consider its concrete implementation. While representing a safe model, the protocol may be incorrectly implemented, leading to security flaws when it is deployed. We have proposed a model-based penetration testing approach for security protocols [44]. This technique relies on the use of mutations of an original protocol, proved to be correct, for injecting realistic errors that may occur during the protocol implementation (e.g. re-use of existing keys, partial checking of received messages, incorrect formatting of sent messages, use of exponential/xor encryption, etc.). Mutations that lead to security flaws are used to build test cases, which are defined as a sequence of messages representing the behavior of the intruder. We have applied our technique on protocols designed in HLPSL, and implemented a protocol mutation tool that performs the mutations. The mutants are then analyzed by the CL-Atse [90] front-end of the AVISPA toolset [74]. Experiments show the relevance of the proposed mutation operators and the efficiency of the CL-Atse tool to conclude on the vulnerability of a protocol and produce an attack trace that can be used as a test case for implementations.

6.4.4. Code-related Test Generation and Static Analysis

Participants: Alain Giorgetti, Frédéric Dadeau, Ivan Enderlin.
In 2011 we have enriched with program slicing [33] an original combination of static analysis and structural program testing for C program debugging presented in 2010, implemented in a prototype called SANTE (Static ANalysis and TEsting). The method first calls a static value analysis which generates alarms when it cannot guarantee the absence of run-time errors. In order to simplify test generation, the method then reduces the program by program slicing and produces one or many simpler programs, while preserving a subset of the alarms. Finally the method performs an alarm-guided test generation to analyze the simplified program(s), in order to confirm or reject alarms. Experiments on real examples have shown that the verification is faster when reducing the code with program slicing. Moreover, the simplified program(s) makes the detected errors and the remaining alarms easier to analyze.

We have designed a grey-box testing and analysis tool [45] for Java programs possibly annotated by JML annotations. This tool uses a set-theoretical constraint representation of the Java code of class methods. It provides an efficient means for (i) generating structural test cases, satisfying a given code-coverage criterion (all-nodes, all-transitions, all-k-paths) and taking into account the JML annotations associated to the method, and (ii) performing static analysis on the Java code, either to detect potential runtime errors (null pointers dereferencing, division by zero, etc.) or to detect non-conformances between the Java program and its JML specifications (invariant, internal precondition or postcondition violation).

We have designed a new annotation language for PHP, named PRASPEL [48] for PHP Realistic Annotation SPEcification Language. This language relies on realistic domains which serve two purposes. First, they assign to a data a domain that is supposed to be specific w.r.t. a context in which it is employed. Second, they provide two features that are used for test generation: (i) samplability makes it possible to automatically generate a value that belongs to the realistic domain so as to generate test data, (ii) predicability makes it possible to check if the value belongs to a realistic domain. This approach is tool-supported in a dedicated framework for PHP which makes it possible to produce unit test cases using random data generators, execute the test cases on an instrumented implementation, and decide the conformance of the code w.r.t. the annotations by runtime assertion checking.

6.4.5. Random Testing

Participant: Pierre-Cyrille Héam.

The random testing paradigm represents a quite simple and tractable software assessment method for various testing approaches. When doing random testing, the main qualities required for the random sampler are that random choices must be objective and independent of tester choices or convictions: a solution is to ask for uniform random generators.

In [86] a method is proposed for drawing paths in finite graphs uniformly and it is showed how to use these techniques in a control flow graph based testing approach of C programs. Nevertheless, a finite graph often represents a strong abstraction of the system under test, and many abstract tests generated by the approach may be impossible to play on the implementation. In [53], we propose a new approach, extending previous work, to manage stack-call during the random test generation while preserving uniformity.

When doing random testing on inputs, the algorithm has to be efficient enough to allow the generation of a huge quantity of data. Moreover every programming language provides good uniform random generators (or pseudo-random to be more precise) for numbers. However, the question is more complex for non-numerical data, such as tree data structures, logical formulas, graphs, etc. In [54], we present the Seed prototype that uniformly generates recursive data structures satisfying a given grammar-like specification. The tool is easy to use, uniform and generation is uniform. Moreover, it manages some equational equivalences on data structures to shape the distribution.

6.5. Verification of Collaborative Systems

We investigate security problems occurring in decentralized systems. We develop general techniques to enforce read and update policies for controlling access to XML documents based on recursive DTDs (Document Type Definition). Moreover, we provide a necessary and sufficient condition for undoing safely replicated objects in order to enforce access control policies in an optimistic way.
6.5.1. Automatic Analysis of Web Services Security

**Participants:** Tigran Avanesov, Mohamed Anis Mekki, Michaël Rusinowitch, Mathieu Turuani, Laurent Vigneron.

Automatic composition of web services is a challenging task. Many works have considered simplified automata models that abstract away from the structure of messages exchanged by the services. For the domain of secured services (using e.g. digital signing or timestamping) we propose a novel approach to automated orchestration of services under security constraints. Given a community of services and a goal service, we reduce the problem of generating a mediator between a client and a service community to a security problem where an intruder should intercept and redirect messages from the service community and a client service till reaching a satisfying state. In his thesis Mohamed Anis Mekki [36][27] presents a tool that compiles the obtained trace describing the execution of a the mediator into its corresponding runnable code. For that the tool computes an executable specification of the mediator as prudent as possible of her role in the orchestration. This specification is expressed in ASLan language, a formal language designed for modeling Web Services tied with security policies that was developed in AVANTSSAR project. Then we can check with automatic tools that this ASLan specification verifies required security properties such as secrecy and authentication. If no flaw is found, we compile the specification into a Java servlet that can be used by the mediator to execute the orchestration.

In his thesis, Tigran Avanesov [13][28] gives a decision procedure for the satisfiability problem of general deducibility constraints. Two cases are considered: the standard Dolev-Yao theory and its extension with an associative, commutative idempotent operator. The result is applied to solve the automated distributed orchestration problem for secured Web services. As a second application a procedure is given to decide the security of a cryptographic protocol in the presence of several non-communicating intruders. It is also shown in this thesis how to detect some XML rewriting attacks on Web services.

6.5.2. Secure Querying and Updating of Recursive XML Views

**Participants:** Bao Thien Hoang, Houari Mahfoud, Abdessamad Imine.

Most state-of-the-art approaches for securing XML documents allow users to access data only through authorized views defined by annotating an XML grammar (e.g. DTD) with a collection of XPath expressions. To prevent improper disclosure of confidential information, user queries posed on these views need to be rewritten into equivalent queries on the underlying documents. A major concern here is that query rewriting for recursive views is still an open problem. In this work, we show that this query rewriting is possible using only the expressive power of the standard XPath [70]. We present the extension of the downward class of XPath, composed only by child and descendant axes, with some axes and operators and we propose a general approach to rewrite queries under recursive XML views. Unlike Regular XPath-based works, we provide a linear rewriting algorithm which processes the queries only over the annotated XML grammar. An experimental evaluation demonstrates that our algorithm is efficient and scales well. Finally, we plan to investigate how to combine read and update policies without revealing sensitive information to unauthorized users.

6.5.3. On the Undoability Problem in Distributed Collaborative Systems

**Participants:** Asma Cherif, Abdessamad Imine.

Combining Operational Transformation (OT) and undo approaches is a challenging problem. Even though various undo solutions have been proposed over the recent years, verifying their correctness still is a challenging problem due to the absence of formal guidelines to undo operations. In this work, we address the undo problem from a theoretical point of view [68]. We provide a necessary and sufficient condition for undoing replicated objects based on OT with respect to three inverse properties. To overcome the difficulty of necessity proof, we use Constraint Satisfaction Problems (CSP) theory in order to cover all possible transformation cases. As the main result, we prove that it is impossible to achieve a correct undo for objects with non-commutative operations. To relax this impossibility result, we sketch a preliminary solution that consists in adding explicitly a new form of idle operations.
5. New Results

5.1. Control-Flow Analysis by Abstract Interpretation

Control-flow analysis (CFA) of functional programs is concerned with determining how the program’s functions call each other. In the case of the lambda calculus, this amounts to computing the flow of lambda expressions in order to determine what functions are effectively called in an application \((e_1 e_2)\). This work shows that it is possible to use abstract interpretation techniques to derive systematically a control-flow analysis for a simple higher-order functional language. The analysis approximates the interprocedural control-flow of both function calls and returns in the presence of first-class functions and tail-call optimization. A number of advantages follow from taking this approach:

- The systematic derivation of a CFA for a higher-order functional language from a well-known operational semantics provides the resulting analysis with strong mathematical foundations. Its correctness follows directly from the general theorems of abstract interpretation.
- The approach is easily adapted to different variants of the source language. We demonstrate this by deriving a CFA for functional programs written in continuation-passing style.
- The common framework of these analyses enables their comparison. We take advantage of this to settle a question about the equivalence between the analysis of programs in direct and continuation-passing style.
- The resulting equations can be given an equivalent constraint-based presentation, providing ipso facto a rational reconstruction and a correctness proof of constraint-based CFA.

This work was presented at the Japanese Shonan workshop on Verification of higher-order functional programs in September 2011. A journal article is accepted to appear in Information and Computation.

5.2. Modular SMT Proofs for Fast Reflexive Checking inside Coq

Participants: Frédéric Besson, Pierre-Emmanuel Cornilleau, David Pichardie.

Satisfiability Modulo Theory (SMT) solvers are efficient automatic provers for combination of theories. Those solvers have proved very successful in program verification because they discharge automatically and efficiently challenging verification conditions. SMT solvers are therefore de facto part of the Trusted Computing Base of many program verification methodologies. A consequence is that a soundness bug in a SMT solver can make the whole program verification process unsound.

To tackle this problem, we propose a new methodology for exchanging unsatisfiability proofs between an untrusted SMT solver and a sceptical proof assistant with computation capabilities like Coq. We advocate modular SMT proofs that separate boolean reasoning and theory reasoning; and structure the communication between theories using Nelson-Oppen combination scheme.

We present the design and implementation of a Coq reflexive verifier that is modular and allows for fine-tuned theory-specific verifiers. The current verifier is able to verify proofs for quantifier-free formulae mixing linear arithmetic and uninterpreted functions. Our proof generation scheme benefits from the efficiency of state-of-the-art SMT solvers while being independent from a specific SMT solver proof format. Our only requirement for the SMT solver is the ability to extract unsat cores and generate boolean models. In practice, unsat cores are relatively small and their proof is obtained with a modest overhead by our proof-producing prover. We present experiments assessing the feasibility of the approach for benchmarks obtained from the SMT competition.

This work has been presented at the CPP conference [15] and the international PxTP workshop [21], [20].
5.3. Secure the Clones: Static Enforcement of Policies for Secure Object Copying

Participants: Thomas Jensen, Florent Kirchner, David Pichardie.

Exchanging mutable data objects with untrusted code is a delicate matter because of the risk of creating a data space that is accessible by an attacker. Consequently, secure programming guidelines for Java stress the importance of using defensive copying before accepting or handing out references to an internal mutable object.

However, implementation of a copy method (like clone()) is entirely left to the programmer. It may not provide a sufficiently deep copy of an object and is subject to overriding by a malicious sub-class. Currently no language-based mechanism supports secure object cloning.

We propose a type-based annotation system for defining modular copy policies for class-based object-oriented programs. A copy policy specifies the maximally allowed sharing between an object and its clone. We provide a static enforcement mechanism that will guarantee that all classes fulfill their copy policy, even in the presence of overriding of copy methods, and establish the semantic correctness of the overall approach in Coq.

The mechanism has been implemented and experimentally evaluated on clone methods from several Java libraries. The work as been presented at ESOP [18] this year and is under reviewing for a journal special issue.

5.4. Fault localization and correction in Constraint Programs

Participants: Nadjib Lazaar, Arnaud Gotlieb.

Nowadays, constraint programs are written in high-level modelling languages. Their verification is currently based on trace analysis techniques but does not integrate systematic testing techniques. In this work, we developed a Testing framework for catching the peculiarities of constraint program development, throughout the notions of conformity relations, fault localization and correction.

Within the context of the Nadjib Lazaar’s PhD (defense on 5 Dec. 2011), we explored in 2011 the testing of constraint programs written in OPL and the development of trace-based fault localization and correction techniques [19]. Lazaar’s tool called CPTEST showed impressive experimental results on four hard problems of the CP Community, leading to a publication (in progress) in the Constraints Journal.

5.5. Floating-point constraint solving

Participants: Matthieu Carlier, Arnaud Gotlieb.

Programs including floating-point computations are known to be hard-to-test. Generating test inputs for those programs requires solving constraints over floating-points computations, which led us to the development of specific constraint filtering techniques. In this work, we extended the Marre and Michel property regarding the use of internal floating-point representation to increase the filtering capabilities of addition to the case of multiplication/division. We came up with an optimized implementation of FPSE (our current FP constraint solver) that was able to deal with large C programs that include (non-linear) floating-point computations. We already got a first publication of this work [17].

5.6. Fast inference of polynomial invariants

Participants: David Cachera, Thomas Jensen, Arnaud Jobin, Florent Kirchner.
The problem of automatically inferring polynomial (non-linear) invariants of programs is still a major challenge in program verification. We have proposed an abstract interpretation based method to compute polynomial invariants for imperative programs. Our analysis is a backward propagation approach that computes preconditions for equalities like \( g = 0 \) to hold at the end of execution. Properties are expressed using ideals, a structure that satisfies the descending chain condition, enabling fixpoints computations to terminate without use of a widening operator. In the general case, termination would be characterized using ideal membership tests and Gröbner bases computations. In order to optimize computational complexity, we propose a specialized analysis dealing with inductive invariants which ensures fast termination of fixpoints computations. The optimized procedure has been shown by experiments to work well in practice, and to be two orders of magnitude faster than state of the art analyzers [23].
6. New Results

6.1. Models

6.1.1. Using the Last-mile Model as a Distributed Scheme for Available Bandwidth Prediction

Participants: Olivier Beaumont, Lionel Eyraud-Dubois, Young Won.

Several Network Coordinate Systems have been proposed to predict unknown network distances between a large number of Internet nodes by using only a small number of measurements. These systems focus on predicting latency, and they are not adapted to the prediction of available bandwidth. But end-to-end path available bandwidth is an important metric for the performance optimisation in many high throughput distributed applications, such as video streaming and file sharing networks. In [34], we propose to perform available bandwidth prediction with the last-mile model, in which each node is characterised by its incoming and outgoing capacities. This model has been used in several theoretical works for distributed applications. We design decentralised heuristics to compute the capacities of each node so as to minimise the prediction error. We show that our algorithms can achieve a competitive accuracy even with asymmetric and erroneous end-to-end measurement datasets. A comparison with existing models (Vivaldi, Sequoia, PathGuru, DMF) is provided. Simulation results also show that our heuristics can provide good quality predictions even when using a very small number of measurements.

6.1.2. Divisible Load Scheduling

Participants: Olivier Beaumont, Nicolas Bonichon, Lionel Eyraud-Dubois.

Malleable tasks are jobs that can be scheduled with preemptions on a varying number of resources. In [31], we focus on the special case of work-preserving malleable tasks, for which the area of the allocated resources does not depend on the allocation and is equal to the sequential processing time. Moreover, we assume that the number of resources allocated to each task at each time instant is bounded. We consider both the clairvoyant and non-clairvoyant cases, and we focus on minimizing the weighted sum of completion times. In the weighted non-clairvoyant case, we propose an approximation algorithm whose ratio (2) is the same as in the unweighted non-clairvoyant case. In the clairvoyant case, we provide a normal form for the schedule of such malleable tasks, and prove that any valid schedule can be turned into this normal form, based only on the completion times of the tasks. We show that in these normal form schedules, the number of preemptions per task is bounded by 3 on average. At last, we analyze the performance of greedy schedules, and prove that optimal schedules are greedy for a special case of homogeneous instances. We conjecture that there exists an optimal greedy schedule for all instances, which would greatly simplify the study of this problem. Finally, we explore the complexity of the problem restricted to homogeneous instances, which is still open despite its very simple expression. (Join work with Loris Marchal from ENS Lyon)

6.1.3. Modeling and Practical Evaluation of a Service Location Problem in Large Scale Networks

Participants: Olivier Beaumont, Nicolas Bonichon, Hubert Larchevêque.
In [33], we consider a generalization of a classical optimization problem related to server and replica location problems in networks. More precisely, we suppose that a set of users distributed over a network wish to have access to a particular service proposed by a set of providers. The aim is then to distinguish a set of service providers able to offer a sufficient amount of resources in order to satisfy the requests of the clients. Moreover, a quality of service following some requirements in terms of latencies is desirable. A smart repartition of the servers in the network may also ensure good fault tolerance properties. We model this problem as a variant of Bin Packing, namely Bin Packing under Distance Constraint (BPDC) where the goal is to build a minimal number of bins (i.e. to choose a minimal number of servers) so that (i) each client is associated to exactly one server, (ii) the capacity of the server is large enough to satisfy the requests of its clients and (iii) the distance between two clients associated to the same server is minimized. We prove that this problem is hard to approximate even when using resource augmentation techniques; we compare the number of obtained bins when using polynomial time algorithms allowed to build bins of diameter at most $\beta d_{\text{max}}$, for $\beta > 1$, to the optimal number of bins of diameter at most $d_{\text{max}}$. On the one hand, we prove that (i) if $\beta = (2 - \epsilon)$, BPDC is hard to approximate within any constant approximation ratio, for any $\epsilon > 0$; and that (ii) BPDC is hard to approximate at a ratio lower than $\frac{3}{2}$ even if resource augmentation is used. On the other hand, if $\beta = 2$, we propose a polynomial time approximation algorithm for BPDC with approximation ratio $\frac{7}{3}$ in the general case. We show how to turn an approximation algorithm for BPDC into an approximation algorithm for the non-uniform capacitated $K$-center problem and vice-versa. Then, we present a comparison of the quality of results for BPDC in the context of several Internet latency embedding tools such as Sequoia and Vivaldi, using datasets based on PlanetLab latency measurements.

6.1.4. Use of Internet Embedding Tools for Heterogeneous Resources Aggregation

Participants: Olivier Beaumont, Nicolas Bonichon, Philippe Duchon, Hubert Larchevêque.

In [28], we are interested in large scale distributed platforms like BOINC, consisting of heterogeneous resources and using the Internet as underlying communication network. In this context, we study a resource clustering problem, where the goal is to build clusters having at least a given capacity and such that any two participants to the same cluster are not too far from each other. In this context, the distance between two participants corresponds to the latency of a communication between them. Our goal is to provide algorithms with provable approximation ratios. In such large scale networks, it is not realistic to assume that the whole latency matrix (that gives the latency between any two participants) is known, and we need to rely on embedding tools such as Vivaldi or Sequoia. These tools enable to work on compact descriptions and well described metric spaces in which the distance between two points can be obtained directly from a small amount of information available at each node. We present the Bin Covering under Distance Constraint problem (BCDC for short), and propose dedicated algorithms for this problem for each metric space induced by each of the embedding tools. Then, we propose a comparison of these algorithms based on actual latency measures, that enables to decide which algorithm/embedding tool pair offers in practice for realistic datasets the best balancing between distance prediction and approximation ratios for the resource clustering problem.

6.1.5. Broadcasting on Large Scale Heterogeneous Platforms with Connectivity Artifacts under the Bounded Multi-Port Model

Participants: Olivier Beaumont, Nicolas Bonichon, Lionel Eyraud-Dubois, Przemyslaw Uznanski.

In [32], we consider the classical problem of broadcasting a large message at an optimal rate in a large scale distributed network. The main novelty of our approach is that we consider that the set of participating nodes can be split into two parts: "green" nodes that stay in the open-Internet and "red" nodes that lie behind firewalls or NATs. Two red nodes cannot communicate directly, but rather need to use a green node as a gateway for transmitting a message. In this context, we are interested in both maximizing the throughput (i.e. the rate at which nodes receive the message) and minimizing the degree at the participating nodes, i.e. the number of TCP connections they must handle simultaneously. We consider both cyclic and acyclic solutions for the flow graph. In the cyclic case, our main contributions are a closed form formula for the optimal cyclic throughput and the proof that the optimal solution may require arbitrarily large degrees. In the acyclic case, we propose an algorithm to achieve the optimal throughput with low degree. Then, we prove a worst case ratio between
the optimal acyclic and cyclic throughput and show through simulations that this ratio is on average very close to 1, which makes acyclic solutions efficient both in terms of throughput and of number of connections.

6.2. Overlays and distributed algorithms

6.2.1. Locally Fair Graph Exploration Strategies

Participants: David Ilcinkas, Ralf Klasing, Adrian Kosowski.

In [16], we considered the problem of exploring an anonymous undirected graph using an oblivious robot. The studied exploration strategies are designed so that the next edge in the robot’s walk is chosen using only local information, and so that some local equity (fairness) criterion is satisfied for the adjacent undirected edges. Such strategies can be seen as an attempt to derandomize random walks, and are natural counterparts for undirected graphs of the rotor-router model for symmetric directed graphs. The first of the studied strategies, known as Oldest-First (OF), always chooses the neighboring edge for which the most time has elapsed since its last traversal. Unlike in the case of symmetric directed graphs, we show that such a strategy in some cases leads to exponential cover time. We then consider another strategy called Least-Used-First (LUF) which always uses adjacent edges which have been traversed the smallest number of times. We show that any Least-Used-First exploration covers a graph \( G = (V,E) \) of diameter \( D \) within time \( O(D|E|) \), and in the long run traverses all edges of \( G \) with the same frequency.

6.2.2. Black Hole Search in Directed Graphs

Participant: Adrian Kosowski.

In [21] we considered a team of agents which has to explore a graph \( G \) where some nodes can be harmful. Robots are initially located at the so called home base node. The dangerous nodes are the so called black hole nodes, and once a robot enters in one of them, it is destroyed. The goal is to find a strategy in order to explore \( G \) in such a way that the minimum number of robots is wasted. The exploration ends if there is at least one surviving robot which knows all the edges leading to the black holes. As many variations of the problem have been considered so far, the solution and its measure heavily depend on the initial knowledge and the capabilities of the robots. We assume that \( G \) is a directed graph, the robots are associated with unique identifiers, they know the number of nodes \( n \) of \( G \) (or at least an upper bound on \( n \)), and they know the number of edges \( \Delta \) leading to the black holes. Each node is associated with a white board where robots can read and write information in a mutual exclusive way. A recently posed question (Czyzowicz et al. 2009) is whether some number of robots, expressed as a function of parameter Delta only, is sufficient to detect black holes in directed graphs of arbitrarily large order \( n \). We give a positive answer to this question for the synchronous case, i.e., when the robots share a common clock, showing that \( O(\Delta^2 \Delta) \) robots are sufficient to solve the problem. This bound is nearly tight, since it is known that at least \( 2^\Delta \Delta \) robots are required for some instances. Quite surprisingly, we also show that unlike in the case of undirected graphs, for the directed version of the problem, synchronization can sometimes make a difference: for \( \Delta = 2 \), in the synchronous case 4 robots are always sufficient, whereas in the asynchronous case at least 5 robots are sometimes required.

6.2.3. Rendezvous for Location-Aware Agents

Participant: Adrian Kosowski.

In [35] we studied rendezvous of two anonymous agents, where each agent knows its own initial position in the environment. Their task is to meet each other as quickly as possible. The time of the rendezvous is measured by the number of synchronous rounds that agents need to use in the worst case in order to meet. In each round, an agent may make a simple move or it may stay motionless. We consider two types of environments, finite or infinite graphs and Euclidean spaces. A simple move traverses a single edge (in a graph) or at most a unit distance (in Euclidean space). The rendezvous consists in visiting by both agents the same point of the environment simultaneously (in the same round). In [35], we propose several asymptotically optimal rendezvous algorithms. In particular, we show that in the line and trees as well as in multi-dimensional Euclidean spaces and grids the agents can rendezvous in time \( O(d) \), where \( d \) is the distance between the initial
positions of the agents. The problem of location-aware rendezvous was studied before in the asynchronous model for Euclidean spaces and multi-dimensional grids, where the emphasis was on the length of the adopted rendezvous trajectory. We point out that, contrary to the asynchronous case, where the cost of rendezvous is dominated by the size of potentially large neighborhoods, the agents are able to meet in all graphs of at most \( n \) nodes in time almost linear in \( d \), namely, \( O(d \log^2 n) \). We also determine an infinite family of graphs in which synchronized rendezvous takes time \( \Omega(d) \).

6.2.4. Boundary Patrolling by Mobile Agents

**Participant:** Adrian Kosowski.

In the boundary patrolling problem, a set of \( k \) mobile agents are placed on the boundary of a simply connected planar object represented by a cycle of unit length. Each agent has its own predefined maximal speed, and is capable of moving around this boundary without exceeding its maximal speed. The agents are required to protect the boundary from an intruder which attempts to penetrate to the interior of the object through a point of the boundary, unknown to the agents. The intruder needs some time interval of length \( \tau \) to accomplish the intrusion. Will the intruder be able to penetrate into the object, or is there an algorithm allowing the agents to move perpetually along the boundary, so that no point of the boundary remains unprotected for a time period \( \tau \)? Such a problem may be solved by designing an algorithm which defines the motion of agents so as to minimize the idle time \( I \), i.e., the longest time interval during which any fixed boundary point remains unvisited by some agent, with the obvious goal of achieving \( I < \tau \). Depending on the type of the environment, this problem is known as either boundary patrolling or fence patrolling in the robotics literature. The most common heuristics adopted in the past include the cyclic strategy, where agents move in one direction around the cycle covering the environment, and the partition strategy, in which the environment is partitioned into sections patrolled separately by individual agents. We have obtained, to our knowledge, the first study of the fundamental problem of boundary patrolling by agents with distinct maximal speeds. In this scenario, we give special attention to the performance of the cyclic strategy and the partition strategy. In [36], we propose general bounds and methods for analyzing these strategies, obtaining exact results for cases with 2, 3, and 4 agents. We show that there are cases when the cyclic strategy is optimal, cases when the partition strategy is optimal and, perhaps more surprisingly, novel, alternative methods have to be used to achieve optimality.

6.2.5. Rendezvous in trees

**Participant:** Adrian Kosowski.

In the rendezvous problem in trees, two identical (anonymous) mobile agents start from arbitrary nodes of an unknown tree and have to meet at some node. Agents move in synchronous rounds: in each round an agent can either stay at the current node or move to one of its neighbors. We consider deterministic algorithms for this rendezvous task. In [51] we have presented a tight trade-off between the optimal time of completing rendezvous and the size of memory of the agents. For agents with \( k \) memory bits, we show that optimal rendezvous time is \( \Theta(n + n^2/k) \) in \( n \)-node trees. More precisely, if \( k \geq c \log n \), for some constant \( c \), we design agents accomplishing rendezvous in arbitrary trees of unknown size \( n \) in time \( O(n + n^2/k) \), starting with arbitrary delay. We also show that no pair of agents can accomplish rendezvous in time \( o(n + n^2/k) \), even in the class of lines of known length and even with simultaneous start. Finally, we prove that at least logarithmic memory is necessary for rendezvous, even for agents starting simultaneously in a \( n \)-node line.

6.2.6. How many oblivious robots can explore a line

**Participant:** David Ilcinkas.

In [20] we consider the problem of exploring an anonymous line by a team of \( k \) identical, oblivious, asynchronous deterministic mobile robots that can view the environment but cannot communicate. We completely characterize sizes of teams of robots capable of exploring a \( n \)-node line. For \( k < n \), exploration by \( k \) robots turns out to be possible, if and only if either \( k = 3 \), or \( k \geq 5 \), or \( k = 4 \) and \( n \) is odd. For all values of \( k \) for which exploration is possible, we give an exploration algorithm. For all others, we prove an impossibility result.
6.2.7. Asynchronous deterministic rendezvous in bounded terrains

**Participant:** David Ilcinkas.

Two mobile agents (robots) have to meet in an a priori unknown bounded terrain modeled as a polygon, possibly with polygonal obstacles. Robots are modeled as points, and each of them is equipped with a compass. Compasses of robots may be incoherent. Robots construct their routes, but the actual walk of each robot is decided by the adversary that may, e.g., speed up or slow down the robot. In [18], we consider several scenarios, depending on three factors: (1) obstacles in the terrain are present, or not, (2) compasses of both robots agree, or not, (3) robots have or do not have a map of the terrain with their positions marked. The cost of a rendezvous algorithm is the worst-case sum of lengths of the robots’ trajectories until they meet. For each scenario we design a deterministic rendezvous algorithm and analyze its cost. We also prove lower bounds on the cost of any deterministic rendezvous algorithm in each case. For all scenarios these bounds are tight.

6.2.8. On the Power of Waiting when Exploring Public Transportation Systems

**Participants:** David Ilcinkas, Ahmed Mouhamadou Wade.

We study the problem of exploration by a mobile entity (agent) of a class of dynamic networks, namely the periodically-varying graphs (the PV-graphs, modeling public transportation systems, among others). These are defined by a set of carriers following infinitely their prescribed route along the stations of the network. Flocchini, Mans, and Santoro [58] (ISAAC 2009) studied this problem in the case when the agent must always travel on the carriers and thus cannot wait on a station. They described the necessary and sufficient conditions for the problem to be solvable and proved that the optimal number of steps (and thus of moves) to explore a \( n \)-node PV-graph of \( k \) carriers and maximal period \( p \) is in \( \Theta(k \cdot p^2) \) in the general case.

In [46], we study the impact of the ability to wait at the stations. We exhibit the necessary and sufficient conditions for the problem to be solvable in this context, and we prove that waiting at the stations allows the agent to reduce the worst-case optimal number of moves by a multiplicative factor of at least \( \Theta(p) \), while the time complexity is reduced to \( \Theta(n \cdot p) \). (In any connected PV-graph, we have \( n \leq k \cdot p \).) We also show some complementary optimal results in specific cases (same period for all carriers, highly connected PV-graphs). Finally this new ability allows the agent to completely map the PV-graph, in addition to just explore it.

6.2.9. The impact of edge deletions on the number of errors in networks

**Participants:** Christian Glacet, Nicolas Hanusse, David Ilcinkas.

In [41], we deal with an error model in distributed networks. For a target \( t \), every node is assumed to give an advice, i.e. to point to a neighbor that take closer to the destination. Any node giving a bad advice is called a liar. Starting from a situation without any liar, we study the impact of topology changes on the number of liars.

More precisely, we establish a relationship between the number of liars and the number of distance changes after one edge deletion. Whenever \( \ell \) deleted edges are chosen uniformly at random, for any graph with \( n \) nodes, \( m \) edges and diameter \( D \), we prove that the expected number of liars and distance changes is \( O(\frac{\ell \cdot D \cdot m}{n^2}) \) in the resulting graph. The result is tight for \( \ell = 1 \). For some specific topologies, we give more precise bounds.

6.2.10. Computations in interconnection networks with a shared whiteboard

**Participant:** Adrian Kosowski.

In [52], we study the computational power of graph-based models of distributed computing in which each node additionally has access to a global whiteboard. A node can read the contents of the whiteboard and, when activated, can write one message of \( O(\log n) \) bits on it. A message is only based on the local knowledge of the node and the current content of the whiteboard. When the protocol terminates, each node computes the output based on the final contents of the whiteboard in order to answer some question on the network’s topology. We propose a framework to formally define several scenarios modelling how nodes access the whiteboard, in a synchronous way or not. This extends the work of Becker et al. where nodes were imposed to create their messages only based on their local knowledge (i.e., with the whiteboard empty). We prove that the four
models studied have increasing power of computation: any problem that can be solved in the weakest one can be solved in the second, and so on. Moreover, we exhibit problems that separate models, i.e., that can be solved in one model but not in a weaker one. These problems are related to Maximal Independent Set and detection of cycles. Finally we investigate problems related to connectivity as the construction of spanning- or BFS-tree in our different models.

6.2.11. Network Verification

Participant: Ralf Klasing.

In [27], we address the problem of verifying the accuracy of a map of a network by making as few measurements as possible on the nodes of the network. In the past, this task has been formalized as an optimization problem that, given a graph $G = (V, E)$, asks for finding a minimum-size subset $Q$ of vertices of $G$ such that the information returned by the queries on $Q$ uniquely identifies $G$. Previously, two global query models have been studied. In [27], we propose a query model that uses only local knowledge about the network. Quite naturally, we assume that a query at a given node $q$ returns the associated routing table, namely a set of entries which provides, for each destination node, a corresponding (set of) first-hop node(s) along an underlying shortest path. First, we show that any network of $n$ nodes needs $\Omega(\log \log n)$ queries to be verified. Then, we prove that there is no $o(\log n)$ approximation algorithm for the problem, unless $P = NP$, even for graphs with diameter 2. On the positive side, we provide an $O(\log n)$-approximation algorithm to verify a network of diameter 2, and we give exact polynomial-time algorithms for paths, trees and cycles of even length.

6.3. Compact and distributed data structures

6.3.1. Query optimization in databases

Participants: Nicolas Hanusse, Sofian Maabout.

Datacubes are data structures designed to query optimization in databases. In [42] we provide some algorithmic solutions in a user centric setting: the request time is guaranteed and the amount of memory space is minimized.

6.3.2. Parallel computations of Borders

Participants: Nicolas Hanusse, Sofian Maabout.

Borders are fundamental building blocks in data mining. They are used to find frequent patterns, dependencies between attributes, ... In [43] we provide an algorithm that computes borders with a speedup of $p$ (under reasonable hypothesis) for $p$ cores.

6.3.3. Node-disjoint multipath spanners and their relationship with fault-tolerant spanners

Participants: Cyril Gavoille, Quentin Godfroy.

Motivated by multipath routing, we introduce a multi-connected variant of spanners. For that purpose we introduce in [40] the $p$-multipath cost between two nodes $u$ and $v$ as the minimum weight of a collection of $p$ internally vertex-disjoint paths between $u$ and $v$. Given a weighted graph $G$, a subgraph $H$ is a $p$-multipath $s$-spanner if for all $u, v$, the $p$-multipath cost between $u$ and $v$ in $H$ is at most $s$ times the $p$-multipath cost in $G$. The $s$ factor is called the stretch.

Building upon recent results on fault-tolerant spanners, we show how to build $p$-multipath spanners of constant stretch and of $O(n^{1+1/k})$ edges, for fixed parameters $p$ and $k$, $n$ being the number of nodes of the graph. Such spanners can be constructed by a distributed algorithm running in $O(k)$ rounds.

Additionally, we give an improved construction for the case $p = k = 2$. Our spanner $H$ has $O(n^{3/2})$ edges and the $p$-multipath cost in $H$ between any two node is at most twice the corresponding one in $G$ plus $O(W)$, $W$ being the maximum edge weight.
6.3.4. On approximate distance labels and routing schemes with affine stretch

**Participant:** Cyril Gavoille.

For every integral parameter $k > 1$, given an unweighted graph $G$, we construct in polynomial time in $[25]$, for each vertex $u$, a distance label $L(u)$ of size $O(n^{2/(2k−1)})$. For any $u, v \in G$, given $L(u), L(v)$ we can return in time $O(k)$ an affine approximation $\delta(u, v)$ on the distance $d(u, v)$ between $u$ and $v$ in $G$ such that $d(u, v) ≤ \delta(u, v) ≤ (2k − 2)d(u, v) + 1$. Hence we say that our distance label scheme has affine stretch of $(2k − 2)d + 1$. For $k = 2$ our construction is comparable to the $O(n^{5/3})$ size, $2d + 1$ affine stretch of the distance oracle of Patrascu and Roditty (FOCS ’10), it incurs a $o(\log n)$ storage overhead while providing the benefits of a distance label.

For any $k > 1$, given a restriction of $o(n^{1+1/(k−1)})$ on the total size of the data structure, our construction provides distance labels with affine stretch of $(2k − 2)d + 1$ which is better than the stretch $(2k − 1)d$ scheme of Thorup and Zwick (J. ACM ’05).

Our second contribution is a compact routing scheme with poly-logarithmic addresses that provides affine stretch guarantees. With $O(n^{3/(3k−2)})$-bit routing tables we obtain affine stretch of $(4k − 6)d + 1$, for any $k > 1$.

Given a restriction of $o(n^{1/(k−1)})$ on the table size, our routing scheme provides affine stretch which is better than the stretch $(4k − 5)d$ routing scheme of Thorup and Zwick (SPAA ’01).

6.3.5. Sparse spanners vs. compact routing

**Participant:** Cyril Gavoille.

Routing with multiplicative stretch 3 (which means that the path used by the routing scheme can be up to three times longer than a shortest path) can be done with routing tables of $\Theta(\sqrt{n})$ bits per node. The space lower bound is due to the existence of dense graphs with large girth. Dense graphs can be sparsified to subgraphs, called spanners, with various stretch guarantees. There are spanners with additive stretch guarantees (some even have constant additive stretch) but only very few additive routing schemes are known.

In $[39]$, we give reasons why routing in unweighted graphs with additive stretch is difficult in the form of space lower bounds for general graphs and for planar graphs. We prove that any routing scheme using routing tables of size $M$ bits per node and addresses of poly-logarithmic length has additive stretch $\Omega(\sqrt{n}/M)$ for general graphs, and $\Omega(\sqrt{n}/M)$ for planar graphs. Routing with tables of size $O(n^{1/3})$ thus requires a polynomial additive stretch of $\Omega(n^{1/3})$, whereas spanners with average degree $O(n^{1/3})$ and constant additive stretch exist for all graphs. Spanners, however sparse they are, do not tell us how to route. These bounds provide the first separation of sparse spanner problems and compact routing problems.

On the positive side, we give an almost tight upper bound: we present the first non-trivial compact routing scheme with $o(\log^2 n)$-bit addresses, additive stretch $O(n^{1/3})$, and table size $O(n^{1/3})$ bits for planar graphs. Actually, our scheme applies to general graphs, and the above bound of $n^{1/3}$ on the stretch and the routing table size holds for all graphs of linear local tree-width, a class of graphs including bounded-genus graphs and apex-minor-free graphs.

---

3Tilde-big-$\mathcal{O}$ notation is similar to big-$\mathcal{O}$ notation up to factors poly-logarithmic in $n$. 
6. New Results

6.1. Intrusion Detection

Metamorphic codes:

In [12], we have proposed an advance code obfuscation technique for metamorphic codes (i.e., codes that automatically recode themselves each time they propagate or are distributed). We have shown that the detection of such codes was a problem for classical nowadays static detection tools. In [25], we focus on a new dynamic detection approach which allows to detect variants produced by our metamorphic engine. In addition, our approach can detect unknown malware as long as their behavior approaches that of a known malware. For this, we propose to use a measure of similarity between program behaviors. This measure is obtained by lossless compression of execution traces in terms of system calls.

Intrusion Detection based on an Analysis of the Flow Control:

In [13], intrusion detection mechanisms based on the construct a model of normal behavior of the supervised entity are studied. Such a model is used during the detection phase to raise an alarm when a deviation is observed. This approach allows to detect unknown attacks.

The most common anomaly detection mechanisms at application level consist in detecting a deviation of the control-flow of a program. A popular method to detect such anomaly is the use of application sequences of system calls. However, such methods do not detect mimicry attacks or attacks against the integrity of the system call parameters. To enhance such detection mechanisms, we propose in [27] an approach to detect in the application the corruption of data items that have an influence on the system calls. This approach consists in building automatically a data-oriented behavior model of an application by static analysis of its source code. The proposed approach is illustrated on various examples, and an injection method is experimented to obtain an approximation of the detection coverage of the generated mechanisms.

Most of today’s MAC implementations can be turned into permissive mode, where no enforcement is performed but alerts are raised instead. This behavior is very close to an anomaly IDS except that the system is configured through a MAC policy. MAC implementations such as SELinux and AppArmor come with a default policy including real life and practical rules ready to be used as is or as a basis for a custom policy. In [30], we first propose an extension of an IDS based on information flow control. We address issues concerning programs execution and improve its expressiveness in terms of security policy. This extended model can be configured to reach a wide variety of different security goals. Particularly, it allows for information flow checking based on users and/or programs dependent policy rules. Furthermore, suspicious modification of binary programs can be detected to avoid malware execution. We also propose an algorithm for deriving an AppArmor MAC policy into an information flow policy, and thus get the advantage of having a ready to use policy offering good security. An integration within Android is described in [37].

Flow based Interpretation of Access Control Policies:

In [32], we introduce a formal property characterizing access control policies for which the interpretations of access control as mechanism over objects and as mechanism over information contained into objects are similar. This leads us to define both a flow based interpretation of access control policies and the information flows generated during the executions of a system implementing an access control mechanism. When these two interpretations are not equivalent, we propose to add a mechanism dedicated to illegal information flow detection to the mechanism of access control over objects. Such a mechanism is parameterized by the access control policy and is proved sound and complete. We also briefly describe two real implementations, at two levels of granularity, of our illegal flow detection mechanism: one for the Linux operating system and one for the Java Virtual Machine.

Intrusion Detection based on Invariants:
RRABIDS (Ruby on Rails Anomaly Based Intrusion Detection System) is an application level intrusion detection system for applications implemented with the Ruby on Rails framework. The goal of this intrusion detection system is to detect attacks against data in the context of web applications. This anomaly based IDS focuses on the modeling of the normal application profile using invariants. These invariants are discovered during a learning phase. Then, they are used to instrument the web application at source code level, so that a deviation from the normal profile can be detected at run-time. On simple examples we show how the approach detects well known categories of web attacks that involve a state violation of the application, such as SQL injections. Finally, an assessment phase is performed to evaluate the accuracy of the detection provided by the proposed approach.

Alert Correlation:
Alert correlation is a crucial problem for monitoring and securing computer networks. It consists in analyzing the alerts triggered by intrusion detection systems (IDSs) and other security related tools in order to detect complex attack plans, discover false alerts, etc. The huge amounts of alerts raised continuously by IDSs and the impossibility for security operators to efficiently analyze them requires tools for eliminating false and redundant alerts on the one hand and prioritize them according the detected activities? dangerousness and preferences of the analysts on the other hand. In [35], we describe an architecture that combines AI-based approaches for representing and reasoning with security operators? knowledge and preferences. Moreover, this architecture allows to combines experts’ knowledge with machine learning and classifier based tools. This prototype collects the alerts raised by security related tools and analyzes them automatically.

Trust-Based IDS for the AODV Protocol:
Routing in ad hoc networks is based on mutual trust between collaborating nodes. Security problems arise when supposedly honest nodes lie deliberately to maximize their profit. In [11], we are interested in detecting misbehaving nodes within the ad hoc routing protocol AODV. We propose and implement a real-time intrusion detection system based on implicit trust relations: a node implementing this system collects its neighbors’ routing messages and reasons on them to decide on their honesty. We also evaluate our implementation, and, based on simulations, show that the system we have developed to detect dishonest behavior is efficient.

Modelization and Simulation of Zombies Behaviours:
In [26], we study the modelization and simulation of zombie machines for the evaluation of Network Intrusion Detection Systems (NIDS), used to detect botnets. We propose an automatic method to infer zombies behaviours through the analysis of messages exchanged with their masters. Once computed, a model provides a way to generate realistic and manageable traffic, which is mandatory for an NIDS evaluation. We propose to use a Stochastic Mealy Machine to model zombies behaviours, and an active inference algorithm to learn it. With our approach, it is possible to generate a realistic traffic corresponding to the communications of botnets while ensuring its controllability in the context of an NIDS evaluation.

6.2. Privacy
Computer privacy is a domain where the education and information of the general public is paramount. In this perspective, through [44] we have participated to the popularization effort in the area, by exposing a survey of accessible computing tools allowing users to better protect their online privacy.

Formal Privacy Policies and Logical Tools:
One of the obstacles to the improvement of the privacy level in distributed applications is the lack of expressiveness, usability and enforceability of the associated policies. This new research track aims at designing better privacy policies for complex systems, more adapted to the specific needs of personal data protection regulations and easier to enforce in a distributed fashion. Logical languages, in particular, are considered as interesting candidates because of the reasoning capabilities attached to the formalisms, allowing autonomous peers to perform efficient, privacy-aware planning. [18] is a contribution to the modal logics used to model formal norms, focusing on specific deadline-related temporal notions often encountered in privacy policies. In [39], we propose an ambitious, collaborative research project based on an epistemic view of
the privacy laws and regulations, which should lead to the design of several tools, including policy writing assistants and validation software. [24] is a generic work in the domain of formal policies, where we propose a logical model of various concepts of responsibility in an organizational framework featuring obligation delegation. This kind of framework is intended to model the handling of complex policies in real-life human institutions.

Privacy in Social Networking Sites:

Social Networking Sites (SNS), such as Facebook and LinkedIn, have become the established place for keeping contact with old friends and meeting new acquaintances. As a result, a user leaves a big trail of personal information about him and his friends on the SNS, sometimes even without being aware of it. This information can lead to privacy drifts such as damaging his reputation and credibility, security risks (for instance identity theft) and profiling risks. Another research challenge stems from the fact that in the digital world where it is possible to copy the information as often as desired, it is not easy to control how information is disseminated once it is out on the Internet. In an ongoing collaboration [23] with Ai Thanh Ho and Esma Aïmeur (Université de Montréal), we investigate tools that can help user to maintain the sovereignty of their data on the World Wide Web. We also introduce PrivacyMarker, an approach drawing on the concept of provenance and accountability to protect user privacy on SNS. More precisely, it is possible to imagine that by a combination of logs and techniques such as watermarking and traitor-tracing schemes, the dissemination of information can be (at least partially) controlled and that in case of a privacy breach, it is possible to identify which persons are potentially suspect because they have previously accessed this information.

Geo-privacy:

A geolocalised system generally belongs to an individual and as such knowing its location reveals the location of its owner, which is a direct threat against his privacy. To protect the privacy of users, a sanitization process, which adds uncertainty to the data and removes some sensible information, can be performed but at the cost of a decrease of utility due to the quality degradation of the data. In a joint work [16] with Marc-Olivier Killijian and Miguel Nunez del Prado (LAAS-CNRS), we describe GEPETO (for GEoPrivacy-Enhancing TOolkit), a flexible open source software which can be used to visualize, sanitize, perform inference attacks and measure the utility of a particular geolocalised dataset. We also introduce a mobility model that we coin as mobility Markov Chain, which can represent in a compact yet precise way the mobility behaviour of an individual. Finally, we describe an algorithm for learning such a structure from the mobility traces of an individual.

Geosocial networks are relatively new compared to the more “traditional” (i.e. non-geolocated) social networking sites such as Facebook or LinkedIn that have been around since more than 6 years, but they are currently growing relatively fast along with the widespread development of other geolocated applications and technologies. In a study [29] done in cooperation with Olivier Heen (Technicolor) and Christophe Potin, we provide a comparative analysis of some existing geosocial networks with respect to privacy in order to (1) highlight some of privacy issues that are raised by the fast development of these system and (2) propose recommendations that could be integrated in the design of these systems to enhance the privacy of their users based on this analysis.

Privacy in Distributed Systems:

In a joint work [19] with Anne-Marie Kermarrec and Mohammad Alaggan (team INRIA ASAP), we address the problem of computing the similarity between two users (according to their profiles) while preserving their privacy in a fully decentralized system and for the passive adversary model. First, we introduce a two-party protocol for privately computing a threshold version of the similarity and apply it to well-known similarity measures such as the scalar product and the cosine similarity. The output of this protocol is only one bit of information telling whether or not two users are similar beyond a predetermined threshold. Afterwards, we explore the computation of the exact and threshold similarity within the context of differential privacy, a recent notion developed that provides a strong privacy guarantee that holds independently of the auxiliary knowledge that the adversary might have. More specifically, we design several differentially private variants of the exact and threshold protocols and we also analyze their complexity as well as their impact on the utility
of the resulting similarity measure. Finally, we provide experimental results validating the effectiveness of the proposed approach on real datasets.

Other ongoing work tackles the problem of computing an aggregation function in a secure and scalable way in a distributed network [42] (joint work with Rachid Guerraoui, Hamza Harkous, Florian Huc and Anne-Marie Kermarrec).

6.3. Accidental and Malicious Faults in Distributed Systems

Induced Churn to Face Malicious Behaviors:

In reputation mechanisms, ensuring durable access to feedbacks is a first barrier against simple attacks. To bias the reputation mechanism, an adversary can create and use several distinct identities. In that case, if the reputation mechanism is solely based on statistical measurements, the trustworthiness can be violated. Our contribution is centered around the study of robust mechanisms that can resist such attacks.

Toward this goal, we have first investigating the problem of uniform sampling in large scale open systems in presence of adversarial nodes. Uniform sampling ensures that any individual in a population has the same probability to be selected as sample. Uniform sampling finds its root in many problems such as data collection, dissemination, load balancing, and data-caching.

By relying on the topological properties of structured peer-to-peer systems, it has been shown that it is possible to guarantee with high probability that any node is equally likely to appear in the local view of each other honest node in a number of rounds polynomial in the size of the system. This is achieved by imposing nodes to frequently depart from their position and move to another random position in the system. Indeed, in [15], we have shown that an adversary can very quickly subvert overlays based on distributed hash tables by simply never triggering leave operations. We have also demonstrated that when all nodes (honest and malicious ones) are imposed on a limited lifetime, the system eventually reaches a stationary regime where the ratio of polluted clusters is bounded, independently from the initial amount of corruption in the system.

In unstructured peer-to-peer systems, nodes cannot rely on the topological nature of structured graphs to detect undesirable behaviors. The sampling has to be uniform and ergodic. Informally, this second property guarantees that each received node id infinitely often has a non-null probability to locally appear as a sample. In [21], we determine necessary and sufficient conditions under which uniform and ergodic sampling is achievable in unstructured peer-to-peer systems potentially populated with a large proportion of Byzantine nodes. Strict restrictions are imposed on the number of messages gossiped by malicious nodes during a given period of time and providing each honest node with a very large memory (in the size of the system).

In [38], we consider the problem of targeted attacks in large scale peer-to-peer overlays. These attacks aimed at exhausting key resources of targeted hosts to diminish their capacity to provide or receive services. To defend the system against such attacks, we rely on clustering and implement induced churn to preserve randomness of nodes identifiers so that adversarial predictions are impossible. We propose robust join, leave, merge and split operations to discourage brute force denial of services and pollution attacks.

Sequence of Consensus Instances:

To be able to coordinate efficiently the activities of replicas, a significant body of work on replication techniques, group communication services and agreement problems has been done. The Consensus service has been recognized as a fundamental building block for fault-tolerant distributed systems. Many different protocols to implement such a service have been proposed, however, little effort has been placed in evaluating their performance. During her PhD thesis [14], Izabela Moise has presented a protocol designed to solve several consecutive consensus instances in an asynchronous distributed system prone to crash failures and message omissions. The protocol [31] follows the Paxos approach [49], [47] and integrates two different optimizations to reduce the latency of learning a decision value. As one optimization is risky [48], dynamics triggering criterion are defined to check at runtime if the context seems to be favorable or not. The proposed protocol [34] is adaptive as it tries to obtain the best performance gain depending on the current context. Moreover, it guarantees the persistence of all decision values. Our experimentation results [
36 ] focus on the impact of the prediction of collisions (i.e., the cases where the use of the risky optimization is counterproductive).

**Transactional Mobile Agent**

Mobile devices are now equipped with multiple sensors and networking capabilities. They can gather information about their surrounding environment and interact both with nearby nodes, using a dynamic and self-configurable ad-hoc network, and with distant nodes via the Internet. While the concept of mobile agent is appropriate to explore the ad-hoc network and autonomously discover service providers, it is not suitable for the implementation of strong distributed synchronization mechanisms. Moreover, the termination of a task assigned to an agent may be compromised if the persistence of the agent itself is not ensured. In the case of a transactional mobile agent, we identify two services, Availability of the Sources and Atomic Commit, that can be supplied by more powerful entities located in a cloud. In [33], we propose a solution where these two services are provided in a reliable and homogeneous way. To guarantee reliability, the proposed solution relies on a single agreement protocol that orders continuously all the new actions whatever the related transaction and service.
5. New Results

5.1. Contributions earlier to 2011 but only published in 2011

Participants: Gérard Biau, Olivier Catoni, Sébastien Gerchinovitz, Vincent Rivoirard, Gilles Stoltz.

We do not discuss here the contributions provided by [12], [13], [14], [17], [18], [20], [22], [23], [25], since they were achieved in 2009 or earlier (but only published this year due to long queues in publication tracks of journals). [32] was revised but is still under review.

5.2. Sparse regression estimation

Participants: Gérard Biau, Olivier Catoni, Sébastien Gerchinovitz, Vincent Rivoirard, Gilles Stoltz, Jia Yuan Yu.

Sébastien Gerchinovitz and Jia Yuan Yu continued the work initiated by the former in the above-mentioned conference paper [25]; they derived from the sparsity results in individual sequences presented therein the minimax optimal rates of aggregation for individual sequences on $\ell^1$ balls. In particular, they exhibited, in certain cases, a phase transition between the $\ln T$ and the $\sqrt{T}$ behavior of the minimax regret, where $T$ denotes the number of instances. These results and all previous ones are summarized in the PhD thesis [10].

Other results were obtained in a stochastic framework, where input–output pairs are given by i.i.d. variables; they are described in the technical report [30]. Let $(X,Y)$ be a random pair taking values in $\mathbb{R}^p \times \mathbb{R}$. In the so-called single-index model, one has $Y = f^*(\theta^T X) + W$, where $f^*$ is an unknown univariate measurable function, $\theta^*$ is an unknown vector in $\mathbb{R}^d$, and $W$ denotes a random noise satisfying $E[W|X] = 0$. The single-index model is known to offer a flexible way to model a variety of high-dimensional real-world phenomena. However, despite its relative simplicity, this dimension reduction scheme faces severe complications as soon as the underlying dimension becomes larger than the number of observations and this is why this estimation problem was considered from a sparsity perspective using a PAC-Bayesian approach.

Last but not least, we mention the edited book [29], which provides a modern overview on high-dimensional estimation.

5.3. Sequential learning with limited feedback; in particular, bandit problems

Participants: Gilles Stoltz, Jia Yuan Yu.

Some of the results cited below are summarized or stated as open problems in the habilitation thesis [11].

5.3.1. Bandit problems

We achieved three contributions. The first is described in the conference paper [27]: it revisits asymptotically optimal results of Lai and Robbins, Burnetas and Katehakis in a non-asymptotic way. The second is stated in the journal article [19] and is concerned with obtaining fast convergence rates for the regret in case of a continuum of arms (of course under some regularity and topological assumptions on the mean-payoff function $f$).

The third one is detailed in [24] and started from the following observation. Typical results in the bandit literature were of the following form: if the regularity of the mean-payoff function $f$ is known (or if a bound on it is known) then the regret is small. Actually, results were usually taking the following weaker form: when the algorithm is tuned with some parameters, then the regret is small against a certain class of stochastic environments. The question was thus to have an adaptive procedure, that, given one unknown environment (with unknown regularity), ensures that the regret is asymptotically small; even better, the desired aim was to control the regret in some uniform manner (in a distribution-free sense up to the regularity parameters). As described in this conference paper, a solution was achieved in the case of Lipschitz environments.
5.3.2. **Approachability in games with partial monitoring**

The conference paper [28] explains how we could re-obtain, in a simple, more straightforward, and computationally efficient manner a result proven by Perchet in his PhD thesis: the necessary and sufficient condition for the approachability of a closed convex set under partial monitoring.

5.4. **Inference**

**Participant:** Gérard Biau.

5.4.1. **Geometric inference**

This line of research is in collaboration with the Geometrica project-team (INRIA Saclay). As the latter says:

Due to the fast evolution of data acquisition devices and computational power, scientists in many areas are demanding efficient algorithmic tools for analyzing, manipulating and visualizing more and more complex shapes or complex systems from approximating data. Many of the existing algorithmic solutions which come with little theoretical guarantees provide unsatisfactory and/or unpredictable results. Since these algorithms take as input discrete geometric data, it is mandatory to develop concepts that are rich enough to robustly and correctly approximate continuous shapes and their geometric properties by discrete models. Ensuring the correctness of geometric estimations and approximations on discrete data is a sensitive problem in many applications.

Thus, motivated by a broad range of potential applications in topological and geometric inference, we introduce in [15] a weighted version of the $k$–nearest neighbor density estimator. Various pointwise consistency results of this estimator are established; the proposed method is also implemented to recover level sets in both simulated and real-life data.

Another problem of geometric inference is the following one, studied in [16]. Principal curves are nonlinear generalizations of the notion of first principal component. Roughly, a principal curve is a parameterized curve in $\mathbb{R}^d$ that passes through the “middle” of a data cloud drawn from some unknown probability distribution. Depending on the definition, a principal curve relies on some unknown parameters (number of segments, length, turn...) which have to be properly chosen to recover the shape of the data without interpolating. In this paper, we consider the principal curve problem from an empirical risk minimization perspective and address the parameter selection issue using the point of view of model selection via penalization. We offer oracle inequalities and implement the proposed approaches to recover the hidden structures in both simulated and real-life data.

5.4.2. **Statistical inference**

We still keep an eye on more traditional mathematical statistics; in particular, the technical report [31] takes place within this field. It shows, for a large class of distributions and large samples, that estimates of the variance $\sigma^2$ and of the standard deviation $\sigma$ are more often Pitman closer to their target than the corresponding shrinkage estimates which improve the mean squared error. The results thus indicate that Pitman closeness criterion, despite its controversial nature, should be regarded as a useful and complementary tool for the evaluation of estimates of $\sigma^2$ and of $\sigma$.

5.5. **Statistical inference for biological systems based on a size-structured population**

**Participant:** Vincent Rivoirard.
The journal paper [21] considers the problem of estimating the division rate of a size-structured population in a nonparametric setting. The size of the system evolves according to a transport-fragmentation equation: each individual grows with a given transport rate, and splits into two offsprings of the same size, following a binary fragmentation process with unknown division rate that depends on its size. In contrast to a deterministic inverse problem approach, this paper takes the perspective of statistical inference: the data consists in a large sample of the size of individuals when the evolution of the system is close to its time-asymptotic behavior, so that it can be related to the eigenproblem of the considered transport-fragmentation equation. By estimating statistically each term of the eigenvalue problem and suitably inverting a certain linear operator, it constructs a more realistic estimator of the division rate that achieves the same optimal error bound as in related deterministic inverse problems. The procedure relies on kernel methods with automatic bandwidth selection. It is inspired by model selection and recent results of Goldenschluger and Lepski.
6. New Results

6.1. New methods for data assimilation

Since the beginning, CLIME has been focused on new techniques for data assimilation. Last year’s focus of the methodological development was on the use of non-Gaussian approaches for inverse modeling, and the construction of a multiscale data assimilation methodology. Several methodological papers have now been published on these topics. This year, the applications of these methodologies are put forward in the inverse modeling section, although new theoretical developments have been added to these approaches. In addition, new topics have been addressed, such as the ensemble Kalman filter with a theorem that puts the EnKF on safer grounds, the use of 4D-Var for the estimation of fields of parameter in dispersion models, and the real-time data assimilation at urban scale.

6.1.1. Ensemble Kalman filtering without the intrinsic need for inflation

Participant: Marc Bocquet.

The main intrinsic source of error in the ensemble Kalman filter (EnKF) is sampling error. External sources of error, such as model error or deviations from Gaussianity, depend on the dynamical properties of the model. Sampling errors can lead to instability of the filter, which, as a consequence, often requires inflation and localization. The goal of this study is to derive an ensemble Kalman filter, which is less sensitive to sampling errors. A prior probability density function conditional on the forecast ensemble is derived using Bayesian principles. Even though this prior is built upon the assumption that the ensemble is Gaussian-distributed, it is different from the Gaussian probability density function defined by the empirical mean and the empirical error covariance matrix of the ensemble, which is implicitly used in traditional EnKFs. This new prior generates a new class of ensemble Kalman filters, called finite-size ensemble Kalman filter (EnKF-N). One deterministic variant, the finite-size ensemble transform Kalman filter (ETKF-N), is derived. It is tested on the Lorenz ’63 and Lorenz ’95 models. In this context, ETKF-N is shown to be stable without inflation for ensemble size greater than the model unstable subspace dimension, at the same numerical cost as the ensemble transform Kalman filter (ETKF). One variant of ETKF-N seems to systematically outperform the ETKF with optimally tuned inflation. However, it is shown that ETKF-N does not account for all sampling errors and necessitates localization like any EnKF, whenever the ensemble size is too small. In order to explore the need for inflation in this small ensemble size regime, a local version of the new class of filters is defined (LETKF-N) and tested on the Lorenz ’95 toy model. Whatever the size of the ensemble, the filter is stable. Its performance without inflation is slightly inferior to that of LETKF with optimally tuned inflation for small interval between updates, and superior to LETKF with optimally tuned inflation for large time interval between updates.

6.1.2. Parameter field estimation for atmospheric dispersion: Application to the Chernobyl accident using 4D-Var

Participant: Marc Bocquet.

Atmospheric chemistry and air quality numerical models are driven by uncertain forcing fields: emissions, boundary conditions, wind fields, vertical turbulent diffusivity, kinetic chemical rates, etc. Data assimilation can help to assess these parameters or fields of parameter. Because those parameters are often much more uncertain than the fields diagnosed in meteorology and oceanography, data assimilation is much more an inverse modeling challenge in this context. In this study, we experiment with these ideas by revisiting the Chernobyl accident dispersion event over Europe. We develop a fast four-dimensional variational scheme (4D-Var), which seems appropriate for the retrieval of large parameter fields from large observations sets, and for the retrieval of parameters that are non-linearly related to concentrations. The 4D-Var, and especially an approximate adjoint of the transport model, is tested and validated using several advection schemes that are
influential on the forward simulation as well as on the data assimilation results. Firstly, the inverse modeling system is applied to the assessment of the dry deposition parameters and of the wet deposition parameters. It is then applied to the retrieval of the emission field alone, to the joint optimization of removal process parameters and source parameters, and to the optimization of larger parameter fields, such as horizontal and vertical diffusivities, or dry deposition velocity field. The physical parameters used so far in the literature for the Chernobyl dispersion simulation are partly supported by the study. The crucial question of deciding whether such an inversion is merely a tuning of parameters, or a retrieval of physically meaningful quantities is discussed. Even though inversion of parameter fields may fail to determine physical values for the parameters, it achieves statistical adaptation that partially corrects for model errors, and, using the inverted parameter fields, leads to considerable improvement in the simulation scores.

![Figure 2](image-url)  
*Figure 2. Validation of the parameter estimation approach using 4D-Var for dry deposition and wet scavenging parameters in the context of the Chernobyl dispersion event. The 4D-Var optimization and the brute force screening value approach lead to the same result.*

### 6.1.3. Real-time data assimilation

**Participants:** Vivien Mallet, Anne Tilloy, Fabien Brocheton [Numtech], David Poulet [Numtech], Cécile Honoré [Airparif], Édouard Debry [INERIS].

Based on Verdandi, Polyphemus and the “Urban Air Quality Analysis” software, real-time data assimilation was carried out at urban scale. The Best Linear Unbiased Estimator (BLUE) was computed for every hourly concentration map that the ADMS model computed. A posteriori tests were conducted over Clermont-Ferrand and Paris. We addressed the key issue of the covariance of the state error. The form of the error covariance between two points was determined based on the road network, considering the distance between points along the road and the distance of each point to the road. A few parameters (primarily two decorrelation lengths) were determined thanks to cross validation with several months of simulations and observations. The results showed strong improvements even at locations where no data was assimilated. The assimilation was carried out in the prototype “Votre Air” ([http://votreair.airparif.fr/](http://votreair.airparif.fr/)) for real-time air quality estimation over a part of Paris, which originally run in the context of the Futur-en-Seine festival and now runs operationally since June 2011.
At larger scale, the data assimilation library Verdandi was used to apply data assimilation (optimal interpola-
tion) with the air quality model Chimere. This preliminary work will help INERIS to apply optimal interpola-
tion in the operational platform Prev’air.

6.2. Inverse modeling

Many of this year’s studies have focused on inverse modeling, including the reconstruction of the Fukushima
radionuclide source term. All were targeted to a particular application. However most of them include new
methodological developments.

6.2.1. Estimation of errors in the inverse modeling of accidental release of atmospheric
pollutant: Application to the reconstruction of the Fukushima Daiichi source term

Participants: Victor Winiarek, Marc Bocquet, Olivier Saunier [IRSN], Anne Mathieu [IRSN].

The aim of this research activity is the implementation of data assimilation methods, particularly inverse
modeling methods, in the context of an accidental radiological release from a nuclear power plant and their
application in the specific case of the Fukushima Daiichi accident. The particular methodological focus is the a
posteriori estimation of the prior errors statistics. In the case of the Fukushima Daiichi accident, the number of
available observations is small compared to the number of source parameters to retrieve and the reconstructed
source is highly sensitive to the prior errors. That is the why they need to be well established and justified.

In this aim, three methods have been proposed: one method relies on an L-curve estimation technique, another
one on the Desroziers’ iterative scheme and the last method, assumed to be the most robust, relies on the
maximum likelihood principle (generalized to a non-Gaussian context).

These three methods have been applied to the reconstruction of cesium-137 and iodine-131 source terms from
the Fukushima Daiichi accident. Because of the poor observability of the Fukushima Daiichi emissions, these
methods provide lower-bounds for cesium-137 and iodine-131 reconstructed activities. Nevertheless, with
the new method based on semi-Gaussian statistics for the background errors, these lower-bound estimates,
$1.2 - 4.0 \times 10^{16}$ Bq for cesium-137, with an estimated standard deviation range of $15 - 20\%$, and $1.9 - 3.8 \times 10^{17}$
Bq for iodine-131, with an estimated standard deviation range of $5 - 10\%$, are of the same order of magnitude
as those provided by the Japanese Nuclear and Industrial Safety Agency, and about 5 to 10 times less than the
Chernobyl atmospheric releases.

6.2.2. Optimal Representation of Source-Sink Fluxes for Mesoscale Carbon Dioxide Inversion

Participants: Lin Wu, Marc Bocquet, Frédéric Chevallier [LSCE, CEA], Thomas Lauvaux [Department of
Meteorology, Pennsylvania State University, USA], Peter Rayner [School of Earth Sciences, University of
Melbourne, Australia], Ken Davis [Department of Meteorology, Pennsylvania State University, USA].

This study is an application of our previous theoretical developments on a consistent Bayesian multiscale for-
malism to optimally design control space (in which control variables are to be estimated). We construct the
optimal adaptive representations of the surface fluxes for mesoscale carbon dioxide inversions. Such repre-
sentations are taken from a large dictionary of adaptive multiscale grids. These optimal representations are
obtained by maximizing the number of Degrees of Freedom for the Signal (DFS) that measures the informa-
tion gain from observations to resolve the unknown fluxes. Consequently information from observations can
be better propagated within the domain through these optimal representations.

The optimal representations are constructed using synthetic continuous hourly carbon dioxide concentration
data in the context of the Ring 2 experiment in support of the North American Carbon Program Mid Continent
Intensive (MCI). Compared with the regular grid at finest scale, optimal representations can have similar
inversion performance with far fewer grid cells. For the Ring 2 network of eight towers, in most cases, the DFS
value is relatively small compared to the number of observations $d$ (DFS/d < 20%). In this multiscale setting,

scale-dependent errors due to the aggregation of flux variables are identified and explicitly formulated for more
reliable inversions. It is recommended that this aggregation error should be taken into account, especially when
the correlations in the errors of a priori fluxes are physically unrealistic. The optimal multiscale grids allow to
adaptively mitigate the aggregation error.
6.3. Monitoring network design

In this section, we report studies that are related to the evaluation of monitoring network and to new monitoring strategies. As opposed to last year’s report, they may not be strictly addressing optimal network design.

6.3.1. Eyjafjallajökull ash concentrations derived from both Lidar and modeling

**Participants:** Patrick Chazette [LSCE], Marc Bocquet, Philippe Royer [LSCE], Victor Winiarek, Jean-Christophe Raut [ATMOS], Philippe Labazuy [OPG/LMV], Mathieu Gouhier [OPG/LMV], Méloody Lardier [LEOSPHERE], Jean-Pierre Cariou [LEOSPHERE].

Following the eruption of the Icelandic volcano Eyjafjallajökull on April 14 2010, ground-based N2-Raman lidar (GBL) measurements were used to trace the temporal evolution of the ash plume from April 16 to April 20 2010, above the southwestern suburb of Paris. The nighttime overpass of the Cloud-Aerosol LIdar with Orthogonal Polarization onboard Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation satellite (CALIPSO/CALIOP), on April 17 2010, was an opportunity to complement GBL observations. The plume shape retrieved from GBL has been used to assess the size range of the particles size. The lidar-derived aerosol mass concentrations (PM) have been compared with model-derived PM concentrations held in the Eulerian model Polair3D transport model, driven by a source term inferred from the SEVIRI sensor on board the satellite Meteosat. The consistency between model and ground-based wind lidar and CALIOP observations has been checked. The spatial and temporal structures of the ash plume as estimated by each instrument and by the Polair3D simulations are in good agreement.

6.3.2. Potential of the International Monitoring System radionuclide network for inverse modeling

**Participants:** Mohammad Reza Koohkan, Marc Bocquet, Lin Wu, Monika Krysta [The Preparatory Commission for the Comprehensive Nuclear Test-Ban Treaty Organization].
The International Monitoring System (IMS) radionuclide network enforces the Comprehensive Nuclear-Test-Ban Treaty, which bans nuclear explosions. We have evaluated the potential of the IMS radionuclide network for inverse modeling of the source, whereas it is usually assessed by its detection capability. To do so, we have chosen the Degrees of Freedom for the Signal (DFS), a well established criterion in remote sensing, in order to assess the performance of an inverse modeling system. Using a recent multiscale data assimilation technique, we have computed optimal adaptive grids of the source parameter space by maximizing the DFS. This optimization takes into account the monitoring network, the meteorology over one year (2009) and the relationship between the source parameters and the observations derived from the FLEXPART Lagrangian transport model. Areas of the domain where the grid-cells of the optimal adaptive grid are large emphasize zones where the retrieval is more uncertain, whereas areas where the grid-cells are smaller and denser stress regions where more source variables can be resolved.

The observability of the globe through inverse modeling is studied in strong, realistic and small model error cases. The strong error and realistic error cases yield heterogeneous adaptive grids, indicating that information does not propagate far from the monitoring stations, whereas in the small error case, the grid is much more homogeneous. In all cases, several specific continental regions remain poorly observed such as Africa as well as the tropics, because of the trade winds. The northern hemisphere is better observed through inverse modeling (more than 60% of the total DFS) mostly because it contains more IMS stations. This unbalance leads to a better performance of inverse modeling in the northern hemisphere winter. The methodology is also applied to the subnetwork composed of the stations of the IMS network that measure noble gases.

6.3.3. Optimal redistribution of the background ozone monitoring stations over France

Participants: Lin Wu, Marc Bocquet.

In this study, the BDQA background stations are partially redistributed over France under a set of design objectives, which are defined on a regular grid that covers France. Spatial interpolations are used to extrapolate simulated concentrations (of chemistry-transport models or assimilation results) to these grid nodes. Three types of criteria are considered: the geostatistical, geometrical, and physical ones. Simulated annealing is employed to select optimally the stations. Significant improvement with all the proposed criteria has been found for the optimally redistributed network against the original background BDQA network. For complex objectives, e.g. that addressing the heterogeneity of ozone field, the physical criteria are more appropriate.

6.4. Ensemble methods

Due to the great uncertainties that arise in air quality modeling, relying on a single model may be not sufficient. Therefore ensembles of simulations are now considered in a wide range of applications, from uncertainty estimation to operational forecast.

6.4.1. Uncertainty estimation based on multimodel ensembles and Monte Carlo simulations

Participants: Damien Garaud, Vivien Mallet, Raphaël Périent, Irène Korsakissok [IRSN], Denis Quéo [IRSN].

Air quality forecasts are limited by strong uncertainties especially in the input data and in the physical formulation of the models. There is a need to estimate these uncertainties for the evaluation of the forecasts, the production of probabilistic forecasts, and a more accurate estimation of the error covariance matrices required by data assimilation.

Because a large part of the uncertainty in the forecast originates from uncertainties in the model formulation (primarily the physical parameterizations), a multimodel ensemble seems to be the adequate tool for uncertainty estimation. Several 100-member ensembles were generated and calibrated (based on observations – see the example in Figure 4) over year 2007 in order to study the impact of EDF thermal plants on air quality. The ensemble simulations were carried out at European scale and at the scale of French regions so as to study the local impact of two EDF plants. This approach allowed us to estimate the uncertainty on the simulated impact of the plants. Based on the calibrated ensembles, we also computed probabilistic forecasts for threshold exceedences.
Specific work has been carried out to decompose the discrepancy between observations and model simulations in three errors: the modeling error, the representativeness error and the observational error. It was shown that the representativeness error might account for a third of the discrepancy.

After the Fukushima nuclear disaster, we worked on uncertainty estimation of the transport simulations at Japan scale. We carried out Monte Carlo simulations with perturbations on most input parameters. The first results showed that the variability of the ensemble simulations is great enough to reasonably sample the uncertainties after a calibration.

![Figure 4. Uncertainty estimate (standard deviation) of two ensembles: a raw ensemble on the left, a calibrated ensemble on the right. The uncertainty estimation is significantly reduced after calibration.](image)

6.4.2. Aggregation of meteorological forecasts

**Participants:** Anne Tilloy, Vivien Mallet, Fabien Brocheton [Numtech], David Poulet [Numtech].

Nowadays it is standard procedure to generate an ensemble of simulations for a meteorological forecast. Usually, meteorological centers produce a single forecast, out of the ensemble forecasts, computing the ensemble mean (where every model receives an equal weight). The generation of a single forecast with a weighted linear combination is called sequential aggregation. Each time new observations are available, the weights of the linear combination are updated and applied for the next forecasts. We applied the discounted ridge regression algorithm, which we previously introduced for sequential aggregation of air quality forecasts, to forecast wind and temperature at given observation stations. The ensemble was generated with forecasts at different range from two models. The aggregation proved to be efficient for one-day forecasts at least.

6.5. Image assimilation

Sequences of images, such as satellite acquisitions, display structures evolving in time. This information is recognized of major interest by forecasters (Meteorologists, oceanographers, etc) in order to improve the information provided by numerical models. However, these satellite images are mostly assimilated in geophysical models on a point-wise basis, discarding the space-time coherence visualized by the evolution of structures such as clouds. Assimilating in an optimal way image data is of major interest and this issue should be considered in two ways:
from the model’s viewpoint, the problem is to control the location of structures using the observations,
from the image’s viewpoint, a model of the dynamics and structures has to be built from the observations.

6.5.1. Divergence-free motion estimation

Participants: Dominique Béréziat [UPMC/LIP6], Isabelle Herlin, Nicolas Mercier, Sergiy Zhuk.

This research addresses the issue of divergence-free motion estimation on an image sequence, acquired over a given temporal window. Unlike most state-of-the-art technics, which constrain the divergence to be small thanks to Tikhonov regularisation terms, a method that imposes a null value of divergence of the estimated motion is defined.

Motion is characterized by its vorticity value and assumed to satisfy the Lagragian constancy hypothesis. An image model is then defined: the state vector includes the vorticity, whose evolution equation is derived from that of motion, and a pseudo-image that is transported by motion. An image assimilation method, based on the 4D-Var technics, is defined and developed that estimates motion as a compromise between the evolution equations of vorticity and pseudo-image and the observed sequence of images: the pseudo-images have to be similar to the acquisitions.

As the evolution equations of vorticity and pseudo-image involve the motion value, the motion field has to be retrieved at each time step of the studied temporal window. An algebraic method, based on the projection of vorticity on a subspace of eigenvectors of the Laplace operator, is defined in order to allow Dirichlet boundary conditions for the vorticity field.

The divergence-free motion estimation method is tested and quantified on synthetic data. This shows that it computes a quasi-exact solution and outperforms the state-of-the-art methods that were applied on the same data.

The method is also applied on Sea Surface Temperature (SST) images acquired over Black Sea by NOAA-AVHRR sensors. The divergence-free assumption is roughly valid on these acquisitions, due to the small values of vertical velocity at the surface. Fig. 5 displays data and results. As no ground truth of motion is available, the method is quantified by the value of correlation between the pseudo-images and the real acquisitions. Again, the method provides the best result compared to other state-of-the-art algorithms.

6.5.2. Improvement of motion estimation by assessing errors on the dynamics

Participants: Dominique Béréziat [UPMC/LIP6], Isabelle Herlin, Nicolas Mercier.

Data assimilation technics are used to retrieve motion from image sequences. These methods require a model of the underlying dynamics, displayed by the evolution of image data. In order to quantify the approximation linked to the chosen dynamic model, we consider adding a model error term in the evolution equation of motion and design a weak formulation of 4D-Var data assimilation. The cost function to be minimized simultaneously depends on the initial motion field, at the begining of the studied temporal window, and on the error value at each time step. The result allows to assess the model error and analyze its impact on motion estimation.

This error assessment method is evaluated and quantified on twin experiments, as no ground truth would be available for real image data. Fig. 6 shows four frames of a series of observations obtained by integrating the evolution model from an initial condition on image and velocity field (the ground truth \( w_{ref}(0) \) displayed on the left of Fig. 7). An error value is added at each time step on the motion value, when integrating the simulation model. This error is a constant bias.

We performed two data assimilation experiments. The first one considers the evolution model as perfect, with no error in the evolution equation. It is denoted PM (for Perfect Model). The second one, denoted IM (for Imperfect Model) involves an error in the motion evolution equation. In fig. 7 are displayed the motion fields retrieved by PM and IM at the beginning of the temporal window.

As it can be seen, IM computes a correct velocity field while PM completely fails.
Figure 5. Results on SST images (observation and motion result).

Figure 6. Observations Images.

Figure 7. Comparaison estimations with ground truth.
The results on this error assessment method are still preliminary. Perspectives are considered in order to correctly retrieve the error on dynamics by constraining its shape. An important application is, for instance, the detection of dynamics changes on long temporal sequences.

6.5.3. Nonlinear Observation Equation For Motion Estimation

Participants: Dominique Béréziat [UPMC/LIP6], Isabelle Herlin.

In the image processing literature, the optical flow equation is usually chosen to assess motion from an image sequence. However, it corresponds to an approximation that is no more valid in case of large displacements. We evaluate the improvements obtained when using the non linear transport equation of the image brightness by the velocity field. A 4D-Var data assimilation method is designed that simultaneously solves the evolution equation and the observation equation, in its non linear and linearized form. The comparison of results obtained with both observation equations is quantified on synthetic data and discussed on oceanographic Sea Surface Temperature (SST) images. We show that the non linear model outperforms the linear one, which underestimates the motion norm. Fig. 8 illustrates this on SST images (motion vectors are displayed by arrows).

![Figure 8. Results on SST images. Top: Non-linear observation equation. Bottom: linear.](image)

The aim of this research is to achieve a correct estimation of motion when the object displacement is greater than its size. In this case, coarse-to-fine incremental methods as well as the non linear data assimilation method fail to retrieve a correct value. The perspective is then to include, in the state vector, a variable describing the trajectory of pixels. The observation operator will then measure the effective displacement of pixels, according to their trajectories, and allow a better estimation of motion value.

6.5.4. Recovering missing data on images

Participants: Dominique Béréziat [UPMC/LIP6], Isabelle Herlin, Nicolas Mercier.
A data assimilation method was designed to recover missing data and reduce noise on satellite acquisition. The state vector includes motion and image fields. Its evolution equation is based on assumptions on the underlying dynamics displayed by the sequence of images and considers the passive transport of images by the velocity field. The observation equation compares the image component of the state vector and the real observations. Missing and noisy data regions are characterized by a gaussian observation error, whose covariance matrix $R$ has an approximately infinitesimal inverse. The noise recovering method computes a solution of the state vector that is a compromise between the evolution equation and the observation equation. The image component of the solution satisfies the assumptions on the dynamics and is close to the real acquisition according to the covariance matrix $R$. This image component provides the reconstruction of the noisy acquisitions.

The recovering method was applied on synthetically noised SST images in order to quantify the quality of the recovering (see Fig. 9).

![Figure 9. Recovering of noisy data.](image)

The method is a promising alternative to those such as space-time interpolation. In the experiments, the Lagrangian constancy of the state vector is used as evolution equation. The perspectives concern the use of more advanced dynamic equations, as for instance the shallow water equations that link the motion field to the thickness of the ocean surface layer, and improved modeling of illumination changes over the sequence, due to various order acquisition times.

### 6.5.5. Validation of velocity estimated with image assimilation

**Participants:** Isabelle Herlin, Etienne Huot, Gennady Korotaev [Marine Hydrophysical Institute, Ukraine], Evgeny Plotnikov [Marine Hydrophysical Institute, Ukraine].

This study is achieved in collaboration with the Marine Hydrophysical Institute (MHI) of Sevastopol. The aim is to estimate and further validate the estimation of Black Sea surface velocity from sequences of satellite images in order to allow an optimal assimilation of these pseudo-observations in 3D ocean circulation models. Several Image Models were designed that express the dynamics of velocity and the temporal evolution of image data. An image assimilation method was developed based on the 4D-Var formalism and estimates motion as a compromise between the Image Model, the image acquisitions and regularity heuristics on the velocity field. Two Image Models were qualitatively and quantitatively compared: the *Stationary Image Model* (SIM) based on the heuristics of stationary motion, which is valid at short temporal scale, and the *Shallow Water Image Model* (SWIM), based on the shallow-water equations.

The comparison between SIM and SWIM results confirms that SIM provides correct results only on short temporal windows, while SWIM allows to process longer image sequences.
The validation of motion estimation by image assimilation requires additional observation data, as no measure of motion is available from satellite sensors. Sea Level Anomaly, measured by satellite altimeters, is then compared to the thickness of the surface layer as estimated by the Shallow Water Image Model. This comparison shows a good adequacy of shape and values \([30]\), \([32]\). As the velocity field is strongly related to this thickness value from the physical evolution laws, these results further validate the estimation of the velocity and the image assimilation approach.

6.5.6. Velocity estimation under the geostrophic equilibrium assumption

**Participants:** Isabelle Herlin, Etienne Huot.

The surface motion of the Black Sea approximately verifies the geostrophic equilibrium property. As the surface velocity can be directly derived from the surface layer thickness \(h\), this allows to simplify the shallow-water equations and the dynamics is expressed by the evolution of \(h\). The Geostrophic Shallow Water Image Model (GSWIM) is then designed based on the evolution of \(h\) and the image data. A 4D-Var assimilation method was designed and developed in order to estimate \(h\) from a sequence of satellite images. The motion field is then computed from the estimation of \(h\).

This method was first tested and quantified on twin experiments with satellite data. Figure 10 simultaneously displays the result of the velocity estimation by GSWIM and the ground truth.

![Figure 10. Left: first image of the sequence, Center: motion estimated by GSWIM, Right: ground truth.](image)

6.5.7. Coupling models for motion estimation on long temporal image sequences

**Participants:** Karim Drifi, Isabelle Herlin.

This study concerns the estimation of motion fields from satellite images on long temporal sequences. The huge computational cost and memory required by data assimilation methods on the pixel grid makes impossible to use these techniques on long temporal intervals. For a given dynamic model (named full model on the pixel grid), the Galerkin projection on a subspace provides a reduced model that allows image assimilation at low cost. The definition of this reduced model however requires defining the optimal subspace of motion. A sliding windows method is thus designed:

- The long image sequence is split into small temporal windows that half overlap in time.
- Data assimilation in the full model is applied on the first window to retrieve the motion field.
- The estimate of motion field at the beginning of the second window makes it possible to define the subspace for motion and a reduced model is obtained by Galerkin projection.
- Data assimilation in the reduced model is applied for this second window.
- The process is then iterated for the next window until the end of the whole image sequence.
Figure 11 summarize the described methodology.

Twin experiments were designed to quantify the results of this sliding windows method. Results on motion estimation are given in Figure 12 and compared with the ground truth. The NRMSE (in percentage) ranges from 1.1 to 4.0% from the first to the sixth window. On the first window, 3 hours are required to estimate the motion fields with the full model. For the next 5 windows, less than 1 minute is required to compute motion.

Figure 11. Sliding windows method.

Figure 12. Estimated Motion (up) compared to the ground truth (down).
6.6. Minimax filtering

Participants: Vivien Mallet, Sergiy Zhuk.

In air quality modeling, the model error is supposed to take into account the uncertainty on the meteorological fields (winds and vertical diffusivities), the segregation and mixing in emission areas that affect the effective kinetic rates of reactions, the boundary condition fields, all physical parameterizations (dry deposition, wet scavenging), etc. All the above sources of error have bounded energy and typically are not normally distributed or independent.

In order to take this into account in the data assimilation process, we applied the Minimax State Estimation (MSE) approach. It is well known that a bottle-neck of minimax estimation algorithms as well as of the family of Kalman-type filters is the dimension issue. To solve it, we applied a powerful version of the minimax filter developed for the so-called differential-algebraic equations. This filter works for any linear ordinary differential equation with time-dependent coefficients on any linear manifold, which can also change in time. Based on this novel approach, we derived a computationally tractable reduced version of the minimax filter. The derivation was made in a new and rigorous framework. In addition to the reduction, the new filter shows all the interesting properties inherited from the minimax setting, especially the description of the model and observational errors, which only need to have bounded energy. The later is important in the context of applications because the errors are always bounded. In contrast, most high-dimensional statistical filters are designed for unbounded random errors with special distribution function.

The algorithm, already implemented in the data assimilation library Verdandi, was further developed to compute a better reduction base.

The algorithm was in addition applied for ensemble sequential aggregation. The minimax filter computes weights for each model in the ensemble and a forecast is generated as the weighted linear combination of the ensemble members. In this case, the dimension is small so that no reduction is needed. The approach shows two noteworthy advantages: the observational errors can be taken into account and a dynamics can be given for the weights.

6.6.1. A posteriori minimax motion estimation

Participants: Sergiy Zhuk, Isabelle Herlin.

Data assimilation algorithms based on the 4D-Var formulation look for the so-called conditional mode estimate. The latter maximizes the conditional probability density function, provided the initial condition, model error and observation noise are realizations of independent Gaussian random variables. However this Gaussian assumption is often not satisfied for geophysical flows. Moreover, the estimation error of the conditional mode estimate is not a first-hand result of these methods. The issues above can be addressed by means of the Minimax State Estimation (MSE) approach. It allows to filter out any random (with bounded correlation operator) or deterministic (with bounded energy) noise and assess the worst-case estimation error. The iterative MSE algorithm was developed for the problem of optical flow estimation from a sequence of 2D images. The main idea of the algorithm is to use the “bi-linear” structure of the Navier-Stokes equations and optical flow constraint in order to iteratively estimate the optical flow. The algorithm consists of the following parts:

1) we construct the pseudo-observations that is the estimate of the image brightness function \( I(x, y, t) \) solving the optical flow constraint such that \( I \) fits (in the sense of least-squares) the observed sequence of images; to do so we set the velocity field in the optical flow constraint to be the current minimax estimate of the velocity field \( v \), obtained at the previous iteration of the algorithm, and construct the minimax estimate \( \hat{I} \) of the solution of the resulting linear advection equation using image sequence as discrete measurements;

2) we plug the estimate of the image gradient, obtained out of pseudo-observations \( \hat{I} \) in 1), into the optical flow constraint and the current minimax estimate \( v \) of the velocity field into the non linear part of Navier-Stokes equations so that we end up with a system of linear PDEs, which represents an extended state equation: it contains a linear parabolic equation for the velocity field and linear advection equation for the image brightness.
function; we construct the minimax estimate of the extended state equation using the image sequence as discrete measurements of the brightness function;

3) we use the minimax estimate of the velocity field obtained in 2) in order to start 1) again.

Currently numerical experiments are carried out in order to study the convergence rate of the algorithm.

6.7. Fire application

6.7.1. Model evaluation for fire propagation

Participants: Hajer Ayed, Vivien Mallet, Jean-Baptiste Fillipi [CNRS], Bahaa Nader [University of Corsica].

In the field of forest fires risk management, important challenges exist in terms of people and goods preservation. Answering to strong needs from different actors (firefighters, foresters), researchers focus their efforts to develop operational decision support system tools that may forecast wildfire behavior. This requires the evaluation of models performance, but currently, simulation errors are not sufficiently qualified and quantified. As the main objective is to realize a decision support system, it is required to establish robust forecast evaluations. In the context of the ANR project IDEA, the evaluation of model simulations has been started with a bibliographical review, the implementation of a series of forecast scores and the definition of a series of ideal cases where some classical scores may fail (especially in taking into account the dynamics).

In addition, we consider that the proper evaluation of a model requires to apply it to a large number of fires – instead of carrying out a fine tuning on just one fire. We implemented a software to simulate a large number of fires (from the Prométhée database, http://www.promethee.com/) with the simulation model ForeFire (CNRS/University of Corsica) and to evaluate the results with our error measures. One simulation requires mainly the following data: the ignition point, the ground elevation, the vegetation cover and the wind field. See the illustration of Fig. 13.

![Figure 13. Fire simulation (using ForeFire) in red elevated contour, and observation (from Prométhée) of the burned area in filled red contour, for a 2003 fire near San-Giovanni-di-Moriani (Corsica).](image)
6. New Results

6.1. Foundations of information hiding

Information hiding refers to the problem of protecting private information while performing certain tasks or interactions, and trying to avoid that an adversary can infer such information.

This is one of the main areas of research in Comète, and two PhD thesis based on this topic have been defended this year in Comète [12], [11] have been defended this year. We are exploring several topics, described below. An overview of our results is contained in [24].

6.1.1. The problem of information hiding in presence of concurrency

The analysis of probabilistic concurrent systems usually relies on the notion of scheduler in order to solve the nondeterminism. Unfortunately the classical notion of scheduler, which is a mathematical functions that chooses the next step depending on the history of the computation, can leak any secret information contained in the history. This creates false positives, and it is known as the problem of the allmighty scheduler. One way to solve this problem, already explored in literature, is to fix the strategy of the scheduler beforehand [31]. However this solution is considered too rigid and unrealistic. In [14] we have propose a milder restriction on the schedulers, and we have defined the notion of strong (probabilistic) information hiding under various notions of observables. Furthermore, we have proposed a method, based on the notion of automorphism, to verify that a system satisfies the property of strong information hiding, namely strong anonymity or no-interference, depending on the context.

6.1.2. Modeling the knowledge of the adversary

In [15] we have developed a game semantics for process algebra with two interacting agents. The purpose of our semantics is to make manifest the role of knowledge and information flow in the interactions between agents and to control the information available to interacting agents. We have defined games and strategies on process algebras, so that two agents interacting according to their strategies determine the execution of the process, replacing the traditional scheduler. We have shown that different restrictions on strategies represent different amounts of information being available to a scheduler. We have also shown that a certain class of strategies corresponds to the syntactic schedulers of Chatzikokolakis and Palamidessi [32], which were developed to overcome problems with traditional schedulers modeling interaction. The restrictions on these strategies have an explicit epistemic flavor.

6.1.3. Opacity

Opacity is a security property formalizing the absence of secret information leakage and we have addressed in [30] the problem of synthesizing opaque systems. A secret predicate $S$ over the runs of a system $G$ is opaque to an external user having partial observability over $G$, if s/he can never infer from the observation of a run of $G$ that the run belongs to $S$. We have chosen to control the observability of events by adding a device, called a mask, between the system $G$ and the users. We have first investigated the case of static partial observability where the set of events the user can observe is fixed a priori by a static mask. In this context, we have shown that checking whether a system is opaque is PSPACE-complete, which implies that computing an optimal static mask ensuring opacity is also a PSPACE-complete problem. Then, we have introduced dynamic partial observability where the set of events the user can observe changes over time and is chosen by a dynamic mask. We have shown how to check that a system is opaque with respect to a dynamic mask and we have also addressed the corresponding synthesis problem: given a system $G$ and secret states $S$, compute the set of dynamic masks under which $S$ is opaque. Our main result is that the set of such masks can be finitely represented and can be computed in EXPTIME and this is a lower bound. Finally we have also addressed the problem of computing an optimal mask.
6.1.4. Interactive systems

In [13] we have considered systems where secrets and observables can alternate during the computation. We have shown that the information-theoretic approach which interprets such systems as (simple) noisy channels is not valid anymore. However, the principle can be recovered if we consider more complicated types of channels, that in Information Theory are known as channels with memory and feedback. We have shown that there is a complete correspondence between interactive systems and such kind of channels. Furthermore, we have shown that the capacity of the channels associated to such systems is a continuous function of the Kantorovich metric.

6.1.5. Differential privacy

Differential privacy is a notion that has emerged in the community of statistical databases, as a response to the problem of protecting the privacy of the database’s participants when performing statistical queries. The idea is that a randomized query satisfies differential privacy if the likelihood of obtaining a certain answer for a database $x$ is not too different from the likelihood of obtaining the same answer on adjacent databases, i.e. databases which differ from $x$ for only one individual.

In [17], [16], we have analyzed critically the notion of differential privacy in light of the conceptual framework provided by the Rényi min information theory. We have shown that there is a close relation between differential privacy and leakage, due to the graph symmetries induced by the adjacency relation. Furthermore, we have considered the utility of the randomized answer, which measures its expected degree of accuracy. We have focused on certain kinds of utility functions called “binary”, which have a close correspondence with the Rényi min mutual information. Again, it turns out that there can be a tight correspondence between differential privacy and utility, depending on the symmetries induced by the adjacency relation and by the query. Depending on these symmetries we can also build an optimal-utility randomization mechanism while preserving the required level of differential privacy. Our main contribution is a study of the kind of structures that can be induced by the adjacency relation and the query, and how to use them to derive bounds on the leakage and achieve the optimal utility.

6.2. Concurrent constraint programming

6.2.1. Bisimilarity

Bisimilarity is one of the main representative equivalences for concurrent behaviour. It captures our intuitive notion of process equivalence; two processes are equivalent if they can match each other’s moves. Furthermore, it provides an elegant co-inductive proof technique based on the notion of bisimulation. Nevertheless, there have been few attempts to define a notion of bisimilarity for concurrent constraint programming (ccp). The ones we were aware of are those in [40] and [36] but they are not completely satisfactory: The first one may tell apart processes with identical observable behaviour, while the second quantifies over all possible inputs from the environment, and hence it is not clear whether it can lead to a feasible proof technique.

Bisimilarity relies on labelled transitions: each evolution step of a system is tagged by some information aimed at capturing the possible interactions of a process with the environment. In [18] we have provided a labelled transition system for ccp and we have proposed a notion of ccp bisimilarity. Intuitively, in this transition system the labels represent the minimal information that processes require from the environment to execute. Furthermore we have shown that, unlike previous approaches, our notion of bisimilarity coincides with the standard notion of equivalence for (deterministic) ccp. This way we have provided ccp with an alternative co-inductive proof technique, coherent with previous equivalences, for process behaviour.

When the state space of a system is finite, the ordinary notion of bisimilarity can be computed via the well-known partition refinement algorithm, but unfortunately, this algorithm does not work for ccp bisimilarity. In [19] we have proposed a variation of the partition refinement algorithm for verifying ccp bisimilarity. To the best of our knowledge this is the first work providing for the automatic verification of program equivalence for ccp.
6.2.2. Modeling cellular signaling systems

The molecular mechanisms of cell communication with the environment involve many concurrent processes governing dynamically the cell function. This concurrent behavior makes traditional methods, such as differential equations, unsatisfactory as a modeling strategy since they do not scale well when a more detailed view of the system is required.

In [19] we have described a modeling strategy for cellular signaling systems based on a temporal and probabilistic extension of ccp. Starting from an abstract model, we have built refinements adding further details coming from experimentation or abstract assumptions. The advantages of our approach are: due to the notion of partial information as constraints in CCP, the model can be straightforwardly extended when more information is available; qualitative and quantitative information can be represented by means of probabilistic constructs of the language; finally, the model is a runnable specification and can be executed, thus allowing for the simulation of the system. We have outlined the use of this methodology to model the interaction of G-protein-coupled receptors with their respective G-proteins that activates signaling pathways inside the cell. Finally, we have presented simulation results obtained from an implementation of the framework.

6.3. Session types

In [22] we have presented a type checking algorithm for establishing a session-based discipline in the pi calculus of Milner, Parrow and Walker [37]. Our session types are qualified as linear or unrestricted. Linearly typed communication channels are guaranteed to occur in exactly one thread, possibly multiple times; afterwards they evolve as unrestricted channels. Session protocols are described by a type constructor that denotes the two ends of one and the same communication channel. We have proved the soundness of the algorithm by showing that processes consuming all linear resources are accepted by a typing system preserving typings during the computation and that type checking is consistent w.r.t. structural congruence.
6. New Results

6.1. Optimal control with singular arcs

Participants: Pierre Martinon, Andrei Dmitruk [Moscow State University], Pablo Lotito [U. Tandil, Argentina], Soledad Aronna, Frédéric Bonnans.

These studies enter in the framework of the PhD thesis of S. Aronna, supervised by J.F. Bonnans and P. Lotito, that ended in December 2011.

In the paper [21] we deal with optimal control problems for systems affine in the control variable. We have nonnegativity constraints on the control, and finitely many equality and inequality constraints on the final state. First, we obtain second order necessary optimality conditions. Secondly, we get a second order sufficient condition for the scalar control case. The results use in an essential way the Goh transformation.

In the report [22], we design a shooting algorithm applied to optimal control problems for which all control variables enter linearly in the Hamiltonian. This shooting algorithm is non standard, in particular since there are more equations than unknowns, and extends some previous algorithms designed for specific structures. We start investigating the case having only initial-final state constraints and free control variable, and afterwards we deal with control bounds. The shooting algorithm is locally well-posed and quadratically convergent if the derivative of its associated shooting function is injective at the optimal solution. The main result of this paper is to provide a sufficient condition for this injectivity, that is very close to the second order necessary condition. We prove that this sufficient condition guarantees the stability of the optimal solution under small perturbations and the well-posedness of the shooting algorithm for the perturbed problem. We present numerical tests that validate our method.

In the report [20] we deal with optimal control problems for systems that are affine in one part of the control variables and nonlinear in the rest of the control variables. We have finitely many equality and inequality constraints on the initial and final states. First we obtain second order necessary and sufficient conditions for weak optimality. Afterwards, we propose a shooting algorithm, and we show that the sufficient condition above-mentioned is also sufficient for the injectivity of the shooting function at the solution.

6.2. Characterization of a local quadratic growth of the Hamiltonian for control constrained optimal control problems

Participants: Frédéric Bonnans, Nikolai Osmolovskii [Systems Research Institute, Warsaw].

In the paper [25] we consider an optimal control problem with inequality control constraints given by smooth functions satisfying the hypothesis of linear independence of gradients of active constraints. For this problem, we formulate a generalization of strengthened Legendre condition and prove that this generalization is equivalent to the condition of a local quadratic growth of the Hamiltonian subject to control constraints.

6.3. Hamilton-Jacobi approach for deterministic control problems

Participants: Albert Altarovici, Olivier Bokanowski, Yingda Cheng [University of Texas], Anna Desilles, Nicolas Forcadel, Zhiping Rao, Chi-Wang Shu [Brown University], Hasnaa Zidani.
The paper [30] deals with deterministic optimal control problem with state constraints and non-linear dynamics. It is known for such a problem that the value function is in general discontinuous and its characterization by means of an HJ equation requires some controllability assumptions involving the dynamics and the set of state constraints. Here, we first adopt the viability point of view and look at the value function as its epigraph. Then, we prove that this epigraph can always be described by an auxiliary optimal control problem free of state constraints, and for which the value function is Lipschitz continuous and can be characterized, without any additional assumptions, as the unique viscosity solution of a Hamilton-Jacobi equation. The idea introduced in this paper bypass the regularity issues on the value function of the constrained control problem and leads to a constructive way to compute its epigraph by a large panel of numerical schemes. Our approach can be extended to more general control problems. We study in this paper the extension to the infinite horizon problem as well as for the two-player game setting. Finally, an illustrative numerical example is given to show the relevance of the approach.

In [34], [19] we study an optimal control problem governed by measure driven differential systems and in presence of state constraints. First, under some weak invariance assumptions, we study in [19] the properties of the value function and obtain its characterization by means of an auxiliary control problem of absolutely continuous trajectories. For this, we use some known techniques of reparametrization and graph completion. Then we give a characterization of the value function as the unique constrained viscosity solution of a Hamilton-Jacobi equation with measurable time dependant Hamiltonians.

The general case without assuming any controllability assumption is considered in [34]. We prove that the optimal solutions can still be obtained by solving a reparametrized control problem of absolutely continuous trajectories but with time-dependent state-constraints.

The paper [17] deals with minimal time problems governed by nonlinear systems under general time dependent state constraints and in the two-player games setting. In general, it is known that the characterization of the minimal time function, as well as the study of its regularity properties, is a difficult task in particular when no controllability assumption is made. In addition to these difficulties, we are interested here to the case when the target, the state constraints and the dynamics are allowed to be time-dependent. We introduce a particular reachability control problem, which has a supremum cost function but is free of state constraints. This auxiliary control problem allows to characterize easily the backward reachable sets, and then, the minimal time function, without assuming any controllability assumption. These techniques are linked to the well known level-set approaches. Our results can be used to deal with motion planning problems with obstacle avoidance, see [16].

Several works have been also carried out in the domain of numerical methods of HJB equations. The paper [31] aims at studying a discontinuous Galerkin scheme for front propagation with obstacles. We extend a first work published in [11], to propose a simple and direct discontinuous Galerkin (DG) method adapted to such front propagation problems. We follow the formulation of [12], leading to a level set formulation driven by a Hamilton-Jacobi variational inequality. The DG scheme is motivated by the variational formulation when the equation corresponds to linear convection problems in presence of obstacles. The scheme is then generalized to nonlinear equations, written in an explicit form. Stability analysis are performed for the linear case with Euler forward, a Heun scheme and a Runge-Kutta third order time discretization. Several numerical examples are provided to demonstrate the robustness of the method. Finally, a narrow band approach is considered in order to reduce the computational cost.

6.4. Stochastic programming

Participants: Frédéric Bonnans, Zhihao Cen, Thibault Christel [Total].

In [29] we consider a model of medium-term commodity contracts management. Randomness takes place only in the prices on which the commodities are exchanged whilst state variable is multi-dimensional. In our previous article, we proposed an algorithm to deal with such problem, based on quantization of random process and a dual dynamic programming type approach. We obtained accurate estimates of the optimal value and a suboptimal strategy from this algorithm. In this paper, we analyse the sensitivity with respect to
parameters driving the price model. We discuss the estimate of marginal price based on the Danisn’s theorem. Finally, some numerical results applied to realistic energy market problems have been performed. Comparisons between results obtained by our algorithm and other classical methods are provided and evidence the accuracy of the estimate of marginal prices.

6.5. Stochastic control

**Participants:** Frédéric Bonnans, Xiaolu Tan [CMAP], Imene Ben Latifa, Mohamed Mnif [ENIT, Tunis].

In [24], we extend a study by Carmona and Touzi on an optimal multiple stopping time problem in a market where the price process is continuous. In this paper, we generalize their results when the price process is allowed to jump. Also, we generalize the problem associated to the valuation of swing options to the context of jump diffusion processes. Then we relate our problem to a sequence of ordinary stopping time problems. We characterize the value function of each ordinary stopping time problem as the unique viscosity solution of the associated Hamilton-Jacobi-Bellman Variational Inequality.

In [27], we consider, in the framework of Galichon, Henry-Labordère and Touzi, the model-free no-arbitrage bound of variance option given the marginal distributions of the underlying asset. We first make some approximations which restrict the computation on a bounded domain. Then we propose a gradient projection algorithm together with a finite difference scheme to approximate the bound. The general convergence result is obtained. We also provide a numerical example on the variance swap option.

6.6. Stochastic control of an hybrid vehicle

**Participants:** Kamal Aouchiche [Renault], Frédéric Bonnans, Giovanni Granato, Hasnaa Zidani.

In the CDC paper [18] we present a stochastic dynamic programming (SDP) algorithm that aims at minimizing an economic criteria based on the We also work on a stochastic dynamic programming (SDP) algorithm that aims at minimizing an economic criteria based on the total energy consumption of a range extender electric vehicle (REEV). This algorithm integrates information from the REEV’s navigation system in order to obtain some information about future expected vehicle speed. The model of the vehicle’s energetic system, which consists of a high-voltage (HV) battery, the main energy source, and an internal combustion engine (ICE), working as an auxiliary energy source), is written as a hybrid dynamical system and the associated optimization problem in the hybrid optimal control framework. The hybrid optimal control problem includes two important physical constraints on the ICE, namely, an activation delay and a decision lag. Three methods for the inclusion of such physical constraints are studied. After introducing the SDP algorithm formulation we comment on numerical results of the stochastic algorithm and its deterministic counterpart.

6.7. Optimal control of PDEs

**Participants:** Frédéric Bonnans, Francisco Silva [U. Roma], Térence Bayen [U. Montpellier II].

In the report [23] we consider an optimal control problem of a semi-linear elliptic equation, with bound constraints on the control. Our aim is to characterize local quadratic growth for the cost function $J$ in the sense of strong solutions. This means that the function $J$ grows quadratically over all feasible controls whose associated state is close enough to the nominal one, in the uniform topology. The study of strong solutions, classical in the Calculus of Variations, seems to be new in the context of PDE optimization. Our analysis, based on a decomposition result for the variation of the cost, combines Pontryagin’s principle and second order conditions. While these two ingredients are known, we use them in such a way that we do not need to assume that the Hessian of Lagrangian of the problem is a Legendre form, or that it is uniformly positive on an extended set of critical directions.

6.8. Global optimization of pipe networks by the interval analysis approach: the Belgium network case

**Participants:** Frédéric Bonnans, Grégoire Spiers, Jean-Léopold Vie.
In [26] we have shown that a classical test problem for the optimization of gas networks, namely the so-called Belgium gas network, could be solved by global optimization techniques. Until now only local algorithms had been used for solving this problem. Using techniques based on interval analysis and constraint propagation we actually recover (and therefore justify) the solution computed so far.
6. New Results

6.1. Introduction
This section presents the results obtained by Compsys in 2011. For clarity, some earlier results are also recalled, when they were continued or extended during the year 2011.

6.2. Studying Optimal Spilling in the Light of SSA
Participants: Florian Brandner, Quentin Colombet, Alain Darte.

Recent developments in register allocation, mostly linked to static single assignment (SSA) form, have shown that it is possible to decouple the problem in two successive phases: a first spilling phase places load and store instructions so that the register pressure at all program points is small enough, a second assignment and coalescing phase maps the remaining variables to physical registers and reduces the number of move instructions among registers. We focused on the first phase, for which many open questions remained: in particular, we studied the notion of optimal spilling (what can be expressed?) and the impact of SSA form (does it help?).

To identify the important features for optimal spilling on load-store architectures, we developed a new integer linear programming formulation, more accurate and expressive than previous approaches. Among other features, we can express SSA $\phi$-functions, memory-to-memory copies, and the fact that a value can be stored simultaneously in a register and in memory. We implemented this formulation in LAO and analyzed in details the static and dynamic results obtained for the SPEC INT 2000 and EEMBC 1.1 benchmarks. We can draw, among others, the following conclusions: a) rematerialization is extremely important, b) SSA complicates the formulation of optimal spilling, especially because of memory coalescing when the code is not in CSSA, c) micro-architectural features are significant and thus have to be accounted for, d) significant savings can be obtained in terms of static spill costs, cache miss rates, and dynamic instruction counts.

This work has been presented at the CASES’11 conference [8].

6.3. Copy Elimination on Data Dependence Graphs
Participants: Florian Brandner, Quentin Colombet.

Register allocation recently regained much interest due to new decoupled strategies that split the problem into separate phases: spilling, register assignment, and copy elimination.

A common assumption of existing copy elimination approaches is that the original ordering of the instructions in the program is not changed. We worked on an extension of a local recoloring technique that we developed earlier, called Parallel Copy Motion [30]. We perform code motion on data dependence graphs in order to eliminate useless copies and reorder instructions, while at the same time a valid register assignment is preserved. Our results show that even after traditional register allocation with coalescing our technique is able to eliminate an additional 3% (up to 9%) of the remaining copies and reduce the weighted costs of register copies by up to 25% for the SPECINT 2000 benchmarks. In comparison to Parallel Copy Motion, our technique removes 11% (up to 20%) more copies and up to 39% more of the copy costs.

This work will be presented at the conference SAC’12 [6].

6.4. Graph-Coloring and Treescan Register Allocation Using Repairing
Participants: Quentin Colombet, Benoît Boissinot, Philip Brisk [University of California, Riverside], Sebastian Hack [Saarland University], Fabrice Rastello.
Graph coloring and linear scan are two appealing techniques for register allocation as the underlying formalism are extremely clean and simple. Our previous work advocated the use of a decoupled approach that first lowers the register pressure by spilling variables, then performs live-range splitting, coalescing, and coloring in a separate phase. This enables the design of simpler, cleaner, and more efficient register allocators.

In this context, we introduced a new and more general approach to deal with register constraints. This approach, called repairing, does not require any preliminary live-range splitting and does not introduce additional spill code. It ignores register constraints during coloring/coalescing and repairs the violated constraints afterwards. We applied this method to develop both a graph-based and a scan-based decoupled approach: one based on the iterated register coalescer (IRC) and the other on a scan algorithm (the treescan) that uses static single assignment (SSA) properties.

Our experimental evaluation shows that, for the graph-based approach, we reduced the number of vertices (edges) in the interference graph by 26% (33%) without compromising the quality of the generated code. The treescan algorithm improved the compile time of the allocation process by $6.97 \times$ over IRC while providing comparable results for the quality of the generated code.

This work was part of a collaboration with the Saarland University and the University of California, Riverside. It has been presented at the conference CASES’11 [7].

6.5. Decoupled Graph-Coloring Register Allocation with Hierarchical Aliasing

Participants: Andre Tavares [UFMG, Brazil], Quentin Colombet, Mariza Bigonha [UFMG, Brazil], Christophe Guillon [STMicroelectronics], Fernando Pereira [UFMG, Brazil], Fabrice Rastello.

Decoupling spilling from register assignment, as mentioned in previous sections, has the main advantage of simplifying the implementation of register allocators. However, the decoupled model faces many problems when dealing with register aliasing, a phenomenon typical in architectures usually seen in embedded systems, such as ARM.

We introduced the semi-elementary form, a program representation that brings decoupled register allocation to architectures with register aliasing. The semi-elementary form is much smaller than program representations used by previous decoupled solutions, which leads to register allocators that perform better in terms of time and space. Furthermore, this representation reduces the number of copies that traditional allocators insert into assembly programs. We have empirically validated our results by showing that how our representation improves two well-known graph-coloring-based allocators, namely the iterated register coalescer (IRC) and Bouchez et al.’s brute force (BF) method, both augmented with Smith et al. extensions to handle aliasing. Running our techniques on SPEC CPU 2000, we have reduced the number of nodes in the interference graphs by a factor of 4 to 5, hence speed-up the allocation time by a factor of 3 to 5. In addition, the semi-elementary form reduces by 8% the number of copies that IRC leaves uncoalesced.

This work is part of a collaboration with the Federal University of Minas Gerais. It has been presented at SCOPES’11 [13].

6.6. A Non-Iterative Data-Flow Algorithm for Computing Liveness Sets in Strict SSA Programs

Participants: Benoît Boissinot, Florian Brandner, Alain Darte, Benoît Dupont de Dinechin [Kalray], Fabrice Rastello.

We revisited the problem of computing liveness sets, i.e., the sets of variables live-in and live-out of basic blocks, for programs in strict static single assignment (SSA). In strict SSA, aka SSA with dominance property, the definition of a variable always dominates all its uses. We exploited this property and the concept of loop-nesting forest to design a fast two-phase data-flow algorithm: a first pass traverses the control-flow graph (CFG), propagating liveness information backwards, a second pass traverses the loop-nesting forest, updating liveness sets within loops. The algorithm is proved correct even for irreducible CFGs.
We analyzed its algorithmic complexity and evaluated its efficiency on SPEC INT 2000. Compared to traditional iterative data-flow approaches, which perform updates until a fixed point is reached, our algorithm is 2 times faster on average. Other approaches are possible that propagate from uses to definitions, one variable at a time, instead of unioning sets as in data-flow analysis. Our algorithm is 1.43 times faster than the fastest alternative on average, when sets are represented as bitsets and for optimized programs, i.e., when there are more variables and larger live-sets and live-ranges.

This work has been presented at the conference APLAS’11 [5].

6.7. SSI Revisited: A Program Representation for Sparse Dataflow Analyses

Participants: Andre Tavares [UFMG, Brazil], Mariza Bigonha [UFMG, Brazil], Roberto Bigonha [UFMG, Brazil], Benoit Boissinot, Fernando Pereira [UFMG, Brazil], Fabrice Rastello.

Dataflow analyses usually associate information about variables to program regions. Informally, if these regions are too small, e.g., a point between two consecutive statements, we call the analysis dense. On the other hand, if these regions include many such points, then we call it sparse. We developed a systematic method to build program representations that support forward and/or backward sparse analyses. To pave the way that leads to this framework, we first clarified the literature on intermediate program representations. We revisited the static single information (SSI) form introduced in the 90s and showed how to simplify the construction of program representations for unidirectional dataflow analyses. We showed how to cope with live-ranges that have multiple uses/definitions without losing the equivalence property with the initial dataflow analysis problem. This allows us to simplify, for unidirectional problems, the SSI construction algorithm.

We also showed that our approach, up to a parameter choice, subsumes other program representations such as the SSA, SSI, and e-SSA forms. We can produce intermediate representations isomorphic to the sparse evaluation graphs (SEGs) of Choi et al. This data structure enables sparse solutions to the class of dataflow problems called partitioned dataflow analysis (PDA). However, contrary to SEGs, we can handle - sparsely - problems that are not PDA. We have implemented this framework in the LLVM compiler and have empirically compared different program representations in terms of size and construction time.

This work is part of a collaboration with the Federal University of Minas Gerais 8.2 and is under reviewing process for the journal Science of Computer Programming.

6.8. Incremental Spilling

Participants: Albert Cohen [Inria, Parkas], Boubacar Diouf [Université Paris Sud, Parkas], Fabrice Rastello.

This work addresses the minimization of the spill code overhead in the contexts of both coupled and decoupled register allocation. We devised a heuristic approach called stacking; it incrementally allocates clusters of variables, as opposed to the conventional incremental spilling approach. We describe two polynomial methods, a stacking-optimal allocator and a greedy stacking-independent-set allocator. The first method is very close to the optimal allocation; the second method outperforms state-of-the-art heuristics for just-in-time compilation.

This work has been submitted for publication.

6.9. Program Analysis and Communication Optimizations for HLS

Participants: Christophe Alias, Alain Darte, Alexandru Plesco.

High-level synthesis (HLS) tools are now getting more mature for generating hardware accelerators with an optimized internal structure, thanks to efficient scheduling techniques, resource sharing, and finite-state machines generation. However, interfacing them with the outside world, i.e., integrating the automatically-generated hardware accelerators within the complete design, with optimized communications, so that they achieve the best throughput, remains a very hard task, reserved to expert designers. The goal of our research on HLS is to study and to develop source-to-source strategies to improve the design of these interfaces, trying to consider the HLS tool as a back-end for more advanced front-end transformations.
Using the C2H HLS tool from Altera, which can synthesize hardware accelerators communicating to an external DDR-SDRAM memory, we showed that it is possible to automatically restructure the application code, to generate adequate communication processes in C, and to compile them all with C2H, so that the resulting application is highly-optimized, with full usage of the memory bandwidth.

These transformations and optimizations, which combine techniques such as double buffering, array contraction, loop tiling, software pipelining, among others, were incorporated in an automatic source-to-source transformation tool, called CHUBA (see Section 5.7), based on the polyhedral model representation. Our study shows that HLS tools can indeed be used as back-end optimizers for front-end optimizations, as it is the case for standard compilation with high-level transformations developed on top of assembly-code optimizers. We believe this is the way to go for making HLS tools viable. The complete automation of the process will be presented at PPoPP’12 [3] and Impact’12 [15].

We also showed how to extend this method to programs with irregular control and array accesses. The main difficulty arises when some data may be redefined in the accelerator but this is not sure. We showed that techniques based on parametric polyhedral optimizations can be used to generate the sets of data to be loaded (resp. stored) just before (resp. after) each tile. An interesting feature is that the previous method appears nicely as a particular case when no approximation is needed. This work is fully described in a research report [23], but is not yet published in a conference or journal.

6.10. Compilation of Hardware Accelerators with Pipelined Arithmetic

Participants: Christophe Alias, Bogdan Pasca [PhD student, Arénaire Inria Team], Alexandru Plesco.

By nature, source-level optimizations cannot perform fine optimizations of the datapath and the control, sometimes mandatory to obtain performances. In high-level synthesis, the circuit generated must be efficient and must produce quality results. This last point is the specialty of the Arénaire Inria-team, which develops the tool FLoPoCO, an open-source FPGA-specific generator of pipelined floating-point arithmetic operators, from a functional description as \((x, y, z) \rightarrow e^x + y \cdot \cos(z)\). The user can specify the precision (mantissa, exponent) and the maximum frequency, then FLoPoCO generates the corresponding operator.

We have developed an algorithm to automatically generate, from a C program, an hardware accelerator that efficiently uses these pipelined operators. The main issue is to reschedule the initial program execution in order to keep the operator’s pipeline as busy as possible, while minimizing memory access. Then, the new execution schedule is used to generate the VHDL code of finite state machines (FSM) controlling the data-flow through the arithmetic operator. This work has been published at the conference ARC’11 [4].

We also showed how our method can be used as a tool to generate control FSMs of multiple parallel computing cores accelerating the same application [25]. This work has been submitted to the journal Microprocessors and Microsystems.

This is still a work in progress and many issues need to be addressed, for example how to extend the program model to general nested loops with more general dependences. These extensions will require to handle properly the communications between the operators and temporary buffers. We believe that the array contraction technique developed in Compsys can be helpful in this context too.

6.11. FPGA Optimized Table Maker’s Dilemma Architecture

Participants: Alexandru Plesco, Florent De Dinechin [Assistant Prof., ARENAIRE Inria Team], Jean-Michel Muller [Research Director, ARENAIRE Inria Team], Bogdan Pasca [PhD student, ARENAIRE Inria Team].

In this work, with some members of the Arénaire team, we developed an algorithm that enables to perform the table maker’s dilemma on a very regular architecture such as an FPGA. The algorithm is crucially different from the algorithm implemented on a standard PC and exploits efficiently the FPGA optimized high-performance arithmetic operators.
The core component (TaMaDi core) of our design is the polynomial evaluator based on the tabulated differences method that uses Remez algorithm. We instantiated multiple TaMaDi cores that work on $2^n$ disjoint intervals obtained from the splitting of the input interval. The TaMaDi cores are connected using a pipelined communication architecture based on the credit communication methodology. We focused on the communication architectures internal to a FPGA that can scale with limited impact on the frequency of the generated data processing architecture. We defined a new pipelined credit based communication interface that leads to a full-rate pipeline data transmission with the cost of small transfer initialization latency. This design has been proven to be effective on parallel design of TaMaDi FPGA specific algorithms. This strategy can be reused in any parallel FPGA design.

This work has been published at ASAP’11 [14] where it received a best paper award.

6.12. Termination of Big Programs

Participants: Christophe Alias, Laure Gonnord, Guillaume Andrieu [Undergraduate Internship, Polytech’Lille].

In a previous work with Alain Darte and Paul Feautrier, we showed how to prove the termination of a certain class of irregular programs with while loops [29]. Our technique amounts to compute a sequential schedule – called ranking function – for the program, reinvesting most of the techniques from [37] to schedule static loops. Our termination method is based on the resolution of a linear programming instance, and does not scale.

In most of big programs, all the information is not relevant for proving termination. Only a few slices need a termination proof. Moreover, inside a loop nest, termination can be proved incrementally. Inner loops are proved to terminate, and then are replaced by a summary. Our contribution is thus a reduction to prove a single loop termination, the price being the approximation made while computing the summary of a given (nest of) loop(s). This method can also be used to schedule irregular programs, which is clearly a need for program optimization.

A prototype has been designed and is currently under testing. A paper is in preparation. This method has been developed during the undergraduate internship of Guillaume Andrieu, from the Engineering School Polytech’Lille.

6.13. Simplification of Boolean Affine Formulas

Participant: Paul Feautrier.

Boolean Affine Formulas, in which affine inequalities are combined by boolean connectives, are ubiquitous in computer science: static analysis, code and hardware generation, symbolic model checking and many other techniques use them as a compact representation of large or infinite sets. Common algorithms tend to generate large and highly redundant formulas, hence the necessity of a simplifier for keeping the overall complexity under control. Simplification is a difficult problem, at least as hard as SMT solving, with a worst case complexity exponential in the number of affine inequalities. Paul Feautrier has proposed a new method, based on path cutting in Ordered Binary Decision Diagrams, which is able to take advantage of any regularity in the subject formula to speed up simplification. The method has been implemented and tested on benchmarks from several application domains.

The method has been presented at the 4th “Rencontres de la communauté française de compilation”. A detailed description has been submitted for publication; see also [28].

6.14. Retiming for Faust

Participants: Alain Darte, Alexandre Isoard [Master 1 student, ENS-Lyon], Yann Orlarey [Grame].

Faust (Functional Audio Stream) is a formal specification stream-like language designed for real-time signal processing and synthesis. Faust programs are compiled into equivalent C++ programs and optimized for parallel execution. One of the core optimizations in Faust is a preliminary phase called normalization, which amounts to change the delays between operators into an equivalent normalized form used for, among others, redundancy elimination.
We showed that this normalization is actually a special form of retiming, a well-known technique in circuit design and loop transformations. However, an important subtlety needs to be considered: the problem of initialization of signals, which is usually not even mentioned in the retiming literature. We proved that the problem comes from “time-dependent” operators in Faust and that all these operators can be decomposed into combinations of regular operators (in the sense that standard retiming applies) and a single elementary time-dependent operator, called init, which transfers any signal with no modification for time $t \geq 0$ and outputs a constant for time $t < 0$.

This collaboration between Compsys and Grame did not go beyond the Master internship of A. Isoard yet and did not lead to an actual implementation within Faust.
6. New Results

6.1. Convergence of adaptive finite element algorithms

Participants: Roland Becker, Shipeng Mao, David Trujillo.

The theoretical analysis of mesh-adaptive methods is a very active field of research. We have generalized our previous results concerning optimality of adaptive methods to nonconforming finite elements [49]. Our results include the error due to iterative solution of the system matrices by means of a simple stopping criterion related to the error estimator. The main difficulty was the treatment of the nonconformity which leads to a perturbation of the orthogonality relation at the heart of the proofs for conforming finite elements. We have been able to extend this result to the Stokes equations, considering different lowest-order nonconforming finite elements on triangular and quadrilateral meshes [16].

In [17] we have shown that the smallness assumption required in all former proofs of optimality of adaptive finite element methods can be overcome, at least in some situations.

Finally, we have shown optimality of a new goal-oriented method in [19].

Our theoretical studies, which are motivated by the aim to develop better adaptive algorithms, have been accompanied by software implementation with the Concha library, see Section 5.1. It hopefully opens the door to further theoretical and experimental studies.

6.2. Finite element methods for interface problems

Participants: Nelly Barrau, Roland Becker, Robert Luce, Erik Burman, Peter Hansbo.

The original formulation of NXFEM [62] is based on the doubling of elements. In some situations, as the case of a moving interface, it is computationally more convenient to have a method with local enrichment, as for the standard XFEM. In [41] we have developed such an approach based on NXFEM. We have developed an hierarchical formulation for a fictitious domain formulation in [13].

One of the technical difficulties is the simultaneous robustness of the method with respect to the size of the intersection of a mesh cell with the interface and with respect to the discontinuous diffusion parameters. This is the subject of the thesis of Nelly Barrau, supervised by Robert Luce and Eric Dubach (LMAP).

6.3. Discontinuous finite element methods

Participants: Roland Becker, Daniela Capatina, Julie Joie.

We have developed a new discontinuous Galerkin scheme for the Stokes equations and corresponding three-fields formulation. In this work, which is part of the Phd Thesis of Julie Joie, we introduce a modification of the stabilization term in the standard DG-IP method. This allows for a cheaper implementation and has a more robust behavior with respect to the stabilization parameter; we have shown convergence towards the solution of non-conforming finite element methods for linear, quadratic and cubic polynomial degrees. This scheme has been extended to the three-field formulation of the Stokes problem, which is a further step towards the polymer project of Section 4.2. Since it is well known that the non-conforming finite element approximations do not verify the discrete Korn inequality, an appropriate further stabilization term is introduced, see [42].

6.4. Stabilized finite element methods

Participants: Roland Becker, Erik Burman, Peter Hansbo.
We have developed a new stabilized finite element formulation based on implicit penalization of the singularities of higher-order derivatives of continuous finite element spaces in \cite{12}. It has been applied to the convection-diffusion problem as well as to the incompressible Euler equations.

### 6.5. A posteriori error estimators based on $H(\text{div})$-reconstructed fluxes

**Participants:** Roland Becker, Daniela Capatina, Robert Luce.

Mesh adaptivity is nowadays an essential tool in numerical simulations; in order to achieve it, reliable and efficient, easily computable a posteriori error estimators are needed. Such estimators obtained by reconstructing locally conservative fluxes in the Raviart-Thomas finite element space have been largely employed in the past years.

We have so far considered the convection-diffusion equation and proposed a unified framework for several finite element approximations (conforming, nonconforming and discontinuous Galerkin). The main advantage of our approach is to use, contrarily to the existing references, only the primal mesh for the flux reconstruction, which presents certain facilities from a computational point of view.

For this purpose, the construction of the $H(\text{div})$-vector involved in the error estimator is inspired by the hypercircle method cf. \cite{53} and is achieved on patches, which may overlap. A patch depends on the type of the employed finite elements and is defined as the support of a basis function.

Our first results were presented in \cite{26}. We are working on the extension to higher-order approximations, to quadrilateral meshes and to other model problems.

### 6.6. A posteriori error analysis of sensitivities

**Participants:** Roland Becker, Daniela Capatina, Robert Luce, David Trujillo.

Most practical applications involve parameters $q = (q_i)_{1 \leq i \leq N}$ of different origins: physical (viscosity, heat conduction), modeling (computational domain, boundary conditions) and numerical (mesh, stabilization parameters, stopping criteria, values of a turbulence model). Numerical simulations can provide information related to the (first order) sensitivity of a quantity of physical interest $I(q)$ with respect to different parameters: $\partial I/\partial q_i$. Their computation can help to validate the physical model, to explain unexpected behaviour and also to guide efforts to improve both the physical and the computational models.

A posteriori error estimates for the functional itself, for fixed values of the parameters $q$, are well-known, cf. for example \cite{47} where a goal-oriented error control is achieved by introducing an adjoint problem. Our goal is to provide a general framework for the a posteriori error estimation of sensitivities $\partial I/\partial q_i - \partial I_h/\partial q_i$, which has not been given yet in the literature.

So far, we have applied the proposed method to the computation of the Nusselt number measuring the efficiency of a cooling process, described in the project Optimal. A cold liquid is injected in a annular domain through several inlets in order to cool a heated interior stator.

First numerical results, including adaptation with respect to the functional and to the sensitivity, have been carried out with the library Concha. They have been presented in \cite{33}, \cite{30}. In Figure 10 one may see the computed temperature and velocity field, while the a posteriori error estimator for the sensitivity of the Nusselt number with respect to the inflow speed at the right-hand side inlet, as well as the adapted mesh, are given in Figure 11.

In the future, several important aspects related to the adaptive method are still to be investigated such as design of an appropriate adaptive algorithm, proof of its convergence and optimality etc.

### 6.7. Viscoelastic fluids modeling and numerical simulation

**Participants:** Roland Becker, Daniela Capatina, Didier Graebling, Julie Joie.

We have continued our activities with respect to numerical simulations of polymer flows.
Figure 10. Computed velocity and temperature fields.

Figure 11. Error estimator for the sensitivity and adapted mesh.
We have further validated [32] the code on both triangular and quadrilateral 2D meshes, by using a mixed non-conforming/DG method. In the case of Giesekus model, comparisons of velocity profile with semi-analytical solutions for Poiseuille flow [70] and with experimental data [73] for the 4:1 contraction are respectively shown in Figures 12 and 13.

The quadrilateral scheme needs an additional stabilization term, in order to ensure uniform consistency and stability for the underlying linear problem. It has been tested in particular on the benchmark case of flow around a 2D cylinder, for which our code converged for high values of the Weissenberg number (We > 70).

We have computed the drag and compared it, see Figure 14, with numerical data found in the literature [58], [65], [76], [57] in the case of the Oldroyd-B model.

The unsteady case has also been treated for different geometries.

The parallelization of the library is ongoing work as described in the section 5.3; first tests have been carried on in the case of viscoelastic liquids.

In order to better describe real polymer flows, the thermal aspects have to be taken into account. As a first step, the coupling of the flow with the energy equation in the Newtonian case was considered in [38], by using a conservative variable. Our next objective is to simulate anisothermal viscoelastic flows, including typical effects such that thermo-dependent viscosity and viscous heating.

With these tools, the long-term goal is to successively build up robust and efficient software in order to tackle design problems.

Moreover, we intend to consider other models of non-Newtonian fluids employed in other application domains such as biomedicine.

6.8. Positivity preserving schemes

Participants: Roland Becker, Daniela Capatina.
Figure 13. Comparison with experimental data for the 4:1 contraction.

Figure 14. Comparison of drag coefficients with the literature.
The stability and robustness with respect to physical parameters of numerical schemes for polymer flows is a challenging question. Indeed, most algorithms encounter serious convergence problems for large Weissenberg numbers. In the recent years, this issue has been associated to the discrete positive definiteness of the so-called conformation tensor. It seems therefore essential for the numerical simulations to employ positivity preserving schemes.

In order to develop such schemes, we have adopted the approach proposed by Lee and Xu [68] in the case of the quasi-linear Oldroyd-B model, based on the similarities between its constitutive equation and differential Riccati equations. We have applied it to a more general matrix equation; a typical example is the nonlinear Giesekus constitutive law. In agreement with our code (see Section 6.7), we have discretized it by a discontinuous Galerkin method combined with an upwinding of the transport terms, whereas the approach of Lee and Xu relies essentially on the characteristics method.

We have shown that a modification of Newton’s method yields a monotone and positive scheme, under certain hypothesis, and we have applied this study to both Oldroyd-B and Giesekus polymer models. This allowed us to better understand and explain the better behaviour of the latter for large Weissenberg numbers. These results have been presented in [24], [31].

We are working on several challenging questions such as the extension to other discretization methods, the improvement of the iterative method or the derivation of energy estimates for the coupled system.

6.9. Discretization of Euler’s equations

Participants: Roland Becker, Kossivi Gopki, Eric Schall, David Trujillo.

Over the past years, significant advances have been made in developing discontinuous Galerkin finite element methods (DGFEM) for applications in fluid flow and heat transfer. Certain features of the method have made it attractive as an alternative to other popular methods such as finite volume and more convenient finite element methods in thermal fluid engineering analyses. The DGFEM has been used successfully to solve hyperbolic systems of conservation laws. It makes use of the same local function space as the continuous method, but with relaxed continuity at inter-element boundaries. Since it uses discontinuous piecewise polynomial bases, the discretization is locally conservative and in the considered lowest-order case, the method preserves the maximum principle for scalar equations.

One of the challenges in Computational Fluid Dynamic (CFD) is to obtain as accurate as possible the solution of the problem under consideration at very low cost in terms of computational time. So our principal work is to find some relevant and robust strategies and technics of meshes adaptation in order to concentrate just the calculation where there are physical phenomena to capture. From Industrial point of view, the aim is to get the stationary solution as quick as possible with as much accuracy as possible. The main limitation of these results in CFD concern the underlying models: for example, nearly nothing seems to be known for (even linear) first-order systems or for realistic nonlinear equations. We therefore have developed different modern techniques, especially adaptive methods, to tackle this kind of problems in compressible CFD. The strategy is to iteratively improve the quality of the approximate solutions based on computed information (a posteriori error analysis). In this way, a sequence of locally refined meshes is constructed, which allows for better efficiency as compared to more classical approaches in the presence of different kind of singularities. The main goal is to improve the aerodynamical design process for complex configurations by significantly reducing the time from geometry to solution at engineering-required accuracy using high-order adaptive methods.

One of our strategies of refinement is based on the creation of hanging nodes commonly called non-conforming refinement. The figures 15 show superposition of two kinds of meshes. One is a non-conforming refined mesh (black color) and the other one is the initial grid (red color) on which the refinement has been performed. It shows the technic of cutting the cells where singularities occur in the scramjet inlet.

The mesh adaptation is designed using some criteria as a posteriori error estimates. We have designed criteria based on the calculation of the jump of physical quantities like density, pressure, entropy, temperature and mach number at the inter-element. This criteria seems to be a very good indicator for the mesh adaptation. Figure 16 is the comparison of isoline of the density in scramjet internal flow at mach 3 of the initial mesh,
Figure 15. Superposition of non-conforming adapted black color) grid and initial grid (red color) – (a) quadrangles and (b) triangles.

The third and the sixth mesh after refinement. The indicator used is the density jump. It shows the impact and the accuracy of the solution obtained after the sixth iteration of the refinement.

Figure 16. Cutlines along the symmetry axis of various meshes for the scramjet test case

The figure 17 shows the streamlines of the density in the scramjet inlet after the seventh iteration. This shows how the adaptation depicts almost clearly and accurately the shock waves and the expansion waves and their interactions in the domain.
Figure 17. Density streamlines on grid obtained after the seventh iteration of adaptive refinement procedure with density jump as indicator

Figure 18 represent the density isolines of a flow past cylinder test case using the non-conforming mesh adaptation with quadrangular and triangular grids.

(a)  (b)

Figure 18. Locally adapted mesh on quadrilaterals (a) and triangles (b)

We have also settled another indication which is hierarchical. It measures the difference of $g_h$ with the physical quantity $g_{h/2}$ obtained by computation on a globally refined mesh $h/2$. This allows us the make comparison
with the previous indicator. The case test considered for this comparison is an external flows past a cylinder airfoil at fixed free stream conditions: \( M_\infty = 3 \). The result is quite surprising the way one type of indicator can capture phenomenon that are not capture by the other one. In fact the hierarchical indicator seems to capture recirculation downstream to the obstacle which was not capture by the jump indicator (see figure 19).

![Figure 19. Streamlines coloured by the density on meshes generated with hierarchical indicator (a) and with jump indicator (b)](image)

We compare the computational time between a non-conforming mesh refinement and a globally mesh refined with nearly the same amount of cells. The meshes contain quadrangles or triangles. We can observe through the following tables that the adapted meshes wether triangular or quadrangular meshes allow to save 20 to 90 times the computational time than the normal globally refined mesh. (see tables 1 and 2).

<table>
<thead>
<tr>
<th>Scramjet test case at mach=3</th>
<th>Flow past cylinder test case at mach=3</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Table 1</strong></td>
<td><strong>Table 2</strong></td>

</tr>
</tbody>
</table>

In table 1, the gain in time is 35 times in quadrangular grid case and 90 times triangular ones and in table 2, the gain in time: 18 times in quadrangular grid case and 58 times triangular ones. So one can say that the adaptive mesh with the strategies and technics we have settled are efficient and robust in capturing physical phenomenon at a very reasonable low cost.

In concluding, the procedure of refinement permit to save computational time and have good accuracy of the approximated solution computed. Our focus is to continue the improve our methods and strategies in order to meet the requirement of accuracy, robustness and efficiency. Many other works are in hand such as slope limiters for high-order Discontinuous Galerkin, low mach number computation with some remarkable approaches.
CONTRANTES Project-Team

6. New Results

6.1. Constraint Handling Rules and Linear Logic

Participants: François Fages, Thierry Martinez, Sylvain Soliman.

Implementations of Constraint Handling Rules (CHR) follow a committed-choice forward chaining execution model: the non-determinism of the abstract semantics is partly refined with extra-logical syntactic convention on the program order and possibly notations for weighted semantics (with priorities or probabilities), and partly left unspecified in the underlying compiler. In [13], we propose an alternative execution model which explores all the possible choices, by opposition to the committed-choice strategy. This execution model is angelic in the sense that if there exists a successful execution strategy (with respect to a given observable), then this strategy will be found. Formally, the set of computed goals is complete with respect to the set of the logical consequences of the interpretation of the initial goal in linear logic. In practice, this paper introduces a new data representation for sets of goals, the derivation nets. Sharing strategies between computation paths can be defined for derivation nets to make execution algorithmically tractable in some cases where a naive exploration would be exponential. Control for refined execution is recovered with the introduction of user constraints to encode sequencing, fully captured in the linear-logic interpretation. As a consequence of angelic execution, CHR rules become decomposable while preserving accessibility properties. This decomposability makes natural the definition in angelic CHR of meta-interpreters to change the execution strategy. More generally, arbitrary computation can be interleaved during head matching, for custom user constraint indexation and deep guard definition.

6.2. Rule-based Modeling Language for Constraint Programming

Participants: François Fages, Raphaël Martin, Thierry Martinez, Sylvain Soliman.

Rules2CP is a rule-based modeling language which allows easy modeling of constraint satisfaction problems, together with specifications for search strategies and heuristic choice criterias by pattern matching. In [23], we study a new compilation scheme for Rules2CP which allows us to deal with dynamic ordering criteria and to generate procedural constraint programming code instead of flattened constraints. The comparison with the static expansion of Rules2CP models shows that the overhead at runtime is limited, with a gain in the size of the generated program which could be exponentially larger by static expansion.

The language Rules2CP is currently extended to deal with hybrid discrete and continuous domains and packing problems with complex shapes, in the framework of the ANR Net-WMS-2 project with KLS-Optim and EMN Inria EPI TASC. The compiler of Rules2CP is currently rewritten in Java in the framework of a collaboration with KLS-Optim supported by Inria DTI.

6.3. Trace Development Methodology

We are working on a general theory of traces design taking traces as primary objects of study. It is based on the observation of the way trace files are accumulated as knowledge bases and elaborated in different fields of activity like software engineering, rule based systems and resolution, learning in context, or personal experience storing systems.

We worked on two main points: the development of an experimental tracer of CHR [11] (see TODAS project) and an application the notion of generic trace to standardization of constraints. In [17] we analyze, and occasionally correct, shortcomings of the former approach based on the generic trace format GENTra4CP, and show the interest that a generic tracer may bring to develop portable applications or to standardization efforts, in particular in the field of constraints.
6.4. Railway Time Tabling Optimization  
**Participants:** François Fages, David Fournier, Sylvain Soliman.

Sustainable development is a key issue for our society. Optimization of resources, energy and costs (as admirably done in living organisms) has thus grown significantly over years to become a major field in industry. In collaboration with General Electric Transportation France which is a key-actor in the field of transportation all around the world, we investigate energy reduction for train and metro service providers through time tabling optimization. In [31], we describe and compare different optimization methods to reduce energy in mass rapid transits (MRT). Most of the literature deals with a special problematic arising in train services: the maximum traction energy. They show that for reducing costs and energy consumption, one method is the reduction of the peak energy over a time period. This objective function has been chosen for this study and the thesis depicts how to implement it on different paradigms, such as mixed-integer linear programming, constraint programming or local search. We conclude on promising approaches in terms of optimization methods for time tabling computation and real-time scheduling.

6.5. Petri Net Analysis of Biochemical Networks  
**Participants:** François Fages, Thierry Martinez, Faten Nabli, Sylvain Soliman.

Bridging the gap between quantitative and qualitative models, Petri nets (also known as place/transition graphs) have recently emerged as a promising tool for modeling and analysis of biochemical networks. In [14], we present a method to compute the minimal siphons and traps of a Petri net as a Constraint Satisfaction Problem (CSP). In our case, siphons and traps are purely structural properties that brings us information about the persistence of some molecular species. We present a constraint program that finds minimal siphons and traps containing specific set of places in a Petri net. This method is compared on models of the biomodels.net repository with other methods based on Mixed Integer Linear Programming (MILP) and Boolean Satisfiability (SAT). The flexibility brought by constraint programming, for instance in the declarative choice of variable enumeration heuristics, seems promising in further improving those results.

6.6. Theory of Subgraph Epimorphisms  
**Participants:** François Fages, Steven Gay, Thierry Martinez, Sylvain Soliman.

The operations of deleting and merging vertices are natural operations for reducing a graph. While graph reductions through a sequence of vertex deletions (resp. mergings) characterize subgraph isomorphisms (resp. graph epimorphisms), sequences of both vertex deletion and merging operations characterize subgraph epimorphisms. Our proposal is thus to use subgraph epimorphism for comparing graphs in applications where a more flexible notion than the classical notion of subgraph isomorphism is required.

In collaboration with Christine Solnon (INSA Lyon), we have developed the theory of subgraph epimorphisms in [5]. We have shown that SEPIs preserve graph completeness and arc symmetry and that, just like SISO and EPI, SEPI is not a well quasi order. We have defined the SEPI, EPI and SISO distances between two graphs as the size of the largest SEPI (resp. EPI, SISO) lower bound graphs. These distances are equal to the minimum number of respectively vertex deletion and/or merging operations that are necessary to obtain isomorphic graphs. They are also metrics on graphs and we have \( d_d \geq d_{md} \) and \( d_m \geq d_{md} \).

From a computational point of view, we have shown that the existence of a SEPI between two graphs is an NP-complete problem and have presented a constraint satisfaction algorithm for solving it. This algorithm is implemented in BIOCHAM.

It is worth noticing that, given two graphs \( G \) and \( G' \), the greatest lower SEPI bounds and the least upper SEPI bounds are also interesting to compute since they represent “intersection” and “union” graphs for the SEPI relation. For instance, in our motivating application in systems biology, these objects correspond to the intersection (resp. union) of models at different levels of details for a given biochemical process. These graphs are not unique but we are confident that the constraint satisfaction algorithm presented in [10] can be interestingly generalized to compute them.
6.7. Parameter Search under Temporal Logic Constraints

**Participants:** Grégory Batt, Elisabetta De Maria, François Fages, Domitille Heitzler, Aurélien Rizk, Sylvain Soliman, Jannis Uhlendorf.

Our method for solving temporal logic constraints in the quantifier-free fragment of first-order linear time logic QFLTL(R), opens up the field of model-checking to optimization through the definition of a continuous degree of satisfaction for temporal logic formulae [8], [2]. This satisfaction degree can be used in a number of ways, e.g. as a fitness function with continuous optimization methods\(^2\) to find unknown parameter values in a model with temporal logic constraints formalizing biological properties [4], [6], or to control a system from a temporal specification of its behavior [15], or to compute the robustness of a system w.r.t. a temporal property and a perturbation of the parameters.

This approach is implemented in BIOCHAM and is one unique feature of this modeling environment.

6.8. Model-based Optimization of Cancer Chronotherapies

**Participants:** Elisabetta De Maria, François Fages, Aurélien Rizk, Sylvain Soliman, Denis Thieffry.

Recent advances in cancer chronotherapy techniques support the evidence that there exist some links between the cell cycle and the circadian clock genes. One purpose for modeling the entrainment in period of the cell cycle by the circadian clock is to better understand how to efficiently target malignant cells depending on the phase of the day and patient characteristics. This is at the heart of our participation in collaboration with the EPI BANG in the EraNet SysBio project C5Sys, follow up of the former EU STREP project TEMPO.

In [4] we show how temporal logic constraints, and the new features of BIOCHAM for parameter search (running on a cluster of 10000 processors at the GENCI) can be used to couple dynamical models in high dimension and more precisely to build a coupled model composed of:

- a four phases model of the mammalian cell cycle by Novak and Tyson,
- a circadian clock model by Leloup and Goldbeter,
- a DNA damage repair model by Ciliberto et al.,
- a model of irinotecan metabolism by Dimitrio and Ballesta,
- a simple model of drug administration control.

This coupled model allows us to minimize the toxicity of irinotecan on healthy cells, using BIOCHAM’s parameter search method applied on the drug administration control law.

Our technology is ready to calibrate models on real patient data, evaluate model predictions and optimize patient-tailored chronotherapeutics. The collaboration currently focuses on the obtaining of consistent data in the C5Sys project and on the improvement of the cell cycle model.

6.9. Analysis of FSH and Angiotensine Signaling

**Participants:** François Fages, Domitille Heitzler, Aurélien Rizk, Sylvain Soliman.

In [6] in collaboration with Eric Reiter (UMR CNRS-INRA 6175) and Frédérique Clément (SISYPHE) in the framework of the Initiative Action REGATE, we have combined experimental approaches with computational modeling to decipher the molecular mechanisms as well as the hidden dynamics governing ERK activation by the angiotensin II type 1A receptor (AT1AR) in HEK293 cells. We have built in BIOCHAM a dynamical model that captures available knowledge and experimental data. The unknown kinetic parameters have been inferred using a temporal logic specification of experimental data in both control and perturbed conditions, using a cluster of 10000 processors at the GENCI.

\(^2\)we use the Covariance Matrix Adaptation Evolutionary Strategy CMAES of Nikolaus Hansen from the EPI TAO. Moreover, this year we have implemented a second method by Particle Swarm Optimization, PSO.
The mathematical model predicts and experiments confirm that, for the AT1AR expressed in HEK293 cells: i) GRK2/3 and 5/6 regulate switching between the G protein and β-arrestin pathways as well as their distinct dynamics by phosphorylating the C-terminal region of the activated receptor; ii) GRK2/3 not only mediate desensitization of G protein activation but also exerts a strong restraining influence on β-arrestin signaling; iii) GRK5/6 exert little effect on G protein-stimulated ERK but are required for β-arrestin-mediated ERK activation; iv) the β-arrestin-dependent ERK pathway undergoes both activation and deactivation through amplified enzymatic processes.

These results convincingly illustrate the value of using computational modeling to decipher the complex signaling mechanisms elicited by 7TMRs [1]. This approach is applied more generally to G protein-coupled receptor signaling which is of great importance in pharmacology.

6.10. Multi-affine Hybrid Automaton Model of Cardiac Cells

Participant: Grégory Batt.

A fundamental question in the treatment of cardiac disorders, such as tachycardia and fibrillation, is whether such a disorder arises? To answer this question, in collaboration with E. Bartocci and R. Grosu at SUNY, Stony Brook, USA, we develop a multi-affine hybrid automaton (MHA) cardiac-cell model, and restate the original question as one of identification of the parameter ranges under which the MHA model accurately reproduces the disorder [12]. The MHA model is obtained from the minimal cardiac model of one of the authors, Fenton from Cornell University, by first bringing it into the form of a canonical genetic regulatory network, and then linearizing its sigmoidal switches in an optimal way. By leveraging the Rovergene tool for genetic regulatory networks, we are then able to successfully identify the parameter ranges of interest.

6.11. Real-time Control of Gene Expression in Yeast

Participants: Grégory Batt, François Fages, Jannis Uhlendorf.

To decipher the dynamical functioning of cellular processes, the method of choice is to observe the time response of cells subjected to well-controlled perturbations in time and amplitude. Efficient methods, based on molecular biology, are available to monitor quantitatively and dynamically many cellular processes. In contrast, it is still a challenge to perturb cellular processes such as gene expression in a precise and controlled manner. In collaboration with Pascal Hersen at MSC lab (Paris Diderot University), in the framework of the Iceberg ANR project, we propose a first step towards in vivo control of gene expression: in real-time, we dynamically control the activity of a yeast signaling cascade thanks to an experimental platform combining a micro-fluidic device, an epi-fluorescence microscope and software implementing control approaches [15]. We experimentally demonstrate the feasibility of this approach, and we investigate computationally some possible improvements of our control strategy using a model of the yeast osmo-adaptation response fitted to our data.

6.12. Artificial Tissue Homeostasis in Mammalian Cells

Participants: Grégory Batt, François Bertaux, Xavier Duportet, François Fages, Szymon Stoma.

Cell-based gene therapy aims at creating and transplanting genetically-modified cells into a patient in order to treat a disease. Ideally, actively-growing cells are used to form a self-maintaining tissue in the patient, thus permanently curing the disease. However, before any real therapeutic use, robust mechanisms enforcing tissue homeostasis, that is, that the size of the newly-introduced tissue remains within admissible bounds, need to be developed. We proposed various designs and tested their robustness using in silico approaches. Preliminary results demonstrated that cell-to-cell variability plays a crucial role for tissue long-term maintenance. More extensive in silico characterizations require the development of efficient multiscale simulation methods. In parallel to the in silico work, done in collaboration with the Bang research group (Dirk Drasdo), we started the construction and in vitro experimental characterization of the most promising designs in collaboration with the Weiss lab (MIT) [24].
6. New Results

6.1. Robotics

6.1.1. Calibration and identification

6.1.1.1. Calibration of a cable-driven robot

Participants: David Daney, Julien Alexandre dit Sandretto, Jean-Pierre Merlet, Gilles Trombettoni.

To improve the accuracy of a cable manipulator, it is necessary to identify the uncertainties of its model. The robots, studied in Cogiro, an ANR National initiative, are redundantly actuated: the number of powered wires is larger than the number of degrees of freedom of the manipulator. Under some cable properties hypothesis, this over-constraint mechanism allows to perform a self-calibration - i.e. the identification of the parameters does not need additional external measurement. A first experimentation, done in Montpellier, validated a novel approach which consists in a simultaneous identification of parameters and robot position (unknown in self-calibration process).

6.1.1.2. Cable properties

Participants: Julien Alexandre dit Sandretto, Gilles Trombettoni, David Daney.

The majority of researches done on cable-driven robot modeling need to take into account that the mass and the elasticity of wires are neglectable. However, they can not prove that these hypotheses are acceptable regarding these objectives. We have proposed an algorithm based on interval analysis to judge the validity of these assumptions for a cable-robot in a specific workspace. This method have been tested on the Tecnalia/LIRMM’s prototype and used for the construction of the Cogiro robot.

6.1.1.3. Optimal calibration poses of a 3-RPR planar parallel robot

Participant: David Daney.

The choice of the measurement configuration is crucial to improve the robustness of the calibration for measurement uncertainties. This year, a geometrical approach has been used to determine formally the set of the optimal poses for the identification of the kinematic parameter of a 3-RPR planar parallel robot. This result is important because it explains the influence of the location of some particular robot poses in their workspaces during the model identification process. A generalization is explored to construct automatically an optimal set for robot calibration and moreover, to improve experimental design algorithms. The aim is now to obtain similar results for cable driven robots calibration.

6.1.1.4. Geometric calibration of a space telescope

Participants: Thibault Gayral, David Daney, Jean-Pierre Merlet.

In October 2010 begun a collaborative work with Thales Alenia Space on the calibration of the mechanical structure of a space telescope. Its architecture is based on a parallel manipulator (type active wrist 6-PUS) used to correct the relative position of two mirrors. The aim is to identify the parameters of this robot, to improve its accuracy and then increase the quality of the images provided by the telescope. Thus, a geometric calibration procedure was considered and a campaign of photogrammetry was performed on the telescope. Using a kinematic description, a final accuracy of at worst 10 µm was reached on the position of the platform of the telescope. The aim of these measures were also to valid or not the model of comportment of the flexible parts of the device. This campaign brought to light the necessity to consider forces and torques acting on the structure in the deformation of the flexible parts in order to reach a submicrometric accuracy.

6.1.1.5. Modelization of flexible articulations of the telescope

Participants: Thibault Gayral, David Daney, Jean-Pierre Merlet.
In order to improve the final accuracy of the above-mentioned space telescope, a novel model including the statics equations in order to calculate deformations of the flexible articulations is currently under study. The main difficulty is to identify parameters (stiffness matrix and geometric parameters) that have different units and are not of the same order of magnitude. To solve this issue, we are focusing our effort to write the problem in a better robust form.

6.1.1.6. Interval Identification

**Participants:** David Daney, Julien Alexandre dit Sandretto, Gilles Trombettoni.

There are many approaches to identify the parameters of a model. In most cases, it consists in providing a particular solution of an over-constraint set of equations which must be robust to measurement to errors: in least square sense, with some statistical properties... However, the interpretation and the validity of the result can be difficult and prone error. We propose to investigate some interval approaches in order to associate to the result some information and a certification of solutions.

6.1.2. Rehabilitation and biomechanics

**Participants:** Sami Bennour, David Daney, Mandar Harshe, Jean-Pierre Merlet [correspondant].

The focus of the work is on analyzing knee joint motion during a walking activity. The measurement system is based on the wire actuated parallel robot architecture. To increase the reliability of our analysis, and decrease the influence of Skin Tissue Artifacts (STA), we also incorporate a passive wire measurement system, IR camera based motion capture system, accelerometers, and force sensors to measure human motions.

The main principle of the system is to observe relative motions of the collars attached to tibia and femur. These are connected to the base by wires and also hold the other sensors. Measurements in the global frame and collar specific local frames give precise data to reconstruct collar (and thus, knee joint) motion.

Over the past year we have finalized the experimental setup, by calibrating the collars and the sensor systems, and adapting the existing wire robot system (MARIONET-REHAB) to work along with the other sensors. The software developed uses a single unified input file to specify all sensor configurations, streamlining experiments. We performed our preliminary experimental trials for walking motion on three subjects using the wire sensors, accelerometers and optical motion capture system.

We began work on processing the data obtained from these trials. Post-processing functions have also been developed to calculate additional collar properties, perform sensor data processing (filtering, noise removal and estimation) and access files in the C3D file format, which is used a binary file format used by the motion capture system.

The main challenge we are working on is to perform sensor data fusion and increase reliability of results. For this we must identify parameters that correlate the different sensor measurements and perform error analysis. Possible solutions include using interval analysis methods to address the uncertainties.

6.1.3. Kinematics of wire parallel robots

**Participant:** Jean-Pierre Merlet.

The kinematics of wire robot is a complex problem because a solution is possible only if the tension in the wire is positive. Hence the static equilibrium has to be taken into account. This problem is not well addressed in the literature. Curiously the forward kinematics of robot (i.e. finding the possible poses of the platform for given wire lengths) with at least 6 wires is straightforward: the distance equations allows to determine all poses and then we use the static equations to calculate the wire tensions and discard the one having at least one negative tension. For robot having less than 6 wires we have to consider simultaneously the distance equations and the static equations in order to get a square system (of \( n + 6 \) equations for a \( n \)-wires robot). We have investigated the case of a 3-wires robot with all wires attached at different points on the platform and have shown that all solutions can be computed provided the solving of an univariate polynomial of degree 158 [17]. Although we are not able to guarantee that the degree of this polynomial cannot be decreased, we believe that nevertheless the order will be too high for robust determination of the solutions and can only be used to determine an upper bound for the maximal number of solutions. We have also investigated theoretically and experimentally the
kinematics of an $n$-wires ($n \geq 4$) robot with all wires attached at the same point (i.e. only the position of the center of the platform can be controlled). Although this robot is apparently redundant, we have shown that in any pose at most 3 wires will be simultaneously under tension and therefore that the redundant wires cannot be used to control the wire tensions.

As the wire length measurements are not sufficient to determine the current pose of the platform (which is necessary for control purposes) we are investigating the use of additional sensors. Our prototypes MARIONET-ASSIST and MARIONET-VR are instrumented to measure wire directions, but with a large uncertainties. We have started a theoretical investigation to determine under which conditions these uncertainties may lead to a non-unique solution and we will validate the results on the two prototypes.

6.1.4. Rehabilitation robots for the immersive space

Participants: Michael Burman, Jean-Pierre Merlet.

The on-site immersive room provides 3D visualization but is lacking of haptic feedback and motion capabilities. We plan to implement in this room a movable system, constituted of:

- a 6 degrees-of-freedom motion base: the motion system 710-6-500-220 by Servos Simulation Inc. has been selected and is now operational and fully calibrated. If necessary the user may stand on this motion base
- the MARIONET-VR wire-driven parallel robot: this robot uses the same actuation principle than the MARIONET-REHAB robot (linear actuator with a pulley system for coiling and uncoiling of the wires), but is able to lift a person. The prototype is basically functionnal but its installation in the immersive room has been delayed because of lack of appropriate fixing elements

The full system will be installed in the immersive room at the beginning of 2012.

6.1.5. Assistance robotics

Participants: Michael Burman, David Daney, Jean-Pierre Merlet.

As mentioned earlier in the report we have started in 2008 a long term strategic move toward assistance robotics, with the objectives of providing low-cost, simple to control, robotized communicant devices that may help disabled, elderly and handicapped people in their personal life, with the credo that they have to be adapted to the end-user and to its everyday environment (by contrast with the existing trend of focusing on a “universal” robot, to which the end-user and its environment have to adapt) [18], [14], [21]. We have started last year the development of a simulated flat in order to explore various full scale scenarii that cover a part of the daily life of an elderly, to develop specific assistance devices and to test them. We describe in the following sections several devices that have been developed/improved during this year. Note that our demonstration in assistance are highlighted during the visit of Sophia (275 visitors have attended our demonstration during 14 visits) and have received serious press coverage (5 papers, 2 TV interviews).

6.1.5.1. Walking aids

Wheeled walking aids are usually the first tools that are used when motricity problems occur. We are developing the family of robotized Assistive Navigation Guide (ANG), which are based on commercially available Rollators, with several objectives (we mention only a few of them):

- fall prevention/detection: fall is a major problem for elderly (it is estimated that fall is the main cause of 10 000 elderly deaths per year in France).
- mobility help: provide an on-demand mobility help
- gait pattern monitoring: we believe that being able to monitor the trajectory of the walking aid will provide useful information on the gait pattern of the user

1 pictures of this assistive flat are available at http://www-sop.inria.fr/coprin/developpements/main.html
For reaching these objectives we have developed two walking aids:

- **ANG-light**: a walking aid with encoders in the wheels, 3D accelerometer, gyrometer. These sensors allow to measure the trajectory of the walking aid and several features of the user’s gait (step pattern, gait asymmetry,...). ANG-light has been tested by the CHU of Nice-Cimiez that was willing to perform an in-depth investigation of its use. For that purpose we have asked in September 2009 for the necessary formal authorization to the local CPP, which has been granted only in December 2011. To prepare this study we have organized a large scale experiment at INRIA, where 24 users were asked to perform the trajectories of the protocol twice, with and without the aid. When not using the aid the users were equipped with 3D accelerometer on the wrists and knees and were using specific shoes with force sensors in the sole. Initial analysis of the records shows that indeed we are able to obtain significant information on the gait pattern, that are not available using the existing tools, and detect differences in the gait pattern for user having even a light pathology in the lower limb. The experiment with elderly patients at CHU will take place in January 2012.

- **ANG-II**: this aid is an evolution of the motorized walker ANG, with a lower weight and better integration

### 6.1.5.2. MARIONET-ASSIST

This wire-driven parallel robot is installed in the ceiling of the flat. It has been used this year in the 4-1 configuration (4 wires attached at the same point), which allows for controlling the position of the platform, but not its orientation. Several platforms have been developed, all of them incorporating a webcam and allowing for a free rotation around the vertical axis, while an accelerometer measure the tilt angle of the platform (which is used to determine in which direction the end-user is willing to move). One of the platform incorporate a 4 d.o.f. robot that may grasp light object (one of our objective is to use also the robot as a manipulator for bringing object back to the user in a more or less autonomous way, which is the subject of the PhD thesis of R. Ramadour).

We have shown that the the robot can be used for sit-to-stand transfer and for lifting handicapped people. A specific attention has been devoted to propose very simple control interface: joystick, remote TV set, control box whose tilt determine the motion axis.

### 6.1.5.3. Other flat equipments

Our scenario includes the management of emergency situations such as the fall. Fall detection can be performed by the ANG walkers but we have also started investigating the inclusion of fall detection system in the clothes of the end-user either through a GEO-300 devices or by incorporating an Arduino Lilypad processor. When a fall is detected indoor an alert is transmitted to a coordinator (a Nabaztag) which will order the walker and the MARIONET-ASSIST robot to move close to the user to provide a support. At the same time two mobile robots will converge to the same location: a remote-controlled, webcam equipped ROVIO (which can provide images of the end-user to a rescue center) and a Pekee II, that we will equip to provide first aid.

An important point in assistance is to be able to have at all time a rough idea of the localization of the patient. Although we plan to use a Kinect for that purpose, we will also investigate the use of non-vision sensors (which are much less intrusive and therefore can be more easily accepted) such as RFID tag (ANG-II has a RIFID tag reader), directive distance sensors and light barriers.

Another axis for assistance is to reduce the risks of fall by using the principle that the objects has to come to the hand of the user (or of the robot), not the opposite. This implies instrumenting the environment with drawer openers and doors manipulation and we have started implementing them on drawers and on the fridge of the flat.

### 6.2. Interval analysis

#### 6.2.1. Inner Regions and Interval Linearizations for Global Optimization

**Participants:** Gilles Trombettoni [correspondant], Bertrand Neveu.
Researchers from interval analysis and constraint (logic) programming communities have studied intervals for their ability to manage infinite solution sets of numerical constraint systems. In particular, inner regions represent subsets of the search space in which all points are solutions. Our main contribution is the use of recent and new inner region extraction algorithms in the upper bounding phase of constrained global optimization.

Convexification is a major key for efficiently lower bounding the objective function. We have adapted the convex interval taylorization proposed by Lin & Stadtherr for producing a reliable outer and inner polyhedral approximation of the solution set and a linearization of the objective function. Other original ingredients are part of our optimizer, including an efficient interval constraint propagation algorithm exploiting monotonicity of functions.

We end up with a new framework for reliable continuous constrained global optimization. This interval Branch & Bound significantly outperforms the best reliable global optimizers [22], [25], [28].

6.2.2. An Interval Extension Based on Occurrence Grouping

Participants: Bertrand Neveu [correspondant], Gilles Trombettoni.

We proposed last year a new “occurrence grouping” interval extension $[f]_{og}$ of a function $f$. When $f$ is not monotonic w.r.t. a variable $x$ in a given domain, we try to transform $f$ into a new function $f^{og}$ which is monotonic w.r.t. two subsets $x_a$ and $x_b$ of the occurrences of $x$: $f^{og}$ is increasing w.r.t. $x_a$ and decreasing w.r.t. $x_b$. $[f]_{og}$ is the interval extension by monotonicity of $f^{og}$ and produces a sharper interval image than the natural extension does.

This year we have improved the linear program and algorithm that minimize a Taylor-based over-estimate of the image diameter of $[f]_{og}$. We have detailed the proofs of correctness and reliability of this occurrence grouping algorithm [8], [29].

6.3. Miscellaneous results

6.3.1. Equilibrium strategies for linked Electricity and CO2 markets

Participant: Odile Pourtallier.

In collaboration with M. Bossy (INRIA -TOSCA Team) and N. Maïzi (CMA - Mines Paristech) O. Pourtallier the study of equilibrium model for coupled electricity and CO2 allowance exchange markets has been pursued. (see also Section 7.1). A static equilibrium model has been studied under various assumptions on the CO2 market design. All the CO2 market designs do not lead equilibrium, which interferes on the (short term day ahead) electricity market, which in turn interferes on the electricity mixe and consequently on the total emission. Together with El-Hadj Dia (INRIA -TOSCA Team) we have also pursued an indifference pricing methodology which is presented in more details in INRIA -TOSCA Team section.

6.3.2. Symbolic tools for modeling and simulation

Participant: Yves Papegay.

This activity is the main part of a long-term ongoing collaboration with Airbus whose goal is to directly translate the conceptual work of aeronautics engineers into digital simulators to accelerate aircraft design.

An extensive modeling and simulation platform has been designed which includes a dedicated modeling language for the description of aircraft dynamics models in term of formulae and algorithms, and a symbolic compiler producing as target an efficient numerical simulation code ready to be plugged into a flight simulator, as well as a formatted documentation compliant with industrial requirements of corporate memory.
Implementation of this platform is a modeling and simulation environment based on symbolic computation tools. It contains several components:

- a model editor, that makes it possible and easy to enter the whole set of equations describing large and complex industrial models,
- an highly interactive and modular evaluation workbench allowing to simulate the models and to visualize the results inside the modeling environment with the benefits for the designer of being able to directly use all its computational functionalities.
- a C code generator which, using these models, automatically generates the numerical real-time simulation engines
- a technical documentation generator

During the year 2011 the technology demonstrated by our prototype has been transferred to our industrial partner. A lot of work has been done on our modeling and simulation environment to improve its robustness and its development level of quality toward industrial standards. Final version of our prototype is to be delivered to Airbus at the end of the year.

6.3.3. Multi-agent aircraft design

Participant: Yves Papegay.

The modeling environment described in the previous section is used, in collaboration with other teams at Airbus, in the framework of the ID4CS project founded by ANR and dedicated to multi-agent optimization of large scale system. Several models of aircraft engines and of aircrafts have been developed as user cases for the project. Automatic generation of extended models namely computing first order derivatives of the original models has been implemented.
6. New Results

6.1. Analysis and control of fluids and of fluid-structure interactions

Participants: Thomas Chambrion, Antoine Henrot, Alexandre Munnier, Yu Ning Liu, Jean-François Scheid, Erica Schwindt, Mario Sigalotti, Takéo Takahashi, Marius Tucsnak, Jean-Claude Vivalda, Jérôme Lohéac.

The study of a fluid-structure system depends on the nature of the fluid considered and in particular on the Reynolds number. We have split the new results of this section according to the viscosity of the fluid. The first part is devoted to the case of a viscous fluid. This is the case that has received more attention from mathematicians in the recent years. In the second part, we have put the results concerning an inviscid fluid. This case is more classical in Fluid Mechanics and could be more interesting to understand self-propelled motions which is one of the main goal of our work. In the last part, we have given some numerical results.

6.1.1. Incompressible viscous fluids

- In [31], García and Takahashi present some abstract results giving a general connection between null-controllability and several inverse problems for a class of parabolic equations. They obtain some conditional stability estimates for the inverse problems consisting of determining the initial condition and the source term, from interior or boundary measurements. They apply this framework for Stokes system with interior and boundary observations, for a coupling of two Stokes system and a linear fluid-structure system.
- Nečasová, Takahashi and Tucsnak consider in [43] the three-dimensional motion of a self-propelled deformable structure into a viscous incompressible fluid. The deformation of the solid is given whereas its position is unknown. Such a system could model the propulsion of fish-like swimmers. The equations of motion of the fluid are the Navier-Stokes equations and the equations for the structure are deduced from Newton’s laws. The corresponding system is a free-boundary problem and the main result they obtain is the existence of weak solutions for this problem.
- In [29] we give a controllability result for a simplified 1D fluid-structure system.
- In [39] we give a detailed analysis of a phase field type model describing the motions of vesicles in a viscous incompressible fluid.
- In [40] we study a controllability problem for a simplified one dimensional model for the motion of a rigid body in a viscous fluid. One of the novelties brought in with respect to the existing literature consist in the fact that we use a single scalar control. Moreover, we introduce a new methodology, which can be used for other nonlinear parabolic systems, independently of the techniques previously used for the linearized problem. This methodology is based on an abstract argument for the null controllability of parabolic equations in the presence of source terms and it avoids tackling linearized problems with time dependent coefficients.

6.1.2. Ideal fluids

- In [42], the author studies the motion of an hyperelastic body immersed in a perfect fluid. The recourse to a strain energy density function in the modeling allows many different constitutive equations for the hyperelastic material to be considered. Numerical simulation are performed, aiming to study passive locomotion (i.e. locomotion at zero energy cost).
- In [27], we study the approximate controllability of 2D swimmer in an ideal fluid. The result includes an approximate tracking result of both the shape and the position of the swimmer.

6.2. Frequency tools for the analysis of PDE’s

Participants: Xavier Antoine, Bruno Pinçon, Karim Ramdani, Bertrand Thierry, Marius Tucsnak.
Our contribution in this direction mainly concerns the numerical approximation of scattering problems.

- In [21], we propose some strategies to solve numerically the difficult problem of multiple scattering by a large number of disks at high frequency. To achieve this, we combine a Fourier series decomposition with the EFIE integral equation. Numerical examples will be presented to show the efficiency of our method.
- In [20], we propose to simulate complex nonlinear physics problems related to the Schrödinger equations by using relaxation techniques coupled with absorbing boundary conditions or PMLs. This shows that these two methods are much more accurate than the usual complex scaling/absorbing potential approaches widely used in physics for domain truncation.
- In [19], complete high order absorbing boundary conditions are proposed, discretize and simulate for one- and two-dimensional nonlinear Schrödinger equations. In [38], we propose new accurate absorbing boundary condition for computing nonlinear eigenvalue problems related to the Schrödinger equation.
- In [57], we propose a review of how pseudo differential operators theory help in building analytical preconditioners and well-posed integral equations for acoustics scattering. In [26], we propose a new efficient and robust domain decomposition method for solving large scale three-dimensional acoustic scattering problems.

6.3. Observability, controllability and stabilization in the time domain

Participants: Fatiha Alabau, Xavier Antoine, Thomas Chambrion, Antoine Henrot, Karim Ramdani, Lionel Rosier, Mario Sigalotti, Takéo Takahashi, Marius Tucsnak, Jean-Claude Vivalda, Ghislain Haine, Roberto Guglielmi.

6.3.1. Observability

- The PhD of Ghislain Haine is devoted to the analysis of observers based techniques for solving inverse problems. In [34], we provide a convergence analysis of the iterative reconstruction algorithm proposed by Ramdani et al. in [81]. More precisely, we propose a complete numerical analysis for semi-discrete (in space) and fully discrete approximations of the iterative algorithm using finite elements in space and an implicit Euler method in time. In order to disseminate our reconstruction method in the community of Automatic and control engineering, we wrote an engineer’s oriented note [33] presenting the main ideas of our algorithm.

6.3.2. Control

- In [48], we develop a model that describes the impact of the amount of soot in the filter on the Diesel engine performance. This model is used to determine the optimal amount of soot on which the regeneration of the particulate filter shall start.
- In [49], we give sufficient conditions for the simultaneous approximate controllability of a bilinear Schrödinger equation driven by a single scalar control in the case where every energy level is non-degenerate and the control potential couples each pair of energy levels.
- In [25], we give sufficient conditions for the simultaneous approximate controllability of a bilinear Schrödinger equation driven by a single scalar control under a generic condition of coupling of all energy levels via a chain of non-degenerate transitions. The result applies for systems with degenerate energy levels or when the coupling operator does not couple directly each pair of energy levels.
- In [16] we prove exact controllability for symmetric coupled wave equations by a single control in the case of coupling and control regions which do not intersect. For this, we use and extend the two-level energy method introduced by Alabau-Boussouira (2001, 2003). Using transmutation, we derive null controllability results for coupled parabolic and Schrödinger equations. This is the first
positive quantitative result, in a multi-dimensional framework with control and coupling regions with empty intersection. Such questions have been considered using Carleman estimates but no positive quantitative results could be derived in the case of control and coupling regions which do not intersect.

- In [30] we propose a new method for the approximation of exact controls of a second order infinite dimensional system with bounded input operator. The algorithm combines Russell’s “stabilizability implies controllability” principle with the Galerkin method. The main new feature of this work consists of giving precise error estimates.

6.3.3. Stabilization

- In [44] we consider the wave equation with a time-varying delay term in the boundary condition in a bounded and smooth domain. We prove exponential stability of the solution, by introducing suitable energies and Lyapounov functionals. Such analysis is also extended to a nonlinear case.

- In [52] we present a course on stabilization of hyperbolic equations given at a CIME session on Control of PDE’s in Italy in July 2010, including well-known results, together with recent ones including nonlinear stabilization, memory-damping and stabilization of coupled systems by a reduced number of controls. In particular, we present the optimal-weight convexity method (Alabau-Boussouira 2005, 2010) in both the finite dimensional and infinite dimensional framework and give applications to semi-discretization of hyperbolic PDE’s.

- In [14], we consider stabilization of coupled systems of hyperbolic PDE’s with hybrid boundary conditions, by a reduced number of closed loop globally distributed controls. We establish polynomial stabilization for such systems under a new compatibility condition. We also derive decay rates for explicit initial data using interpolation theory.

- In [15], we consider stabilization of coupled systems of wave-type, with localized couplings and either localized internal closed loop controls or boundary control. We establish polynomial decay rates for coupling and damping regions which do not intersect in the one-dimensional case. We also derive results in the multi-dimensional case, under multiplier type conditions for both the coupling and damping regions. The novelty and difficulty is to consider localized couplings.

- In [13] we give a constructive proof of Gibson’s stability theorem, some extension and further positive and negative applications of this result.

Very few lower energy estimates are available in the literature. The main one has been proved in the one-dimensional case for a locally distributed power-like damping for the wave equation in 1995 by Haraux. This approach does not generalize to multi-dimensional cases and for systems of equations. In [11], we prove strong energy and weak velocity lower estimates for the nonlinearly damped Timoshenko beams (coupled system), and for Petrowsky equations in two space dimensions.

- In [12], we show that if a linear system is observable through a locally distributed (resp. boundary) observation, then any dissipative nonlinear feedback locally distributed (resp. active only on a part of the boundary) stabilize the system and we give quasi-optimal energy decay rates, under the optimal condition of geometric optics of Bardos-Lebeau-Rauch (1992). The approach is based on the optimal-weight convexity method (Alabau-Boussouira 2005, 2010). Our results generalize previous results by Haraux (1989) and Ammari and Tucsnak (2001) for linear feedbacks.

- In [17], we study the stabilization of Bresse system, which models vibrations of a beam through three coupled wave equations. We establish polynomial stabilization of the full system by a single feedback control.

- In [23], Badra (University of Pau) and Takahashi consider the stabilization of the system $y' = Ay + Bu$ where $A : \mathcal{D}(A) \rightarrow X$ be the generator of an analytic semigroup and $B : U \rightarrow \mathcal{D}(A^*)$ a quasi-bounded operator. They consider controls $u$ which are the linear combination of a finite family $(v_1, ..., v_K)$. They show that if $(A^*, B^*)$ satisfies a unique continuation property and if $K$ is greater or equal to the maximum of the geometric multiplicities of the
the unstable modes of \( A \), then the system is generically stabilizable with respect to the family \((v_1, ..., v_K)\). With the same functional framework, they also prove the stabilizability of a class of nonlinear system when using feedback or dynamical controllers. They apply these results to stabilize the Navier–Stokes equations in 2D and in 3D by using boundary control with an optimal number of controllers.

- In [32] we tackle an unsolved difficulty in the control of vibrating systems, consisting in the fact that a small delay in the application of a feedback control may destroy the stabilizing effect of the control. We consider a vibrating string that is fixed at one end and stabilized with a boundary feedback with delay at the other end and we show that certain delays (large, in general) in the boundary feedback preserve the exponential stability of the system.

- In [18] we consider \( N \) Euler-Bernoulli beams and \( N \) strings alternatively connected to one another and forming a chain beginning with a string. We study the strong and polynomial stabilities of this system on this network and the spectrum of the corresponding conservative system.

- In [45] we study the asymptotic behavior of the solution of the non-homogeneous elastic systems with voids and a thermal effect. Our main results concern strong and polynomial stabilities (since this system suffers of exponential stability).

- In [24] we are interested in an inverse problem for the wave equation with potential on a star-shaped network. We prove the Lipschitz stability of the inverse problem consisting in the determination of the potential on each string of the network with Neumann boundary measurements at all but one external vertices. Our main tool, proved in this article, is a global Carleman estimate.

- In [35] we consider switched systems on Banach and Hilbert spaces governed by strongly continuous one-parameter semigroups of linear evolution operators. We provide necessary and sufficient conditions for their global exponential stability, uniform with respect to the switching signal, in terms of the existence of a Lyapunov function common to all modes.

- In [47], we investigate sufficient conditions for the convergence to zero of the trajectories of linear switched systems. We apply our result to the synthesis of an observer for the three-cell converter.

### 6.3.4. Other problems

- In [37], we study a spectral problem related to a reaction-diffusion model where the preys and the predators do not live on the same area. We are interested in the optimal zone where the control should take place. First we prove existence of an optimal domain in a natural class. Then, it seems plausible that the optimal domain is localized in the intersection of the living areas of the two species. We prove this fact in one dimension for small size of domains.

- In [41], we explain why Donnelly’s proof of the gap conjecture is not correct.

- In [22], we study the set of points, in the plane, defined by \( \{(x, y) = (\lambda_1(\Omega), \lambda_2(\Omega)), |\Omega| = 1\} \), where \((\lambda_1(\Omega), \lambda_2(\Omega))\) are either the two first eigenvalues of the Dirichlet-Laplacian, or the two first non trivial eigenvalues of the Neumann-Laplacian. We consider the case of general open sets together with the case of convex open domains. We give some qualitative properties of these sets, show some pictures obtained through numerical computations and state several open problems.

- In [28], we look for the minimizers of the functional \( J_\lambda(\Omega) = \lambda|\Omega| - P(\Omega) \) among planar convex domains constrained to lie into a given ring. We prove that, according to the values of the parameter \( \lambda \), the solutions are either a disc or a polygon. In this last case, we describe completely the polygonal solutions by reducing the problem to a finite dimensional optimization problem. We recover classical inequalities for convex sets involving area, perimeter and inradius or circumradius and find a new one.
6. New Results

6.1. Spiking neurons

Participants: Hana Belmabrouk, Yann Boniface, Mohamed-Ghaïth Kaabi, Dominique Martinez, Horacio Rostro, Thierry Viéville, Thomas Voegtlin.

6.1.1. Mathematical modeling

- We demystify some aspects of coding with spike-timing, through a simple review of well-understood technical facts regarding spike coding, allowing to better understand to which extent computing and modeling with spiking neuron networks might be biologically plausible and computationally efficient. Considering a deterministic implementation of spiking neuron networks, we are able to propose results, formula and concrete numerical values, on several topics: (i) general time constraints, (ii) links between continuous signals and spike trains, (iii) spiking neuron networks parameter adjustment. This should prevent one from implementing mechanisms that would be meaningless relative to obvious time constraints, or from artificially introducing spikes when continuous calculations would be sufficient and more simple.

- We propose a generalization of the existing maximum entropy models used for spike train statistics analysis, bringing a simple method to estimate statistics and generalizing existing approaches based on Ising model or one step Markov chains to arbitrary parametric potentials. Our method enables one to take into account memory effects in dynamics. It provides directly the “free-energy” density and the Kullback-Leibler divergence between the empirical statistics and the statistical model. Furthermore, it allows the comparison of different statistical models and offers a control of finite-size sampling effects, inherent to empirical statistics, by using large deviations results. This work is submitted for publication.

- Following some theoretical work about back-engineering from spike recordings, we study the possibility to design an artificial vision system based on spiking neurons, for which neural connections and synaptic weights are directly derived from recordings of spiking activities in the human visual system through a back-engineering approach. A specific simple spiking model has been defined that mathematically enables this back-engineering process from biological data. From a hardware point of view, this model results in an efficient implementation on FPGAs.

6.1.2. Biophysical modeling

Our understanding of the computations that take place in the human brain is limited by the extreme complexity of the cortex, and by the difficulty of experimentally recording neural activities, for practical and ethical reasons. The Human Genome Project was preceded by the sequencing of smaller but complete genomes. Similarly, it is likely that future breakthroughs in neuroscience will result from the study of smaller but complete nervous systems, such as the insect brain or the rat olfactory bulb. These relatively small nervous systems exhibit general properties that are also present in humans, such as neural synchronization and network oscillations. Our goal is therefore to understand the role of these phenomena by combining biophysical modelling and experimental recordings, before we can apply this knowledge to humans. In the last year, we obtained the following results:

- We have explored the role of subthreshold membrane potential oscillations in stabilizing the oscillation frequency in a model of the olfactory bulb [9].

- We have developed several biophysical models of the insect olfactory system to explain the transformation from first-order [10] to second-order neurons [6], [16]. We show in particular how cellular and network mechanisms contribute to coding efficiency.
6.2. Dynamic Neural Fields

Participants: Lucian Aleçu, Frédéric Alexandre, Yann Boniface, Laurent Bougrain, Mauricio Cerda, Georgios Detorakis, Hervé Frezza-Buet, Bernard Girau, Axel Hutt, Mathieu Lefort, Jean-Charles Quinton, Nicolas Rougier, Wahiba Taouali, Thierry Viéville, Thomas Voegtlin.

The work reported this year represents both extensions of previous works and new results linked to the notion of neural population, considered at (i) a formal level (theoretical studies of neural fields), (ii) a numerical level (study of functioning and learning rules) and (iii) a more embodied one (implementations of specific functions).

6.2.1. Formal Level

- study of the differences between synchronous and asynchronous (without a central clock) evaluation: The hallmark of most artificial neural networks is their supposed intrinsic parallelism where each unit is evaluated concurrently to other units in a distributed way. However, if one gives a closer look under the hood, one can soon realize that such a parallelism is an illusion since most implementations use what is referred to as synchronous evaluation, or using a central clock. Here we propose to consider different evaluation methods (namely asynchronous and event based evaluation methods) and study their properties in some restricted but illustrative cases. This work is also in preparation for publication.
- taking into account transmission speed between units in a neural field: Neurons in populations are connected to each other by axonal branches sending electric pulses. The pulse propagation with finite speed delays the neuron interactions. The developed numerical algorithm illustrates how to simulate neural fields in two spatial dimensions involving finite axonal transmission speeds. The algorithm is derived analytically shows how to implement a Fast Fourier Transform in the computation scheme.
- study of the bridge between an ensemble of spiking neurons and the population firing rate to extend neural fields by shunting inhibition effects. Shunting inhibition is an important effect in real neural systems, e.g. in the context of general anaesthesia. We re-derive the population firing rate well-known in neural fields from the single neuron firing statistics. This derivation assumes McCulloch-Pitts neurons with a trivial f-I curve. Then we exchange the McCulloch-Pitts neurons by more realistic type I-neurons with a non-trivial f-I curve and gain a different, more realistic population firing rate. This formulation allows to consider some shunting inhibition effects [44].

6.2.2. Numerical Level

6.2.2.1. Numerical studies of DNF and related mechanisms

At the numerical level, specific developments were carried out to assess our software platform, to master functioning rules and to study the performances of new learning rules:

- The problem of adjusting the parameters of a mesoscopic event and valued neural field with delayed connections is addressed here at the programmatic level. An effective computational framework, with the implementation of a general algorithm is developed allowing us to effectively design non-trivial input/output transformations of events and values, using a class of biologically plausible distributed functional models. This work is in preparation for publication.
- In order to clarify the notion of distributed computing, general concepts and definitions in the framework of artificial neural networks have been reviewed, within the scope of dynamic field theory, proposing an unequivocal definition of asynchronous computation. An innovative way to perform such asynchronous computation has been proposed, following theoretical developments in process formalization. Several consequences on both the trajectories and the stability of the whole system have been drawn, including a few practically usable methods and quantitative bounds that can guarantee most of the mesoscopic properties of the system [15].
- Novel numerically efficient algorithm to compute spatio-temporal activity in two-dimensional neural fields involving finite transmission speed.
- Study of the possibility to obtain properties of self-organization with dynamic neural fields and proposition of a new learning rule for self-organization [1], [5].
- We designed a variation of the self-organising map algorithm [14] where the original time-dependent (learning rate and neighbourhood) learning function has been replaced by a time-invariant one. This allows for on-line and continuous learning on both static and dynamic data distributions. One of the property of the newly proposed algorithm is that it does not fit the magnification law and the achieved vector density is not directly proportional to the density of the distribution as found in most vector quantisation algorithms. From a biological point of view, this algorithm sheds light on cortical plasticity seen as a dynamic and tight coupling between the environment and the model.
- Adaptation of the BCM rule to multi-modality by adapting the dynamics of the threshold by the use of a feed-back signal generated by a neural field map [22], [39], [45].
- Following [25], we are now studying a computational model of the primary somato-sensory cortex based on the neural field theory where cortical representations develop through the modification of thalamocortical synapses (from thalamus to layer 4), while cortico-cortical synapses (layer 2/3 and 4) provide a distributed competitive mechanism between cortical pyramidal neurons of layer 2/3. Preliminary results explains both the initial development and the self-organization of cortical representations in the primary sensory cortex as well as the dynamic reorganization following a lesion or a sensory deprivation. In this context, the so-called critical period during childhood would correspond to the development and learning of the intra-cortical competitive mechanism that is critical for cortex plasticity.

6.2.2.2. Gaussian mixture based approximation of neural maps

We have studied the advantages of our new implementation of the Continuous Neural Field Theory (CNFT) using a Gaussian mixture based model of the neural field activity, when using high dimensional inputs [40]. It exploits the rapid convergence of the activity to a reduced set of localized bubbles when competition occurs. These bubbles of activity can be accurately approximated by Gaussian distributions, that are directly computed in any n-dimensional space, instead of projecting high dimensional inputs onto 2D maps (which generally leads to topological distortions). This implementation is thus used to evaluate the possibilities of sensorimotor or multimodal associations without prior self-organization on 2D cortical maps, and could be directly interfaced with high dimensional artificial systems.

6.2.3. Embodied Level

6.2.3.1. Motion detection

We develop bio-inspired neural architectures to extract and segment the direction and speed components of the optical flow from sequences of images. Following this line, we have recently built additional models to code and distinguish different visual sequences. The structure of these models takes inspiration from the course of visual movement processing in the human brain, such as in area MT (middle temporal) that detects patterns of movement, or area FBA where neurons have been found to be sensitive to single spatio-temporal patterns. This work has been recently extended to complex movements: to fight, to wave, to clap, using real-world video databases [2], as well as using speech-driven visual animations of faces [28].

6.2.3.2. Modeling the superior colliculus by mean of a neural field.

In the context of the ANR MAPS project (cf. § 7.2), we have been studying the superior colliculus in tight collaboration with Laurent Goffart from the Institut de Neurosciences Cognitives de la Méditerranée. Considering the cortical magnification induced by the non homogeneous distribution of retina rods and cones on the retina surface, we modeled the superior colliculus using a dynamic neural field that may explain the stereotyped nature of colliculus activity. This year, we have extended this approach to wider contexts:

- Using Neural Fields to model the Superior Colliculus in a task of saccade generation
- Arrangement of several neural fields to model several cortical areas engaged in visual attention
6.2.3.3. Modeling of neural activity during anaesthesia.

Anaesthesia plays an important role in medical surgery though its neural mechanism is still poorly understood. Besides several different molecular and behavioral phenomena, the administration of anaesthetic agents affects the power spectrum of electro-encephalographic activity (EEG) in a characteristic way. The theoretical study aims to model the power spectrum changes in EEG subject to the concentration of the specific anaesthetic agent propofol. The work developed a neural model [38] involving two neuron types and synapse types while taking into account the synaptic effect of propofol. The mathematical derivation of the power spectrum allows for the investigation of suitable physiological parameters which reproduce the experimental effect of propofol. Several mathematical conditions on physiological parameters have been derived and the EEG-power spectrum during the administration of different concentration levels of propofol has been modeled successfully.

6.3. Higher level functions

Our activities concerned information analysis and interpretation and the design of numerical distributed and adaptive algorithms in interaction with biology and medical science. To better understand cortical signals, we choose a top-down approach for which data analysis techniques extract properties of underlying neural activity. To this end several unsupervised methods and supervised methods are investigated and integrated to extract features in measured brain signals. More specifically, we worked on Brain Computer Interfaces (BCI).

6.3.1. Detection of partial amplitude synchronization in multivariate data

To gain information on the interactions between neural structures, several electrodes may be implanted in cortical areas to measure Local Field Potentials. The developed method aims to extract time windows in which a subset of measured time series exhibit an amplitude synchronization in certain frequency bands [12].

6.3.2. Brain-Computer Interface based on motor imagery to control a robotic arm in 3D

The interface we develop aims to control in 3D a Jaco robotic arm by Kinova, using the Graz Motor Imagery detection paradigm for two or three motor actions in an online situation. The interface is part of the OpenViBE software. The user can switch in different modes to control a specific part of the robotic device (arm, wrist, fingers). We plan to use five different motor imageries: right hand, left hand, foot, rest and both hands. The actions are not available all together for a specific control. The interface is already done. More experiments will be done to adjust the classifier.

6.3.3. Reinforcement learning to better control a robotic arm

The approach we proposed in Cobras is innovative. Many studies attempt to improve the recognition rate of a BCI order with new methods for treatment of signal. These studies are placed upstream of the BCI to facilitate the retrieval of information in the signal. However, the signal to noise ratio is so low that the improvements are limited. Rather than improving signal processing upstream, we wanted to improve the recognition rate by adding information in the controlled system. Thus, we placed downstream and added, as inputs of our control system, mechanical data concerning robotic arm. Initially, we validated the possibility of finding -using an inverse algorithm of reinforcement learning- the policy of the expert from a set of trajectories followed in a maze. We defined then a scenario to achieve different trajectories with the robotic arm to reach several buttons. In a third step, we used this algorithm on a maze-type problem but for which we have completed the state vector with the classifier outputs. This study is ongoing.
6.3.4. Mutual influence of firing rates of corticomotoneuronal cells for learning a precision grip task

As a part of a Brain-Machine Interface, we define a model for learning and forecasting muscular activity, given sparse cortical activity in the form of action potential signals (spike trains). We have a collection of experiments in which a trained monkey performs a precision grip. More precisely, its neuronal activity is partially recorded from corticomotoneuron cells of the hand area (area 4) as the monkey clasps two levers between its index finger and thumb. The underlying model parameters are interpreted with respect to the physiological aspects, though the model itself is not bio-physical. The method used is based on a system of first degree linear equations involving the firing rate of the recorded neurons, two sets of thresholds associated to them, and the variation of the global neuronal activity. We build a module to translate the data in the form of spikes trains into the event structure of OpenViBE triggers which is more appropriate than signals. The enslavement of the clamp according to the order generated by OpenViBE was also done. These solutions can demonstrate the capabilities of our algorithms for decoding cortical signals in the task of handling.

6.3.5. Hysteresis thresholding for Wavelet denoising applied to P300 single-trial detection

Template-based analysis techniques are good candidates to robustly detect transient temporal graphic elements (e.g. event-related potential, k-complex, sleep spindles, vertex waves, spikes) in noisy and multi-sources electroencephalographic signals. More specifically, we studied the significant impact on a large dataset of wavelet denoisings to detect evoked potentials in a single-trial P300 speller. We applied the classical thresholds selection rules algorithms and compared them with the hysteresis algorithm by R. Ranta which combine the classical thresholds to detect blocks of significant wavelets coefficients based on the graph structure of the wavelet decomposition.

6.4. Embodied and embedded systems

Participants: Yann Boniface, Hervé Frezza-Buet, Bernard Girau, Mathieu Lefort, Dominique Martinez, Jean-Charles Quinton, Nicolas Rougier.

6.4.1. InterCell

Our research in the field of dedicated architectures and connectionist parallelism mostly focuses on embedded systems (cf. § 3.5). Nevertheless we are also involved in a project that considers coarse-grain parallel machines as implementation devices. The core idea of this InterCell project (cf. http://intercell.metz.supelec.fr) is to map fine grain computation (cells) to the actual structure of PC clusters. The latter rather fit coarse grain processing, using relatively few packed communication, which a priori contradicts neural computing. Another fundamental feature of the InterCell project is to promote interaction between the parallel process and the external world. Both features, cellular computing and interaction, allow to consider the use of neural architectures on the cluster on-line, for the control of situated systems, as robots.

6.4.2. Embodied/embedded olfactory systems

6.4.2.1. How can animals successfully locate odour sources?

Our goal is to investigate this question. Two different classes of strategies are possible for olfactory searches: those based on a spatial map, e.g. Infotaxis, and those where the casting-and-zigzagging behaviour observed in insects is purely reactive. We have implemented Infotaxis in a robot and shown that it produces trajectories that feature zigzagging and casting behaviours similar to those of moths. This result however should not be interpreted as evidence that the corresponding moth behaviour is driven by Infotaxis. Whether or not moths use infotactic or reactive strategies is still unclear. To compare both strategies, we have developed a cyborg using the antennae of a tethered moth as sensors (no artificial sensor for pheromone molecules is presently known). Experiments are in progress to compare the trajectories of the cyborg controlled by infotactic and reactive search strategies to those obtained with the same cyborg but driven by the moth’s brain.
6.4.2.2. How can technology emulate biological olfactory processing?

Glomerular microcircuits in the first stage of the olfactory pathway reformat odor representation. First, many ORNs expressing the same receptor protein, yet presenting heterogeneous dose-response properties, converge onto each glomerulus [10]. Second, onset latency of glomerular activation is believed to play a role in encoding odor quality and quantity in the context of fast information processing [6]. Taking inspiration from biology, we designed a simple yet robust glomerular latency coding scheme for processing gas sensor data [7]. The proposed bio-inspired approach was evaluated using an Sn02 sensor array. Glomerular convergence was achieved by noting the possible analogy between receptor protein expressed in ORNs and metal catalyst used across the fabricated gas sensor array. Ion implantation was another technique used to account both for sensor heterogeneity and enhanced sensitivity. The response of the gas sensor array was mapped into glomerular latency patterns, whose rank order is concentration-invariant.

6.4.3. Hardware implementations of neural models

In the field of dedicated embeddable neural implementations, we use our expertise in both neural networks and FPGAs so as to propose efficient implementations of applied neural networks on FPGAs, as well as to define hardware-friendly neural models.

- Following our results on the design of spiking models back-engineered from spike recordings, recent works have focused on the analysis of the influence of precision onto asymptotic dynamics of FPGA-embedded integrate-and-fire neural models [13].
- We design hardware-friendly adaptations of dynamic neural fields that use spiking neurons. In this field, we have derived a highly simplified version of such spiking neural fields, and we have experimentally shown that the main properties of standard neural fields are maintained in the context of visual attention [29].
- We currently intend to minimize the topological constraints of FPGA-embedded spiking neural fields using reduced neighborhoods but randomly propagating spikes. A preliminary result has been obtained so as to implement massively distributed pseudo-random number generators based on cellular automata that use minimal areas [21].

6.4.4. Towards brain-inspired hardware

Our activities on dedicated architectures have strongly evolved in the last years. We now focus on the definition of brain-inspired hardware-adapted frameworks of neural computation. Our current works aim at defining hardware-compatible protocols to assemble various perception-action modalities that are implemented and associated by different bio-inspired neural maps.

6.4.4.1. Anticipatory mechanisms in neural fields

We have defined first models of neural fields that include anticipatory mechanisms through the integration of spatiotemporal representations into the lateral interactions of a dynamic neural field [23]. This work targets increased robustness and goal-oriented action selection within sensori-motor systems.

6.4.4.2. Multimodal learning through joint dynamic neural fields

This work relates to the development of a coherent multimodal learning for a system with multiple sensory inputs.

- We have modified the BCM synaptic rule, a local learning rule, to obtain the self organization of our neuronal inputs maps and we use a CNFT based competition to drive the BCM rule. In practice, we introduce a feedback modulation of the learning rule, representing multimodal constraints of the environment [39].
- We have introduced an unlearning term in the BCM equation to solve the problem of the different temporalities between the raise of the activity within modal maps and the multimodal learning of the organization of the maps [22].
6. New Results

6.1. On the Existence of Strict Optimal Controls for Constrained, Controlled Markov Processes in Continuous-Time

Participant: François Dufour.

Closedness and convexity conditions are identified under which optimal controls in the class of strict controls exist for a large class of stochastic processes under infinite-horizon discounted, long-term average, first exit, finite-horizon and discretionary stopping criteria in the presence of hard and/or soft constraints. The results are more general than results obtained by Haussmann and Lepeltier for a controlled diffusion under a mixed optimal-stopping/finite-horizon/first-exit criterion. The approach taken in this work is to utilize equivalent linear programming formulations of the control problems which provides a unified LP formulation for the problems. The conditions of Haussmann and Lepeltier are shown to imply the sufficient conditions of this paper when the process is a controlled diffusion. Simpler conditions are also identified for Markov chains, simple Markov jump processes, diffusions with jumps, regime-switching diffusions and solutions to Levy stochastic differential equations.

These results have been obtained in collaboration with Richard Stockbridge, Department of Mathematical Sciences, University of Wisconsin Milwaukee, USA. It has been accepted for publication in Stochastics [14].

6.2. Approximation of Markov Decision Processes with General State Space

Participant: François Dufour.

In this work, we deal with a discrete-time finite horizon Markov decision process with locally compact Borel state and action spaces, and possibly unbounded cost function. Based on Lipschitz continuity of the elements of the control model, we propose a state and action discretization procedure for approximating the optimal value function and an optimal policy of the original control model. We provide explicit bounds on the approximation errors. Our results are illustrated by a numerical application to a fisheries management problem.

These results have been obtained in collaboration with Tomas Prieto-Rumeau, Department of Statistics and Operations Research, UNED, Madrid, Spain. It has been accepted for publication in Stochastics [13].

6.3. Asymmetry tests for Bifurcating Auto-Regressive Processes with missing data

Participants: Benoîte de Saporta, Anne Gégout-Petit.

Using the properties of the estimators studied in [20], we have constructed symmetry tests for bifurcating autoregressive processes (BAR) when some data are missing. BAR processes typically model cell division data. Each cell can be of one of two types odd or even. The goal of this work is to test asymmetry between odd and even cells in a single observed lineage. We have also derived asymmetry tests for the lineage itself, modeled by a two-type Galton-Watson process observed in a non standard scheme. We present applications on both simulated and real data.

This work is in collaboration with Laurence Marsalle of Lille 1 university. It will be soon submitted for publication.

6.4. Statistical study of asymmetry in cell lineage data

Participants: Benoîte de Saporta, Anne Gégout-Petit.
Simulation studies of the asymmetry in a single lineage data have shown a lack of power of the tests when the number of available generation is limited. This work proposes a rigorous methodology to study cell division data in the context of observation of several lineages. It generalizes [20]. We model the data by an asymmetric bifurcating autoregressive (BAR) process and take into account possibly missing data by modeling the genealogies with a two-type Galton Watson (GW) process. Our inference is based on several lineages, i.e. independent and identically distributed replicas of the coupled BAR and GW processes. We propose a least-squares estimator of the unknown parameters of the BAR process and an estimator of the parameters of the GW process, study their asymptotic properties and propose symmetry tests. Our results are applied on real data of Escherichia coli division.

This work is in collaboration with Laurence Marsalle of Lille 1 university. It will be soon submitted for publication.

6.5. Estimation of the jump rate of a PDMP

Participants: Romain Azaïs, François Dufour, Anne Gégout-Petit.

We estimate the jump rate of PDMP. We suppose the flow given by physics laws and we want to make some inference on $\lambda, \phi$ being deterministic, the problem can be rewritten as a problem of estimation of the rate $\lambda(z, t)$ with $z \in E$ with $E$ an open set of a separable metric space. We have an ergodicity assumption on the observed PDMP and the asymptotic is in the time of observation of the process.

We distinguish three cases:

1. $E$ is finite. In this case, we easily estimate each of the cumulated risk functions $\Lambda(z, t) = \exp(-\int_0^t \lambda(z, s) \, ds)$ corresponding to each of $z \in E$ by a Nelson Aalen estimator. The results is based on the decomposition in semi-martingale of the following counting process in an appropriate filtration:

$$\forall t \geq 0, \quad N_n(z, t) = \sum_{i=0}^{n-1} 1_{\{S_{i+1} \leq t\}} 1_{\{Z_i = z\}}, \quad (5)$$

We obtain the estimator of the rate $\lambda(z, t)$ by smoothing of the estimator of $\Lambda$.

2. $E$ is an open set of a general separable metric space but the transition measure $Q$ does not depend on the time spent in the current regime. In this case, we suppose the rate $\lambda(z, t)$ Lipschitz and the process ergodic with a stationary law denoted by $\nu$. We first construct an estimation of the cumulated rate knowing that $z$ belongs to a set $A$ such that $\nu(A) > 0$ by:

$$\hat{L}_n(A, t) = \sum_{i=0}^{n-1} \frac{1}{Y_n(A, S_{i+1})} 1_{\{S_{i+1} \leq t\}} 1_{\{Z_i = z\}} \quad \text{with} \quad Y_n(A, t) = \sum_{i=0}^{n-1} 1_{\{S_{i+1} \geq t\}} 1_{\{Z_i \in A\}}. \quad (6)$$

We show the consistence of the estimator. Smoothing $\hat{L}_n(A, t)$ and using a fine partition of $E$ allow us to obtain an uniform result for the approximation of the rate $\lambda(z, t)$, in some sense in $t$ and $z$.

3. $E$ is an open set of a general separable metric space and the transition measure $Q$ depends on the time spent in the current regime. Here, we loose some conditional independence between the $S_i$’s and the whole set of the locations of the jump $\{Z_1, ..., Z_n\}$. We have to make a detour for the estimation of the law of the time $S_{k+1}$ knowing the current $Z_k$ by the the law $S_{k+1}$ knowing $(Z_k, Z_{k+1})$. The method gives an estimation of the conditional density of $S_{k+1}$ given $Z_k$.

We have made simulation studies that give expected results. A R package for this estimation method is in progress.
6.6. Detection of a damaged operating mode of optronic equipment using Hidden Markov Model

Participants: Camille Baysse, Anne Gégout-Petit, Jérôme Saracco.

As part of optimisation of the reliability, Thales Optronics now includes systems that examine the state of its equipment. This function is performed by HUMS (Health & Usage Monitoring System). The aim is to implement a program based on these observations that can determine the lifetime of this optronic equipment and optimize its maintenance.

Our study focuses on a simple example of HUMS. As part of our research, we are interested in a variable called "time-to-cold" noted TMF, which reflects the state of the system. Using these informations about this variable, we seek to detect as soon as possible a damaged state and propose a maintenance before failure. This would allow the Thales Optronics company to improve its maintenance system and achieve many economies.

For this we use a hidden Markov model. The state of our system at time t is then modeled by a continuous time Markov chain $X(t)$ with three states: stable, damaged and failure. However we do not observe directly this chain but indirectly through the TMF, a noisy function of this chain. Thanks to filtering equations, we obtained results on the probability that an equipment is in a damaged state at time t, knowing the history of the TMF until this moment. We have subsequently studied the method on simulated data, before applying these results on the analysis of our real data and we have checked that the results are consistent with the reality. This work will be used by Thales Optronique for the optimization of the maintenance.

This work is a part of the CIFRE PhD Thesis of Camille Baysse founded by Thales Optronique. It is the object of a technical report [48] and was presented in [29] in an internal Thales seminar.

6.7. Optimal quantization applied to Sliced Inverse Regression

Participants: Romain Azaïs, François Dufour, Anne Gégout-Petit, Jérôme Saracco.

We tackle the well known Slice Inverse Regression (SIR) method for a semiparametric regression model involving a quantitative variable $X$ and including a dimension reduction of $X$ via a parameter $\beta$. The response variable $Y$ is real. Our goal is to estimate $\beta$ and to predict the response variable conditionally to $X$. We adapt SIR method using optimal quantization [57] in the first time only for the independent variable $X$ for the estimation of $\beta$. In a second time, we quantize the variable $(\hat{\beta}_n, Y)$ in order to propose a discrete conditional law of $Y$ given $X = x$. We show the convergence of the estimator of $\beta$ and of the conditional law. Simulation studies show the numerical qualities of our estimates. This work is the object of a publication in Journal of Statistical Planning and Inference [15] and was presented in a national conference [23].

6.8. Multivariate Analysis for the detection of the effect of a treatment

Participant: Anne Gégout-Petit.

The aim of this work is to give some statistical rules to determine if a patient is meeting a given treatment (a BD here). The criterium commonly used to determine if a patient is meeting a BD treatment is based only on one physiological parameter: if this parameter increases, the patient is meeting. But now, many physiological parameters are measured in routine and physiologists "ont le sentiment" that a patient could have a global amelioration of his health state due to the treatment without an increase of the single used parameter.
Using the measures of six variables before and after the treatment, the expected value of this variable under the hypothesis of good health, we first propose indices of amelioration. Using standard multivariate analysis techniques, we first study the correlation between these indices. We use classification in order to constitute groups of patients whose present homogeneous treatment responses. The method used on a cohort of 100 subjects gives three groups: in the first one, the mean of the indices is near zero, the treatment has no effect. In the second one, subjects present significant amelioration regarding two of the indices but not the indices related to the commonly used one. The last group show an amelioration for all the indices.

We have proposed criteria to discriminate the three groups. These criteria where used on a validation cohort to constitute three groups. Their global characteristics were the same as in the original cohort and it comforts the validity of the method. This work will be used by physiologists to propose new criteria for the measure of the effect of a BD treatment. It is in collaboration with physiologists from Bordeaux and Nantes universities and is the object of a paper that will be soon submitted in an international peer-reviewed journal in the domain of pneumology.

6.9. Numerical computation of expectations of PDMP’s

Participants: Adrien Brandejsky, Benoîte de Saporta, François Dufour.

This work concerns the computation of expectations of functionals of piecewise deterministic Markov processes (PDMP’s). We propose a numerical scheme to approximate such expectations, analyze the convergence of our scheme and derive bounds for the convergence rate. More precisely, we are interested in the approximation of expectations of the form

$$E_x \left[ \int_0^{T_N} l(X_t)dt + \sum_{j=1}^{N} c(X_{T_j}^-)I(X_{T_j}^- \in \partial E) \right]$$

where \((X_t)_{t \geq 0}\) is a PDMP, \((T_j)\) are its jump times and \(l\) and \(c\) are some non negative, real-valued, bounded functions. Such expectations are discussed by M.H.A. Davis in [50], chapter 3. They often appear as cost or reward functions in optimization problems. The first term is referred to as the running cost while the second may be called the boundary jump cost. Besides, they are quite general since M.H.A. Davis shows how a wide variety of apparently different functionals can be obtained from the above specific form. For example, this wide variety includes quantities such as a mean exit time and even, for any fixed \(t \geq 0\), the distribution of \(X_t\), (i.e. \(E_x[I_F(X_t)]\) where \(F\) is a measurable set).

There are surprisingly few works in the literature devoted to the actual computation of such expectations, using other means than direct Monte Carlo simulations. M.H.A Davis showed that these expectations satisfy integro-differential equations. However, the set of partial differential equations that is obtained is unusual. Roughly speaking, these differential equations are basically transport equations with a non-constant velocity and they are coupled by the boundary conditions and by some integral terms involving kernels that are derived from the properties of the underlying stochastic process. This approach is currently under study in this project by LATP.

The main difficulty comes from the fact that the domains on which the equations have to be solved vary from one equation to another making their numerical resolution highly problem specific. Another similar approach has been recently investigated in [49], [54]. It is based on a discretization of the Chapman Kolmogorov equations satisfied by the distribution of the process \((X_t)_{t \geq 0}\). The authors propose an approximation of such expectations based on finite volume methods. Unfortunately, their method is only valid if there are no jumps at the boundary.

Our approach is completely different and does not rely on differential equations, but on the fact that such expectations can be computed by iterating an integral operator \(G\). This operator only involves the embedded Markov chain \((Z_n, S_n)_{n \in \mathbb{N}}\) and conditional expectations. It is therefore natural to propose a computational method based on the quantization of this Markov chain, following the same idea as [8]. We also addressed two important aspects that had not been investigated in [8]. The first one consists in allowing \(c\) and \(l\) to be time depending functions, although still Lipschitz continuous, so that we may compute expectations of the form
\[
E_x \left[ \int_0^{T_N} l(X_t, t) dt + \sum_{j=1}^{N} c(X_{T_j}^{-}, T_j) I\{X_{T_j}^{-} \in \partial E\} \right].
\]

This important generalization has huge applicative consequences. For instance, it allows discounted cost or reward functions such as \( l(x, t) = e^{-\delta t} l(x) \) and \( c(x, t) = e^{-\delta t} c(x) \) where \( \delta \) is some interest rate. To compute the above expectation, our strategy consists in considering, as it is suggested by M.H.A. Davis in [50], the time augmented process \( \tilde{X}_t = (X_t, t) \).

The second important generalization is to consider the deterministic time horizon problem. Indeed, it seems crucial, regarding to the applications, to be able to approximate
\[
E_x \left[ \int_0^{t_f} l(X_t, t) I\{t \leq t_f\} dt + \sum_{j=1}^{+\infty} c(X_{T_j}^{-}, T_j) I\{X_{T_j}^{-} \in \partial E\} I\{T_j \leq t_f\} \right]
\]
for some fixed \( t_f > 0 \) regardless of how many jumps occur before this deterministic time. To compute this quantity, we start by choosing a time \( N \) such that \( P(T_N < t_f) \) be small so that the previous expectation boils down to
\[
E_x \left[ \int_0^{T_N} l(X_t, t) dt + \sum_{j=1}^{N} c(X_{T_j}^{-}, T_j) I\{X_{T_j}^{-} \in \partial E\} I\{T_j \leq t_f\} \right].
\]
We deal with the two indicator functions in two different ways. On the one hand, we prove that it is possible to relax the regularity condition on the running cost function so that our algorithm still converges in spite of the first indicator function. On the other hand, since the same reasoning cannot be applied to the indicator function within the boundary jump cost term, we bound it between two Lipschitz continuous functions. This provides bounds for the expectation of the deterministic time horizon functional.

An important advantage of our method is that it is flexible. Indeed, as pointed out in [47], a quantization based method is obstacle free which means, in our case, that it produces, once and for all, a discretization of the process independently of the functions \( l \) and \( c \) since the quantization grids merely depend on the dynamics of the process. They are only computed once, stored off-line and may therefore serve many purposes. Once they have been obtained, we are able to approximate very easily and quickly any of the expectations described earlier. This flexibility is definitely an important advantage of our scheme over standard methods such as Monte-Carlo simulations since, with such methods, we would have to run the whole algorithm for each expectation we want to compute.

The theoretical part of this work with rigorous proofs is under review for an international peer-reviewed journal [10]. F. Dufour presented this work in an invited session at an international conference [22].

### 6.10. Optimal stopping under partial observation

**Participants:** Adrien Brandejsky, Benoîte de Saporta, François Dufour.

In continuation of our work on optimal stopping for Piecewise deterministic Markov processes (PDMP’s) [8], we have started investigating the optimal stopping problem when the process is only partially observed. We supposed that the jump times of the process are observed, but the post jump locations are observed through a noise.
The first step is to rewrite the optimal stopping problem for the partially observed PDMP as a totally observed stopping problem for a new Markov chain, obtained by filtering the observation process. Then, one has to study precisely this filter, which is non standard due to the possible jumps of the process. The next step is to derive the dynamic programming equation adapted to our framework. Finally, we propose a numerical method based on quantization to approximate the value function and \( \epsilon \)-stopping times. Tracking is also kept of the error bounds all through our numerical procedure.

This work is still in progress and should be submitted to an international peer-reviewed journal shortly.

6.11. Efficient simulation of the availability of a feedwater control system

Participants: Benoîte de Saporta, François Dufour, Huilong Zhang.

In the reliability modeling of complex control systems, classical methodologies such as even-trees/fault-trees or Petri nets may not represent adequately the dynamic interactions existing between the physical processes (modeled by continuous variables) and the functional and dysfunctional behavior of its components (modeled by discrete variables). This paper proposes a framework for modeling and simulation of a water level control system in the steam generator (SG) in the secondary circuit of a nuclear power plant. A similar benchmark system was described by the U.S. Nuclear Regulatory Commission [46] to compare two approaches to dynamic reliability: DFM (Dynamic Flowgraph Methodology) and Markov/CCMT (Cell-to-Cell Mapping Technique). But the report released by the NRC is not sufficient to reconstruct a realistic model. We have developed a complete benchmark case. The behavioral model of SG is obtained from a linearized model published in 2000 by EDF [55]. Detailed description of the components, failure modes and control laws of the principal components is presented. For modeling the system, we use the piecewise deterministic Markov processes (PDP) framework [50] and for implementation we chose Simulink associated with Stateflow. PDP’s offer a very general modeling framework to deal with dynamic reliability problems; Simulink is a good tool to simulate non linear differential equations and their controller, while Stateflow implementation is appropriate for finite state machine descriptions of different components.

In our benchmark system, four physical processes are considered: feedwater flowrate, steam flow, narrow range water level and wide range water level. A PID controller is used to maintain the water level within limits of set-points. The system is composed of seven components: 1 passive system representing vapor transport system, 3 extraction pumps, 2 feeding turbopumps, and 1 waterflow regulation valve. The functional and dysfunctional behaviors and the failure rates of each component are based on operational experience.

We show that PDP modeling is suitable for dynamic reliability analysis, and that Simulink associated with Stateflow provides an interactive simulator (graphical block diagramming), which makes the simulator scalable. This work is submitted for presentation to an international conference in 2012.

6.12. Orthogonal Rotation in PCAMIX

Participants: Marie Chavent, Jérôme Saracco.

The aim of this work is to propose an efficient algorithm for rotation in PCAMIX, a principal component method for a mixture of qualitative and quantitative variables. We give a new presentation of PCAMIX where the principal components and the squared loadings are obtained from a Singular Value Decomposition. The loadings of the quantitative variables and the principal coordinates of the categories of the qualitative variables are also obtained directly. In this context, we propose a computationaly efficient procedure for varimax rotation in PCAMIX and a direct solution for the optimal angle of rotation. A simulation study shows the good computational behavior of the proposed algorithm. An application on a real data set illustrates the interest of using rotation in MCA. All source codes are available in the R package “PCAmixdata”. This work is in revision for publication [45] and has been presented in [36].

Participants: Marie Chavent, Jérôme Saracco.
In this work, we consider block-wise evolving data streams. When a semi-parametric regression model involving a common dimension reduction direction $\beta$ is assumed for each block, we propose an adaptive SIR (for sliced inverse regression) estimator of $\beta$. This estimator is faster than usual SIR applied to the union of all the blocks, both from computational complexity and running time points of view. We show the consistency of our estimator at the root-$n$ rate and its asymptotic normality. We also propose an extension of this method to multiple indices model. In simulation studies, we illustrate the good numerical behavior of our estimator. We also provide a graphical tool in order to detect if there exists a drift of the dimension reduction direction or some aberrant blocks of data. We illustrate our approach with various scenarios. We apply this approach on the following real data problem.

As an illustration, we consider a nonlinear inverse problem in remote sensing. The goal is to estimate the physical properties of surface materials on the planet Mars from hyperspectral data. The method is based on the estimation of the functional relationship between some physical parameters $Y$ and observed spectra $X$. For this purpose, a database of synthetic spectra is generated by a physical radiative transfer model. We propose to reduce the high dimension of spectra ($p = 352$ wavelengths) with a regularized version of SIR. The need to regularize SIR in very high dimensions is well-known. In practice, the database of synthetic spectra may be so large that it cannot be stored in a computer memory. Thus, a stream of smaller sub-databases is generated and we apply our “SIR datastream” approach to this context.

This work will be submitted for publication very soon and it has been presented in the international conference [31].

6.14. Classification of EEG data by evolutionary algorithm for the study of vigilance states

Participants: Marie Chavent, Laurent Vézard.

The objective of this work [42] is to predict the state of vigilance of an individual from the study of its brain activity (EEG signals). The variable to predict is binary (alertness "normal" or "relaxed"). EEG of 44 participants in both states (88 records) were collected with a helmet with 58 electrodes. After a pretreatment step and data validation, a test called "test slope" was chosen. The usual methods of supervised classification (k nearest neighbors, binary classification trees, random forests, and discriminant sparse PLS) were used to provide predictions of the state of participants. The test was then refined using a genetic algorithm, which has built a reliable model (average true classification rate by using CART equal to $86.68 \pm 1.87\%$) and to select an electrode from the initial 58. This work is in collaboration with Pierrick Legrand (EPI Alea) and Frédérique Faïta (EA 487 "Sciences cognitives et facteur humain".

6.15. Comparison of Kernel Density Estimators on Environmental Data with Assumption on Number of Modes

Participants: Jérôme Saracco, Raphaël Coudret.

In this work, we consider valvometric data samples, that is measurements of distances between the two parts of the shell of bivalves. The movements of a few oysters are monitored in different places (like Arcachon Bay or Santander port) by a laboratory called Environnements et Paléoenvironnements Océaniques et Continentaux (EPOC). The aim of these experiments is to determine water quality via the observation of the bivalves behavior. Previous related works have been published on this subject. EPOC team studied this animals in a copper pollution context via investigations using kernels methods. In our study, we consider each day the density of the distance between the two parts of the shell. This density is reasonably assumed to have 2 modes, the first one corresponds to a close status of the shell and the second one to an open status. The study of the evolution of this density along the time provides informations on bivalves behavior. We provide theoretical results on our bandwidth choice with a bounded support kernel and we give a procedure to determine this bandwidth. We also provide asymptotic results for a density kernel estimator with a kernel that has it support on $\mathbb{R}$. We present an extensive simulation study in order to compare numerical performances of various density
estimators based or not on the two modes assumption. From the results obtained from the simulated data, we derive the suitable estimator for our real data application. This work will be submitted for publication very soon and it has been presented in the international conference [37].
5. New Results

5.1. Specification and verification of database driven systems

Participants: Serge Abiteboul, Pierre Bourhis, Luc Segoufin, Szymon Toruńczyk, Victor Vianu.

Modelization and verification of data centric systems. We have intensively studied the Active XML model. It is a high-level specification language tailored to data-intensive, distributed, dynamic Web services. Active XML is based on XML documents with embedded function calls. The state of a document evolves depending on the result of internal function calls (local computations) or external ones (interactions with users or other services). Function calls return documents that may be active, so may activate new subtasks. Our first line of result is a comparison of the specification power of various workflow control mechanisms within the Active XML framework and beyond [23].

AXML is very powerful and many static analysis problems are undecidable. We have also introduced a model of automata designed for modeling infinite runs of systems equipped with static relational databases. The automata model is equipped with finitely many variables, each of which can store values from a linearly ordered domain, such as the natural numbers. The transitions of the automata depend on a conjunctive query involving the database and the current values of the variables. For verifying infinite runs of such automata, an extension of temporal logic is considered, capable of comparing values stored in the variables and the database, at different times of the run. The main contribution of the work is the proof that automated verification of such temporal properties of the system can be carried out in PSpace. For more details, see [35].

Static analysis of query languages. XPath is arguably the most widely used XML query language as it is implemented in XSLT and XQuery and it is used as a constituent part of several specification and update languages. Hence in order to perform static analysis on a system manipulating XML data it is important to master the static analysis for XPath. Most of the important static analysis problems reduce to satisfiability checking: does a given query return a non-empty answer on some data. In general, in the presence of data values, the satisfiability of XPath is undecidable. We have shown that when restricted to its vertical navigational power, XPath becomes decidable [30].

5.2. Distributed data management

Participants: Serge Abiteboul, Emilien Antoine, Daniel Deutch, Alban Galland, Wojciech Kazana, Yannis Katsis, Luc Segoufin, Cristina Sirangelo.

Distributed knowledge base. As a foundation for managing distribution, we have proposed a model of a distributed knowledge base, that handles data and meta-data, as well as access control and localization, in a unique integrated setting. To support automatic reasoning on this knowledge base, we also introduced a novel rule-based language supporting the exchange of rules, namely Webdamlog. This work has been presented [21] and demonstrated [26] at major database conferences.

Probabilistic XML. Data from the Web are imprecise and uncertain. To manage this imprecision in a well-principled way, we have made significant advances in the field of probabilistic databases, and specifically, probabilistic XML. We have introduced new tractable probabilistic models for representing uncertain hierarchical information, and carried out in-depth studies of query evaluation, aggregation, and updates in various probabilistic XML models. These results have matured and some of the results are available in journal articles, e.g., [14].
Enumeration of query answers. In many applications the output of a query may have a huge size and enumerating all the answers may already consume too many of the allowed resources. In this case it may be appropriate to first output a small subset of the answers and then, on demand, output a subsequent small numbers of answers and so on until all possible answers have been exhausted. To make this even more attractive it is preferable to be able to minimize the time necessary to output the first answers and, from a given set of answers, also minimize the time necessary to output the next set of answers - this second time interval is known as the delay. We have shown that this was doable with a linear preprocessing time and constant enumeration delay for first-order queries over structures of bounded degree [19].

Data exchange and Web incomplete information. We have addressed the problem of restructuring data exchanged between communicating applications on the Web. We have proposed and analyzed a new language to specify data restructuring rules (schema mappings). This language generalizes existing mapping dependencies, by allowing a more flexible specification mechanism [20].

Jorge. We also invested a lot of effort in a textbook (undergraduate and graduate level) on Web data management (nicknamed Jorge) to be published at Cambridge University Press [38]. The book is already available on the Webdam Web site http://webdam.inria.fr/Jorge

5.3. Tree automata theory

Participants: Stéphane Demri, Florent Jacquemard, Luc Segoufin.

Most of our results for this section concern data words and data trees. Those are words and trees where each position contains a data value together with the classical label. Data trees can be seen as a model for XML data. We have studied automata model using registers or memory or allowing constraints that can involve data comparisons in its transitions.

Register Automata. These extend the classical model of finite automata with auxiliary registers storing data values for later comparison.

We have introduced a new model of automata over data trees and shown the decidability of its emptiness problem [30]. These automata were used for obtaining decidability results for the static analysis for some fragments of XPath presented in the previous section.

Automata with counters. In [39], a survey chapter on the verification of infinite-state systems is presented that is focused on the verification of counter systems. Verification problems for vector addition systems and recursive Petri nets are considered. Moreover, we introduce subclasses of counter systems for which reachability questions can be solved in Presburger arithmetic viewed as a means to symbolically represent sets of tuples of natural numbers.

Automata with isomorphism tests among subtrees. We have also considered some models described by tree automata enriched with a feature testing for isomorphisms between subtrees. Such constraints could be used for testing monadic key constraints over XML documents. For these models, the main challenge is to establish the decidability of the non-emptiness of the language specified by a given automaton [18].

Rewriting Controlled by Selection Automata. Motivated by the problem of static analysis of XML update programs, we have studied [33] the combination, called controlled term rewriting systems (CTRS), of term rewriting rules with constraints selecting the possible rewrite positions. These constraints are specified, for each rewrite rule, by a selection automaton which defines a set of positions in a term based on tree automata computations. We have established several decidability and complexity results for several cases of the reachability and regular model checking problems for this tree transformation formalism.
5. New Results

5.1. Co-Modeling for HP-SoC with MARTE

5.1.1. Diagonal mesh modeling with MARTE

As a continuation of this work on modeling at system level, a methodology for modeling concepts of NoC-based architectures is proposed especially the modeling of all kinds of topologies (regular, irregular or hierarchical) and routing algorithms. This contribution includes a VHDL code generation. On the other side we proposed a VLSI implementation of a new NoC topology called diagonal mesh that it designed to offer a good tradeoff between hardware cost and theoretical quality of service (QoS). This NoC is based on a new router architecture called FeRoNoC (Flexible, extensible Router NoC).

5.1.2. MARTE extension for reconfigurable hardware models

Reconfigurable System-on-Chip (RSoC), mainly FPGAs, offer several advantages such as flexibility, adaptivity and especially their capability to allow switching several implementations at run-time, i.e., PDR. PDR feature requires multiple run-time changes in RSoC such as:
- QoS factors: changes in executing functionalities due to designer requirements, or changes due to resource constraints of targeted hardware/platforms.
- The changes can also take place due to other environmental criteria such as communication quality, time and area consumed for reconfiguration and energy consumption.

In previous work [86], we provided an initial contribution to the modeling of these systems by extending UML MARTE profile to incorporate significant design criteria such as power consumption. Furthermore, high flexibility of RSoC implies high design complexity of the control of such system. This makes designing a robust control for managing reconfiguration a studious task. In [25], we present a high level design approach using UML MARTE for modeling dynamic reconfiguration controllers. Our proposed controller is based on distributed monitoring of runtime changes and distributed decision making. Our approach allows to increase flexibility and design reusability compared to centralized solution.

Indeed, in its current version, UML MARTE profile lacks dynamic reconfiguration concepts and requirements for the reconfiguration control mechanism. Even these later are necessary to model and implement rapid prototypes for complex systems. We can only model a state machine at high abstraction levels which is responsible for switching between the available configurations.

So we define a new design methodology using the proposed version of RecoMARTE (extended MARTE) to model PDR concepts at different abstraction levels, mainly architecture (structural and physical models) and allocation (software to Hardware allocation (Sw/Hw Allocate) and Hardware to Hardware allocation (Hw/Hw Allocate)). We also define necessary requirements for the reconfiguration control mechanism in order to manage reconfiguration at every design level. In addition, our solution allows to describe global contracts and constraints for combining automata. As future works, we plan to carry out model transformations to enable automatic code generation of configuration files. The code can then be used as input for commercial tools for final FPGA synthesis.

5.1.3. Comparaison of SAC and ArrayOL for parallelism expression

In this joint work with the University of Hertfordshire, we compare and analyze two such schemes. One of them is a domain-specific language, ArrayOL, to OpenCL. The other one is a transformation mechanism for mapping a image/signal processing transformation route for mapping a high-level general purpose array processing language, Single Assignment C (SaC) to CUDA. Using a real-world image processing application as a running example, we demonstrate that albeit the fact of being general purpose, the array processing language be used to specify complex array access patterns generically. Performance of the generated CUDA code is comparable to the OpenCL code created from domain-specific language.
5.1.4. Gaspard Modeling Improvements

Gaspard2 is the IDE proposed by the DaRT team. Its usage can be painful for beginners as well as for experts. We try to improve the usage of Gaspard in different ways:

- By allowing modifications at any model level, and let propagate the modifications to the higher and lower models (Amen Souissi).
- By providing missing diagrams in Papyrus (Amine El Kouen) By customizing the Gaspard User Interface (UI). Modeling in Gaspard is done with the Papyrus Modeler. We participate to the Papyrus development, which allow us to propose some customization tools. These later, are used to provide a modeling UI more adapted to embedded system co-modeling. This work is done by Rahma Yangui (INRIA engineer).
- By allowing to adapt dynamically the UML modeler environment according to the steps of the modeling process (Amine El Kouen’s thesis). This allows to guide the user in its development process, and to propose a simplified UI, oriented to the current development step.

Also, we have migrated from Papyrus I to Papyrus Eclipse.

5.2. Formal Methods for general-purpose and domain-specific languages

5.2.1. Formal Semantics for Domain Specific Modeling Languages

Domain-Specific Modelling Languages (DSMLs) are languages dedicated to modelling in specific application areas. Recently, the design of DSMLs has become widely accessible to engineers trained in the basics of Model-Driven Engineering (MDE): one designs a metamodel for the language’s abstract syntax; then, the language’s operational semantics is expressed using model transformations over the metamodel.

The democratisation of DSM design catalysed by MDE is likely to give birth to numerous languages. One can also reasonably expect that there shall be numerous errors in those languages. Indeed, getting a language right (especially its operational semantics) is hard, regardless of whether the language is defined in the modern MDE framework or in more traditional ones.

Formal approaches can benefit language designers by helping them avoid or detect errors. But, in order to be accepted by non-expert users, formal approaches have to operate in the background of a familiar language design process, such as the MDE-based one mentioned above.

In 2011 we have migrated from [21], which uses the general Maude semantic framework, towards using the more language-definition specific the K-semantic framework to formalise the basic MDE ingredients used in DSML definition: models, metamodels, and model transformations. We have implemented a prototype tool that takes as input any DSML described in using MDE, and generates formal K definitions for the language’s syntax, static semantics, and operational semantics. Since the definitions are executable, we get execution and formal verification engines for free [44]. A subproject of this work has been a formal definition for a substantial fragment of the OCL language [45].

5.2.2. A new abstraction for signal programs, and improvement of the compilation process

In this work we propose a sound abstraction for an efficient static analysis of synchronous programs describing multi-clock embedded systems in Signal. This abstraction combines the Boolean theory and numeric interval approximation to adequately address clock relations defined as combinations of logical and numerical expressions. Through a few examples, we show how the proposed solution is used to determine absence of reaction captured by empty clocks; mutual exclusion captured by two or more clocks whose associated signals never occur at the same time; or hierarchical control of component activations via clock inclusion. We also show this analysis improves the quality of the code generated automatically by the Signal compiler, e.g., a code with smaller footprint, or a code executed more efficiently thanks to optimizations enabled by the new abstraction [38].
5.2.3. Using bounded model checking to focus fixpoint iterations

Two classical sources of imprecision in static analysis by abstract interpretation are widening and merge operations. Merge operations can be done away by distinguishing paths, as in trace partitioning, at the expense of enumerating an exponential number of paths. In this article, we describe how to avoid such systematic exploration by focusing on a single path at a time, designated by SMT-solving. Our method combines well with acceleration techniques, thus doing away with widenings as well in some cases. We illustrate it over the well-known domain of convex polyhedra [40].

5.2.4. A formal definition of a compiler for the Kermeta metamodeling language in K

Kermeta [109] is a DSL designed as a kernel for metamodel engineering. It unifies metamodeling, constraints, semantics and transformation features into a statically typed language. It is object-oriented and allows for metamodeling features such as attributes, associations, and multiplicities. It also includes design-by-contract, aspect-oriented features, and genericity. This makes Kermeta a large and complex language: indeed, combining all these features into one language may easily lead to inconsistencies.

Christophe’s postdoctoral work, starting in September 2010, has been to formally specify Kermeta. He did so via a specification of compiler for Kermeta in K [117]. K formal specifications are executable, hence, Christophe’s compiler can be used to actually compile Kermeta programs. The compiler it completely self-contained and generates bytecode for an abstract machine also formally specified in K.

This work led to the discovery of several errors and inconsistencies in Kermeta’s manual and existing interpreter. The errors are reported to the Kermeta designers (Triskell project-team at Inria Rennes-Bretagne Atlantique), who, as it turns out, are also writing a compiler of Kermeta in the traditional, informal way. We are planning to make them benefit from the experience we gained in formal compilation.

5.2.5. A generic approach and tool for tracing executions back to a DSML’s operational semantics

Model-driven engineering allows users to define abstract syntaxes for their own DSMLs in terms of metamodels. Several approaches for defining operational semantics for DSMLs have also been proposed. These approaches allow, in principle, for model execution and for formal analyses of the DSMLs. However, most of the time, the executions/analyses are performed via transformations to other languages: code generation, resp. translation to the input language of a model checker. The consequence is that the results (e.g., a program crash log, or a counterexample returned by a model checker) may not be straightforward to interpret by the users of a DSML. We propose a formal and operational framework for tracing such results back to the original DSML’s syntax and operational semantics. We implement the approach in a generic tool written in Kermeta, and illustrated in on the xSPEM language, a timed language for expressing the execution of activities constrained by time, resources, and precedences [31].

5.3. Optimization and compilation techniques

5.3.1. Generated Code Optimization

Performing a model-to-source transformation, whereby a high-level language is mapped to CUDA or OpenCL, is an attractive option. In particular, it enables to harness the power of GPUs without any expertise on the GPGPU programming. In this work, we add a new compilation option for the Gaspar2 transformation chain: UM2OpenCL to detect shareable data zone. The tilers from ArrayOL, which allow express the data parallelism from repetitive tasks, are analyzed in time compilation to create areas of shared data. The identification of these areas is crucial to allow us loading data on shared areas of memory that have high throughput. Consequently, programs automatically generated shall have performances comparable to manually well written programs.
5.3.2. Methodology to generate OpenCL code from MARTE models

In order to reduce design complexity, we propose an approach to generate code for OpenCL API, an open standard for parallel programming of heterogeneous systems. This approach is based on Model Driven Engineering (MDE) and Modeling and Analysis of Real-Time and Embedded Systems (MARTE) standard proposed by Object Management Group (OMG). The aim is to provide resources to non-specialist in parallel programming to implement their applications. Moreover, concepts like reuse and platform independence are present. Since we have designed an application and execution platform architecture, we can reuse the same project to add more functionalities and/or change the target architecture. Consequently, this approach helps industries to achieve their time-to-market constraints. The resulting code, for the host and compute devices, are compilable source files that satisfy the specifications defined on design time.

5.3.3. Profiling into Models

Regarding the models fine tuning, we propose integrating software-profiling results to higher-level specification models [56]. The aim is to optimize the models and, consequently, the generated code. The model optimization approach relies on the Gaspard2 branch dedicated to code generation for OpenCL and GPUs [58]. We offer software execution feedback, based on models transformation traceability [75], to model designers. These feedbacks enable the designers to tune their models in order to improve the software performances even if they do not have in-depth knowledge on the running platform (GPU). First, the code is generated from a first designed model using Gaspard2. The resulting code is then executed within an existing profiling environment. Afterwards, profiling results are delivered directly to designer as annotations in the model. Basically, we move up two types of information, using traceability. The first type directly results from the profiler, e.g. processor occupancy, onto specific regions in the model, enlightening the regions that requires tuning. The second type correspond to results of an expert system analysis that we provide. Information of this second type is delivered to designers as advices in the model annotations. The expert system generates these advices from platform features and running results. For example, it can suggest changing the shape of a task in order to optimize the processor occupancy. The more we feed the knowledge base and engine of the expert system, the more it is able to give better advices.

The model optimization relies on the hypothesis that the high level models are error free. Since these models are complex, it is difficult for the designers to conceive them correctly the first time. We propose a new approach, enabling the model designer to debug its models. For this purpose, we offer a quick and automatic code instrumentation to the model designer. As for the model optimisation, we take advantage of the model transformation traceability to keep the link between models and software execution and to provide execution information feedback. Hence, the information produced in the running environment during the software execution is moved up directly onto the models, allowing the model designers verifying the behavior of their software, directly on the high level models.

5.3.4. Static Analysis of Polychronous Specifications with SMT Theory

As opposed to single clocked synchronous programming paradigms, polychronous formalism allows specification of concurrent data flow computation on signals such that various data flows can evolve asynchronously with respect to each other. We formulated the clock analysis in Signal compilation [38] and the detection of false loops in MRICDF as a decision problem in Satisfiability Modulo Theory (SMT) [30][59]. Due to recent interests in SMT solvers, a number of efficient solvers are available which offer a greater expressiveness in dealing with non Boolean constraints and allow us to discern false loops from realizable causalities in reasonable computation time. We demonstrated that several polychronous specifications rejected by current compilers due to their inability to identify only true causal loops, can be synthesized as correct sequential embedded software.

5.3.5. Programming functional and real-time aspects simultaneously

An embedded system is usually required to respect real-time constraints related to physical constraints, either those of its environment or those of the physical devices it controls. First, it is often multi-periodic since its devices have different physical characteristics and must therefore be controlled at different rates. Second,
the system must respect deadline constraints, which may correspond for instance to a maximum end-to-end latency requirement between observations (inputs) and the corresponding reactions (outputs). A correct implementation must respect all the real-time constraints and must also be functionally deterministic, meaning that the outputs of the system are always the same for a given sequence of inputs. Current practice often deals with this two aspects separately, while our objective is to deal with them simultaneously.

To this intent, we must first introduce real-time primitives at the programming language level. We carried on previous work on the PRELUDE language [19], which provides such primitives in a synchronous data-flow language. We produced a complete end-to-end framework for the design and the implementation of embedded systems on a symmetric multicore: the PRELUDE-SCHEDCORE toolset [32]. We recently started a Master research project to study how real-time aspects could be introduced in more traditional programming paradigms with the SCALA a language.

The PRELUDE compiler translates a program into a set of dependent periodic tasks. We proposed a new dynamic priority-based scheduling policy capable of dealing with the extended precedence constraints (constraints between tasks of different periods) of such systems in [36], [48].

Finally, as PRELUDE's semantics defines formally both the functional and the temporal behaviour of a system, we studied temporal formal verification in [46].

5.3.6. Chaining Localized Model Transformation

Usually, two transformations can only be chained if the output metamodel of the first one is included into the input metamodel of the second one. This compliance issue forces to design either tailored fine-grain model transformations for a dedicated chain or large and complex transformations. In both cases, transformations are not reusable and hardly maintainable.

In order to solve this problem, we have introduced localized transformations which apply to a (typically very small) subset of an input metamodel of a transformation. Each localized transformation is designed and implemented to accomplish a specific transformation task, and involves and is applicable to a few concepts. The input and output metamodels of these transformations are not disjoint contrarily to traditional transformations; new chaining constraints have to be defined. We have thus defined new chaining constraints based on a type analysis to specify when two transformations can be chained in one, both or any order [96]. In some cases, this analysis concludes that the transformations can be chained in both order but with some input models, the two output models resulting of the two chaining, are not the same. We have introduce an intermediary abstraction level independent of any transformation language that focuses on read, modified, created and deleted metaelements. We are pursuing our investigations with this new abstraction level.

5.4. Green computing on SoC

5.4.1. Correct and Energy-Efficient Design of a Multimedia Application on SoC

We studied the design and analysis of multimedia applications such as the JPEG encoder on multiprocessor architectures [55] [24] [13]. A model-based approach was adopted by using the UML Marte specifications [54]. An abstract clock analysis has been proposed to deal with the correctness of system behaviors and to find the most suitable execution platform configurations regarding performance and energy consumption. Our approach offers a rapid and reliable design space analysis, which is crucial when implementing complex systems [37].

5.4.2. Design Space Exploration for Efficient Data Intensive Computing on SoCs

Finding efficient implementations of data intensive applications, such as radar/sonar signal and image processing, on a system-on-chip is a very challenging problem due to increasing complexity and performance requirements of such applications. One major issue is the optimization of data transfer and storage micro-architecture, which is crucial in this context. We proposed a comprehensive method to explore the mapping of high-level representations of applications into a customizable hardware accelerator [52]. The high-level representation is given in a language named Array-OL. The customizable architecture uses FIFO queues and
a double buffering mechanism to mask the latency of data transfers and external memory access. The mapping of a high-level representation onto a given architecture is achieved by applying loop transformations in Array-OL. A method based on integer partition is used to reduce the space of explored solutions. Our proposition aims at facilitating the inference of adequate hardware realizations for data intensive applications. It is illustrated on a case study consisting in implementing a hydrophone monitoring application.

5.4.3. Power Estimation

Within the context of the OPEN-PEOPLE project, we aim at addressing the power estimation challenges of embedded system design with a new approach, combining Functional Level Power Analysis with advanced SystemC – Transaction Level Modeling (TLM) simulation techniques, in order to formally prove qualitative and quantitative properties of the final system power estimation. This approach requires the construction of a power models from FLPA for different embedded boards (FPGA and ASIC) and building up system level simulation environment for the analysis of power model and proofs of properties of the simulated system [42].

As a main contribution, we propose a new hybrid system-level power consumption estimation methodology for complex embedded systems [41]. A key word in our contribution is hybridization between abstraction levels. Almost all the previous studies focus on power estimation for a given abstraction level without overcoming the wall of speed/accuracy trade-off. The idea here is to build up a hybrid power estimation tool that combines Functional Level Power Analysis (FLPA) for hardware power modeling and Transactional Level Modeling (TLM) simulation technique for rapid system prototyping and fast power estimation. Basically, the FLPA is used for processor power modeling. In the frame of this work, it will be extended to cover the other hardware components used in the MultiProcessor System-on-Chip (MPSoC) such as the memory and the reconfigurable logic. After that, we go further in terms of scalability to target heterogeneous multiprocessor architectures. The functional power estimation part is coupled with a fast SystemC simulator in order to obtain the needed micro-architectural activities for power models, which allows us to reach a superior bargain between accuracy and speed [43].

5.5. Dynamic reconfiguration for HP-SoC

5.5.1. Context switching for volatile IP

Dynamic reconfigurations require configuration decisions from smart controllers. Such a decision implies context saving of an existing IP or switching from an IP to another (loading a new bitstream). The store/restore operations can be managed by the operating system or by using a dedicated hardware component. In this work, a new model for hardware IP context storage and management is proposed. The approach is based on a flexible hardware wrapper which can make IP reconfigurable. In fact, these wrappers contain a naming system supporting efficient runtime context switching.

5.5.2. A generic broadcast network for HP-SoC architecture

The hNoC model proposes a specific network on chip dedicated to the massively parallel architecture SCAC. This model is composed of huge number of complex routers, called node elements (the NEs), communicating and working in perfect synchronizations. Each NE is potentially connected to its neighbors via a regular connection. Furthermore, each NE is connected to a heterogeneous set of computing groups (clusters) allow asynchronous processing. Each group includes a combination of processors programmable, the PEs (software processing units) and specialized hardware accelerators (hardware processing units) to perform critical tasks demanding the more performance. All the system is controlled by a Network Controller Unit, the NCU. The NCU and The PEs are implemented with the Forth processor.

The aim of our works is to design a new kind of communication network model for SCAC architecture to overcome firstly the overlapping communications with computations and secondly to increase significantly the external performances in terms of throughput. The difficulty of designing hNoC is a compromise between an optimal quality of broadcasting, high bandwidth and important flexibility of use, while reducing power consumption and silicon area.
Our first contributions defined a broadcast with mask model integrated in the communication network hNoC of SCAC architecture. This model is based on subnetting the network of processing nodes which separate the control of communication and processing. Our model was implemented in synthesizable VHDL code that is simulated and targeted Xilinx Virtex6 (XC6VLX240T) board.

5.5.3. Distributed control for dynamic reconfiguration

The aim of our current work is to propose a distributed approach for reconfiguration control on FPGAs. The main reason for choosing a distributed control approach is that, with the ever growing complexity and size of the modern reconfigurable systems, the traditional centralized approach is no more efficient. Instead, a distributed control has many advantages in terms of performance and design efficiency. Indeed, the distributed control allows to avoid communication bottlenecks and to increase the parallelism compared to the centralized one, allowing a better performance which is a critical issue especially for high-performance applications. At the design level, the distributed control has many advantages. It allows to decrease the design complexity of the control by dividing the intelligence between the controllers, which allows a shorter design time and an easier verification. It also facilitates the reuse of the controllers instead of redesigning a centralized controller for different systems, which allows also a higher scalability in order to adapt to the growing size of the modern SoC. Our approach for reconfiguration control is an event-driven control, where events come from a variety of sources in order to ensure a high adaptivity of the reconfigurable systems. Reconfiguration can be triggered by a user input, a change in the environment condition (e.g. changes in lightening condition) or a change in performance or power consumption requirements, etc. Therefore, we propose a modular structure of each controller allowing three major tasks: monitoring, decision making and reconfiguration realization. In order to respect the global constraints of the system, the controllers communicate their decisions to each other in order to handle cooperation and conflicts. In [25], we proposed a high-level design of our approach using Model Driven Engineering aiming to combine the advantages of the distributed control with the high-level design in order to decrease design complexity and automate code generation increasing thus design productivity.

At the physical level, the distributed control has been implemented for simple applications in order to test the different modules of the controllers (monitoring, decision making, communication between controllers). As a future work, we plan to implement the distributed control for more complex applications in order to highlight the advantages of our approach and study its limits.

5.5.4. Avionic test bench on heterogeneous reconfigurable platform

The aim goal of this thesis is to design the next Eurocopter avionic test bench generation. For the past 20 years, Test Systems have always be considered as a must do in the avionic development cycle. In early 2008, the Eurocopter research department has undertaken a profound reflection on the vocation Pro-Active Test Systems [15]. Hitherto, the test systems were based on real time specific CPU boards that run proprietary real time operating systems and plugged with Input/Output (I/O) boards to communicate with the equipments under test. In current industrial practice, the well-spread VME CPU boards are widely used. Due to the present test system performance requirement, an increase in the computation rates is needed, but it cannot be delivered by the VME CPU boards any-more. Furthermore, this solution is considered as an expensive maintainable technology. To overcome these drawbacks, the usage of multicore hosts (PC or workstation) allows an immediate increase in the capacity of computation. An important outcome of this transition is the refusal of the obsolete CPU boards. However, this solution cannot guarantee the real-time criteria while the execution of concurrent tasks due to the lack of an appropriate Operating System (OS) environment. In addition, this solution brings new communication latencies between the CPUs and I/O boards plugged in the VME backplane. In this work, our proposal is to make profit from the new available hardware computing resource (FPGA) and to make up hybrid avionic test systems [27]. Indeed, FPGA technology could offer a higher computation rates comparing to CPUs up to 10x. It could implement heavy models in a hardware fashion with the management of the parallelism degree to answer the real-time constraints of the application. The main challenge of hybrid (CPU/FPGA) architectures concerns the programming model and the design methodology. We need to deal with the heterogeneity of both hardware and software parts in order to obtain a fast system prototyping. In current industrial practice, manual coding is still widely adopted in the development of hybrid architectures, which is clearly not suited to manage the complexity intrinsic in these systems. For designers,
this approach is very tedious, error-prone and expensive. In the first part of our work we emphasized the usage of Model Driven Engineering (MDE) for heterogeneous systems in order to reduce the design complexity of CPU-FPGA architectures [72]. In ReCoSoC paper, we focused on the prototyping environment and the related development tools in order to map existing software into CPU-FPGA architectures by detecting all data dependencies and get the parallelism degree. Moreover, we presented communication solutions comparing fast links such as Ethernet and PCIe. Secondly Multi-Core optimizations in different environments such as Linux with Open Source real-time patches (Xenomai) and processor affinities capabilities. Then, we presented in [28] a new generation of adaptive and generic avionic test benches using FPGA reconfigurability capabilities. Indeed, nowadays, each Eurocopter test bench is related to a specific embedded part and a specific aircraft. Proposing such generic architecture will reduce the helicopter design cycle significantly by Testing different embedded systems at the same time.

5.6. Application case-studies

5.6.1. Experimentations for electromagnetism simulations

The electrical and electronic engineering has used parallel programming to solve its large scale complex problems for performance reasons. However, as parallel programming requires a non-trivial distribution of tasks and data, developers find it hard to implement their applications effectively. Thus, we used our approach, based on Model Driven Engineering (MDE) and the MARTE profile, to generate code for a sparse solver and achieve a good speed-up. Moreover, thanks to model reuse capacity, we can add/change functionalities or the target architecture and still keep a good scalability.

5.6.2. H.264 modeling on NoC, implementation and synthesis

In addition, the H.264 coder is modeled using MARTE profile and a hardware description for all components is proposed, particularly the Motion Estimation (ME), adopts many new features to increase the coding performance such as block matching algorithm, motion vector prediction, variable block size motion estimation, etc. However, VBSME is utilized in the MPEG4-AVC/H.264 standard which leads to a higher computational complexity and a higher data dependence that makes the hardware implementation very complex. The aim of our work is to propose a VLSI architecture for full-search VBSME (FSVBSME). This contribution allows the reusing smaller sub-blocks for the computation results, sharing sub-blocks comparator and offering low power consumption.

5.7. Axellience

Based on the good results of the localized transformations coupled with MDFactory in Gaspard in term of reusability, modifiability and understandability, Alexis Muller (Expert Engineer) decided to study the opportunity to create a start-up company from these works. Due to his past experiment in the domain of information system and the maturity of the model usage by the enterprises, the idea was to target the automatic generation of information system from UML model and no more to address embedded systems. Joined by Thomas Legrand (Software Engineer), they developed new localized transformations and new chains. The results and the first feed-backs from enterprises in the domain of information systems are very encouraging. Furthermore, the Axellience project has win the national competitive examination of helping to the creation of innovating enterprises (Oseo). A technological transfer concerning MDFactory is foreseen between the DaRT team and the Axellience project in order to create the start-up company in the early beginning of the 2012 year. Straight collaborations between the company and the DaRT team should continue via the works around localized transformations.
6. New Results

6.1. Sampling methods for inverse scattering problems

6.1.1. Sampling methods with time dependent data

Participants: Houssem Haddar, Armin Lechleiter, Simon Marmorat.

We considered the extension of the so-called Factorization method to far-field data in the time domain. For a Dirichlet scattering object and incident wave fronts, the inverse problem under investigation consists in characterizing the shape of the scattering object from the behaviour of the scattered field far from the obstacle (far-field measurements). We derive a self-adjoint factorization of the time-domain far-field operator and show that the middle operator of this factorization possesses a weak type of coercivity. This allows to prove range inclusions between the far-field operator and the time-domain Herglotz operator.

We also extended the near-field version of the linear sampling method to causal time-dependent wave data for smooth, band-limited incident pulses, considering different boundary conditions as for instance Dirichlet, Neumann or Robin conditions [27].

6.1.2. Inverse problems for periodic penetrable media

Participants: Armin Lechleiter, Dinh Liem Nguyen.

Imaging periodic penetrable scattering objects is of interest for non-destructive testing of photonic devices. The problem is motivated by the decreasing size of periodic structures in photonic devices, together with an increasing demand in fast non-destructive testing. In this project, linked to the thesis project of Dinh Liem Nguyen, we considered the problem of imaging a periodic penetrable structure from measurements of scattered electromagnetic waves. As a continuation of earlier work, we considered an electromagnetic problem for transverse magnetic waves (earlier work treats transverse electric fields), and also the full Maxwell equations. In both cases, we treat the direct problem by a volumetric integral equation approach and construct a Factorization method.

6.1.3. Inverse problems for Stokes-Brinkmann flows

Participants: Armin Lechleiter, Tobias Rienmüller.

Geometric inverse problems for flows arise for instance when controlling pipelines and oil reservoirs. In this project, we considered the Stokes-Brinkmann equations that model, for instance, porous penetrable inclusions in a free background. The factorization method is able to characterize the inclusions from the relative Dirichlet-to-Neumann operator. Numerical examples show the feasibility of the method.

6.1.4. Inverse scattering from screens with impedance boundary conditions

Participants: Yosra Boukari, Houssem Haddar.

We are interested in solving the inverse problem of determining a screen (or a crack) from multi-static measurements of electromagnetic (or acoustic) scattered field at a given frequency. An impedance boundary condition is assumed to be verified at both faces of the screen. We extended the so-called factorization method to this setting. We also analyzed a data completion algorithm based on integral equation method for the Helmholtz equation. This algorithm is then coupled to the so-called RG-LSM algorithm to retrieve cracks inside a locally homogeneous background. This work is conducted in collaboration with F. Ben Hassen.

6.1.5. Transmission Eigenvalues and their application to the identification problem

Participants: Anne Cossonnière, Houssem Haddar, Giovanni Giorgi.
The so-called interior transmission problem plays an important role in the study of inverse scattering problems from (anisotropic) inhomogeneities. Solutions to this problem associated with singular sources can be used for instance to establish uniqueness for the imaging of anisotropic inclusions from muti-static data at a fixed frequency. It is also well known that the injectivity of the far field operator used in sampling methods is equivalent to the uniqueness of solutions to this problem. The frequencies for which this uniqueness fails are called transmission eigenvalues. We are currently developing approaches where these frequencies can be used in identifying (qualitative informations on) the medium properties. Our research on this topic is mainly done in the framework of the associate team ISIP http://www-direction.inria.fr/international/PHP/Networks/LiEA.php with the University of Delaware. A review article on the state of art concerning the transmission eigenvalue problem has been written in collaboration with F. Cakoni [24].

The main topic of the PhD thesis of A. Cossonnière is to extend some of the results obtained above (for the scalar problem) to the Maxwell’s problem. In this perspective, theoretical results related to solutions of the interior transmission problem for medium with cavities and existence of transmission eigenvalues have been obtained [14]. This work is then extended to the case of medium with perfectly conducting inclusions. Only the scalar case has been studied [35]. In collaboration with M. Fares and F. Collino from CERFACS we investigated the use of a surface integral equation approach to find the transmission eigenvalues for inclusions with piecewise constant index. The main difficulty behind this procedure is the compactness of the obtained integral operator in usual Sobolev spaces associated with the forward scattering problem. We solved this difficulty by introducing a preconditioning operator associated with a “coercive” transmission problem. The obtained procedure has been validated numerically in 2D and 3D cases. We also analyzed the transmission eigenvalue problem using this surface integral equation approach. This technique allowed us to generalize discretness results on the spectrum to cases where the contrast can change sign [2].

With G. Giorgi, we developed a method that give estimates on the material properties using the first transmission eigenvalue. This method is based on reformulating the interior transmission eigenvalue problem into an eigenvalue problem for the material coefficients. We validated our methodology for homogeneous and inhomogeneous inclusions and backgrounds. We also treated the case of a background with absorption and the case of scatterers with multiple connected components of different refractive indexes [26].

6.1.6. The factorization method for EIT with inhomogeneous background

Participants: Giovanni Migliorati, Houssem Haddar.

We developed a numerical inversion scheme based on the Factorization Method to solve the (continuous model of) Electrical Impedance Tomography problem with inhomogeneous background. The numerical scheme relies on the well chosen approximation by the finite element method of the solution to the dipole-like Neumann boundary-value problem. Two regularization techniques are tested, i.e. the Tikhonov regularization embedding Morozov principle, and the classical Picard Criterion. The numerical analysis of the method and the results obtained are presented in the INRIA report [28].

6.2. Iterative Methods for Non-linear Inverse Problems

6.2.1. Inverse medium problem for axisymmetric eddy current models

Participants: Houssem Haddar, Zixian Jiang, Armin Lechleiter.

We are interested in shape optimization methods for inclusion detection in an axisymmetric eddy current model. This problem is motivated by non-destructive testing methodologies for steam generators. We investigated the validity of the eddy current model for these kinds of problems and developed numerical methods for the solution of the direct problem in weighted Sobolev spaces. Then we computed the shape derivative of an inclusion which allows to use regularized iterative methods to solve the inverse problem [23]. We also develop asymptotic models to identify thin highly conducting deposits.

6.2.2. Hybrid methods for inverse scattering problems

Participants: Grégoire Allaire, Houssem Haddar, Dimitri Nicolas.
It is well admitted that optimization methods offer in general a good accuracy but are penalized by the cost of solving the direct problem and by requiring a large number of iterations due to the ill-posedness of the inverse problem. However, profiting from good initial guess provided by sampling methods these method would become viable. Among optimization methods, the Level Set method seems to be well suited for such coupling since it is based on capturing the support of the inclusion through an indicator function computed on a cartesian grid of probed media. Beyond the choice of an optimization method, our goal would be to develop coupling strategies that uses sampling methods not only as an initialization step but also as a method to optimize the choice of the incident (focusing) wave that serves in computing the increment step.

We investigated a coupling approach between the level set method and LSM where the initialization is done using a crude estimate provided by the linear sampling method. The obtained results validate the efficiency of this coupling in the case of simply and multiply connected obstacles that are well separated.

### 6.3. Shape and topology optimization

#### 6.3.1. Incorporating manufacturing constraints in topology optimization

**Participant:** Grégoire Allaire.

With G. Michailidis and F. Jouve we study how to incorporate manufacturing constraints in topology optimization of structures using the level set method. The goal is to obtain a structure with optimal mechanical behaviour, which at the same time respects some predefined constraints imposed by the fabrication process. In this way, the final optimal shape is manufacturable and thus the method of shape and topology optimization turns to be industrially applicable.

The first constraints we have tackled are related to the limits of thickness a structure is forced to respect. We need to avoid optimal shape that contain very thin or thick members or even members that are very close between them. To achieve this, we have adopted two different approaches, a geometrical and a mechanical one. In the geometrical one, we have made extensive use of the notion of the signed-distance function to a domain. We have formulated a global constraint which guarantees that, at the end of the optimization process, the optimal structure respects the thickness limits. In the mechanical approach, we have tried to simulate the solidification process of a structure constructed via casting. We have set a time contraint, i.e. we have required that the structure cools earlier than some predefined time limit. We have started working on a more complicated thermal equation, a non-linear model with phase change, in order to describe more accurately the solidification process.

#### 6.3.2. Optimization of composite materials draping

**Participant:** Grégoire Allaire.

With G. Delgado we work on the optimization of composite materials draping. These composite structures are constructed by lamination of a sequence of unidirectional reinforced layers or plies. Each ply is typically a thin sheet of carbon fibers impregnated with polymer matrix material. The optimization variables are the geometries of these layers and they are parameterized by a level set function. In a first instance, we treat the problem of mass minimization (with a constraint on the maximal compliance) for a cantilever type composite structure, laminated with four layers of a given orthotropic material at different angles. The elasticity analysis is performed with the software Freefem++, coupled with a C++ routine to solve, by a finite difference scheme, the evolution of the level sets.

#### 6.3.3. A hybrid optimization method

**Participant:** Grégoire Allaire.
With Ch. Dapogny and P. Frey we develop a new method of geometric optimization for structures that relies on two alternative descriptions of shapes: on the one hand, they are exactly meshed so that mechanical evaluations by finite elements are accurate; on the other hand, we resort to a level-set characterization to describe their deformation along the shape gradient. The key ingredient is a meshing algorithm for building a mesh, suitable for numerical computations, out of a piecewise linear level-set function on an unstructured mesh. Therefore, our approach is at the same time a geometric optimization method (since shapes are exactly meshed) and a topology optimization method (since the topology of successive shapes can change thanks to the power of the level-set method). Our first results in 2-d have been announced. We continue to work on the 3-d case.

6.3.4. DeHomogenization

Participant: Olivier Pantz.

In most shape optimization problems, the optimal solution does not belong to the set of genuine shapes but is a composite structure. The homogenization method consists in relaxing the original problem thereby extending the set of admissible structures to composite shapes. From the numerical viewpoint, an important asset of the homogenization method with respect to traditional geometrical optimization is that the computed optimal shape is quite independent from the initial guess (even if only a partial relaxation is performed). Nevertheless, the optimal shape being a composite, a post-treatment is needed in order to produce an almost optimal non-composite (i.e. workable) shape. The classical approach consists in penalizing the intermediate densities of material, but the obtained result deeply depends on the underlying mesh used and the details level is not controllable. We proposed in [40] a new post-treatment method for the compliance minimization problem of an elastic structure. The main idea is to approximate the optimal composite shape with a locally periodic composite and to build a sequence of genuine shapes converging toward this composite structure. This method allows us to balance the level of details of the final shape and its optimality. Nevertheless, it was restricted to particular optimal shapes, depending on the topological structure of the lattice describing the arrangement of the holes of the composite. We lifted this restriction in order to extend our method to any optimal composite structure for the compliance minimization problem in [39]. Since, the method has been improved and a new article presenting the last results is in preparation. Moreover, we intend to extend this approach to other kinds of cost functions. A first attempt, based on a gradient method, has been made. Unfortunately, it was leading to local minima. Thus a new strategy has to be worked out. It will be mainly based on the same ideas than the one developed for the compliance minimization problem, but some difficulties are still to be overcome.

6.3.5. Level-Set Method

Participant: Olivier Pantz.

We have begin to work, with Gabriel Delagado, on a new level-set optimization method, based on a gradient method. The key idea consists in computing directly the derivative of the discretized cost functions. The main advantage is that it is usually more simple to implement than the standard approach (consisting in using a discretized version of the gradient of the cost function). Moreover, the results obtained are as good or even better than the one obtained in previous works. Nevertheless, this method has its drawbacks, since the cost function is only derivable almost everywhere (the zero level-set has to be transverse to the triangulation of the mesh). It follows that convergence toward the minimum by the gradient method is not granted. To overcome this problem, we intend to use a mix-formulation for the state function. An article is in preparation on this subject.

6.3.6. Robust Optimization

Participant: Olivier Pantz.

One of the main problem in shape optimization problems is due to the fact that the gradient is never computed exactly. When the current solution is far from a local optimum, this is not a problem: even a rough approximation of the gradient enable us to exhibit a descent direction. On the contrary, when close to a local optimum, a very precise computation of the gradient is needed. We intend, with G. Delgado, to use a-posteriori error estimates evaluate the errors made on the computation of the gradient and to ensure that at each step, a genuine descent direction is used in the gradient method.
6.3.7. Optimization of a sodium fast reactor core

Participants: Grégoire Allaire, Olivier Pantz.

In collaboration with D. Schmidt, G. Allaire and E. Dombre, we apply the geometrical shape optimization method for the design of a SFR (Sodium Fast reactor) core in order to minimize a thermal counter-reaction known as the sodium void effect. In this kind of reactor, by increasing the temperature, the core may become liable to a strong increase of reactivity $\rho$, a key-parameter governing the chain-reaction at quasi-static states. We first use the 1 group energy diffusion model and give the generalization to the 2 groups energy equation. We then give some numerical results in the case of the 1 group energy equation. Note that the application of our method leads to some designs whose interfaces can be parametrized by very smooth curves which can stand very far from realistic designs. We don’t explain here the method that it would be possible to use for recovering an operational design but there exists several penalization methods that could be employed to this end. This work was partially sponsored by EDF. Our results will be published in the proceedings of the CEMRACS’11, during which part of the results have been obtained.

6.4. Asymptotic models

6.4.1. Inverse scattering problem for coated obstacles

Participants: Nicolas Chaulet, Houssem Haddar.

In collaboration with L. Bourgeois, we considered the inverse scattering problem consisting in the identification of both an obstacle and its “equivalent impedance” from farfield measurements at a fixed frequency. The first specificity of this work is to consider the cases where this impedance is not a scalar function but a second order surface operator. The latter can be seen as a more general model for effective impedances and is for instance widely used for scattering from thin coatings. The second specificity of this work is to characterize the derivative of a least square cost functional with respect to this complex configuration. We provide in particular an extension of the notion of shape derivative to the cases where the impedance parameters cannot be considered as the traces of given functions. For instance, the obtained derivative does not vanish (in general) for tangential perturbations. The efficiency of considering this type of derivative is illustrated by some 2D numerical experiments based on a (classical) steepest descent method. The feasibility of retrieving both the obstacle and the impedance functionals is discussed in further numerical experiments [33].

6.4.2. Interface conditions for thin dielectrics

Participant: Houssem Haddar.

Jointly with B. Delourme and P. Joly we established transmission conditions modelling thin interfaces that has (periodic) rapid variations along tangential coordinates. Motivated by non destructive testing experiments, we considered the case of cylindrical geometries and time harmonic waves. We already obtained a full asymptotic description of the solution in terms of the thickness in the scalar case using so called matched asymptotic expansions. This asymptotic expansion is then used to derive generalized interface conditions and establish error estimates for obtained approximate models [15]. The analysis of the approximate problem for Maxwell’s equations is the subject of a forthcoming publication.

6.4.3. Homogenization

Participant: Grégoire Allaire.

With I. Pankratova and A. Piatnitski we considered the homogenization of a non-stationary convection-diffusion equation posed in a bounded periodic heterogeneous domain with homogeneous Dirichlet boundary conditions. Assuming that the convection term is large, we give the asymptotic profile of the solution and determine its rate of decay. In particular, it allows us to characterize the “hot spot”, i.e., the precise asymptotic location of the solution maximum which lies close to the domain boundary and is also the point of concentration. Due to the competition between convection and diffusion, the position of the “hot spot” is not always intuitive as exemplified in some numerical tests.
With Z. Habibi we studied the homogenization of heat transfer in periodic porous media where the fluid part is made of long thin parallel cylinders, the diameter of which is of the same order than the period. The heat is transported by conduction in the solid part of the domain and by conduction, convection and radiative transfer in the fluid part (the cylinders). A non-local boundary condition models the radiative heat transfer on the cylinder walls. To obtain the homogenized problem we first use a formal two-scale asymptotic expansion method. The resulting effective model is a convection-diffusion equation posed in a homogeneous domain with homogenized coefficients evaluated by solving so-called cell problems where radiative transfer is taken into account. In a second step we rigorously justify the homogenization process by using the notion of two-scale convergence. One feature of this work is that it combines homogenization with a 3D to 2D asymptotic analysis since the radiative transfer in the limit cell problem is purely two-dimensional. Eventually, we provide some 3D numerical results in order to show the convergence and the advantages of our homogenization method.

6.4.4. Modelling and simulation for underground nuclear waste storage.

Participants: Grégoire Allaire, Harsha Hutridurga.

In the framework of the GDR MOMAS (Groupement de Recherches du CNRS sur les MOdélisations MAthématiques et Simulations numériques liées aux problèmes de gestion des déchets nucléaires) I am working with R. Brizzi, H. Hutridurga, A. Mikelic and A. Piatnitski on upscaling of microscopic models by homogenization (i.e. finding macroscopic models and effective coefficients).

We studied the Taylor dispersion of a contaminant in a porous medium. The originality of the model is that it takes into account surface diffusion and convection on the pores boundaries. We rigorously obtained the homogenized equation and studied the behavior of the effective dispersion tensor when varying various parameters.

In collaboration with a team of chemists (around J.-F. Dufrêche from the GNR Paris), we have undertaken the rigorous homogenization of a system of PDEs describing the transport of a N-component electrolyte in a dilute Newtonian solvent through a rigid porous medium. The motion is governed by a small static electric field and a small hydrodynamic force, which allowed us to use O’Brien’s linearized equations as the starting model. Convergence of the homogenization procedure was established and the homogenized equations were discussed. Based on the rigorous study of the underlying equations, it was proved that the effective tensor satisfies Onsager properties, namely is symmetric positive definite. This result justified the approach of many authors who used Onsager theory as a starting point.

6.4.5. A new membrane/plate modeling

Participant: Olivier Pantz.

Using a formal asymptotic expansion, we have proved with K. Trabelsi, that non-isotropic thin-structure could behave (when the thickness is small) like a shell combining both membrane and bending effects. It is the first time to our knowledge that such a model is derived. An article on this project is in preparation.

6.4.6. A new Liouville type Rigidity Theorem

Participant: Olivier Pantz.

We have recently developed a new Liouville type Rigidity Theorem. Considering a cylindrical shaped solid, we prove that if the local area of the cross sections is preserved together with the length of the fibers, then the deformation is a combination of a planar deformation and a rigid motion. The results currently obtained are limited to regular deformations and we are currently working with B. Merlet to extend them. Nevertheless, we mainly focus on the case where the conditions imposed to the local area of the cross sections and the length of the fibers are only "almost" fulfilled. This will enable us to derive rigorously new non linear shell models combining both membranar and flexural effects that we have obtained using a formal approach.

6.4.7. Lattices

Participant: Olivier Pantz.
With A. Raoult and N. Meunier (Université Paris Descartes), we have compute the asymptotic limit of a square lattice with three-points interactions. An article currently under review has been submitted on this work.

**6.4.8. Homogenization of axon Bundles**

**Participant:** Olivier Pantz.

With E. Mandonnet (Lariboisière Hospital), we have developed a new modeling for bundles of axons using homogenization technique. Previous works only focus (even if not explicitly) in the low density case: That is when the axon density is small. The aim is to determine which kind of electrical stimulation could trigger a signal into the axon. Under the low density assumption, the external electric field is independent of the membrane potential of the axon. If not, both are strongly coupled. Moreover, we have performed numerical simulations to determine what is the best position of the electrodes to enable the activation of the axons. This work has lead to the publications of an article [20] and a technical report [29]. Finally, we have begin to investigate more realistic modelings of the ionic flux based on the works of FitzHuch-Nagumo with a student, Xinxin Cheng, who spend three months at the CMAP.

**6.5. Diffusion MRI**

**6.5.1. Homogenized diffusion tensor and approximate analytical formulae for the long time ADC**

**Participants:** Jing-Rebecca Li, Houssem Haddar.

We model the bulk magnetization in biological tissue due to a diffusion gradient at the voxel level by a two compartment Bloch-Torrey partial differential equation. The cell membranes are modelled as infinitely thin permeable interfaces. We show the simulated long time apparent diffusion tensor of the PGSE sequence is close to the effective diffusion tensor from homogenization theory for both isotropic and anisotropic diffusion. For nearly isotropic diffusion we give analytical approximate formulae for the long time apparent diffusion coefficient in two and three dimensions. The approximate formulae allow us to robustly estimate the change in the cellular volume fraction from ADC measurements before and after cell swelling if the cells are approximately uniform in size. We can also use the formulae to estimate the average cell size.

**6.5.2. General ODE model of diffusion MRI signal attenuation**

**Participants:** Jing-Rebecca Li, Hang Tuan Nguyen.

We model the magnetization in biological tissue due to a diffusion gradient by a two compartment Bloch-Torrey partial differential equation with infinitely thin permeable membranes. We formulate a ODE model for the magnetization and show the simpler ODE model is a good approximation to the Bloch-Torrey PDE model for a variety of gradient shapes. Using the ODE model we determine of the change in the cellular volume fraction from the signal attenuation obtained before and after cell swelling. This method requires only the ADC and Kurtosis of the two signal attenuations and the numerical solution of an ODE system.
6. New Results

6.1. Modelling and Identification

6.1.1. Multi-Dimensional Wrist Musculoskeletal Modeling for Tremor Simulation

Participants: Peng Yao, Mitsuhiro Hayashibe, Dingguo Zhang (Shanghai Jiao Tong Univ.).

In this work, we established multi-dimensional wrist musculoskeletal model to be used for suppressing the wrist joint’s tremor by functional electrical stimulation. Often the wrist model for FES control is based on 1DOF biomechanical model for the simplicity and convenience to develop the controller. However, wrist motion is generated by complex interactions of multiple muscles spanning the wrist joint. Here, we have tried to have 3DOF wrist model considering main muscles involved in flex-extension, radial-ulnar deviation, and pron-supination as in the left of Fig. 1 (opensim model). Inertia of 3DOF joint model was obtained based on the work of de Leva which modified Zatsiorsky parameters. Joint dynamics was formed by inertia, gravitational torque, and passive visco-elastisity. As for the mapping between torque and muscles, the moment arm matrix \((3 \times 4)\) was obtained from opensim software, thus anatomical information could be considered along with muscle parameters such as muscle-length, isometric maximal forces. For this first trial, 4 muscles were considered based on Hill-type model. In order to confirm the generated motion by muscle activation, we activated the ECRB (extensor carpi radialis brevis) and FCU (flexor carpi ulnaris) in antiphase, the corresponding 3DOF wrist angles were obtained as in Fig. 1. Qualitatively, we know that ECRB can generate negative flexion angle, negative deviation angle and positive pronation when it is activated; while FCU can produce positive flexion angle, positive deviation angle and positive pronation angle. When both ECRB and FCU are activated in order, the reasonable wrist angles could be generated. We will work on the development of tremor controller in the future work.

Figure 1. 3DOF Wrist Musculoskeletal Modeling. Anatomical layout of principle wrist muscles, moment arm matrix was obtained from opensim (left). 3DOF wrist angles were generated by tremor like activation in ECRB and FCU (right).

6.1.2. Multi-functional EMG classification for dynamic EMG-motion modeling

Participants: Lizhi Pan, Mitsuhiro Hayashibe, Dingguo Zhang, Xiangyang Zhu (Shanghai Jiao Tong Univ.).
EMG signal is widely used to control a limb protheses such as exoskeleton. It would be also useful to control prosthetic hand for upper-extremity amputees. Especially for upper limb control, hybrid control both for position and torque is required for dynamic motions. In this work, we aimed at establishing the EMG-joint angle model for dynamic motions, to effectively decode EMG signals to reproduce the corresponding motion in different velocity. In the experiment, the subject performed the wrist flexion-extension with different speeds along with EMG measurements on flexor and extensor muscles. ARX model, of which the parameters are adaptively identified by extended kalman filter, was applied to represent 1 DoF (degree of freedom) EMG-joint angle model. The result shows that the EMG-angle model could produce good angle tracking as shown in Fig. 2. We have observed that three principal parameters $a_1$, $a_2$, $a_3$ for autoregressive term are almost constant at the same angular speed and different angular speeds correspond to different model parameters. With this regular pattern, SR (Switch Rregime) model would be possible to be used to switch the model to reproduce the motion in different conditions. In the further work, we work on creating a SR EMG-angle model using learning and classification technique to dynamically decode the EMG signals into the corresponding motions only based on EMG without angle information.

![Figure 2. Dynamic EMG-motion modeling and identification. Subject performed the wrist flexion-extension with different speeds along with EMG measurements on flexor and extensor muscles. Adaptive identification was implemented with Kalman filtering. Model parameters and speed will be used for classification.](image)

6.1.3. Real-time Volumetric Skeletal Muscle Deformation

**Participants:** Yacine Berranen, Mitsuhiro Hayashibe, Benjamin Gilles.

In this work, we explore skeletal muscle volumetric deformation. The current available simulation for musculoskeletal model is basically using wire-type muscle model which considers only principal longitudinal path of the muscle-tendon units. If we aim at the simulation of the interaction between muscles and objects like orthosis, exoskeleton keeping classical biomechanical property, wire-type modeling is not sufficient. In addition, muscle modeling in volumetric way gives another advantage to reflect microscopic muscle fiber direction and function. We have tried to implemente real-time volumetric skeletal muscle deformation as in Fig. 3 using the INRIA SOFA environment. The idea is making more realistic musculoskeletal simulation from the current approximation of muscle model as wire element to physically and functionally detailed simulation as volumetric element.

6.1.4. Muscle Strength and Mass Distribution Identification in Musculoskeletal Modeling

**Participants:** Mitsuhiro Hayashibe, Gentiane Venture (Tokyo Univ. of Agriculture and Technology), Ko Ayusawa (Univ. of Tokyo), Yoshihiko Nakamura (Univ. of Tokyo).
In current biomechanics approach, the assumptions are commonly used in body-segment parameters and muscle strength parameters due to the difficulty in accessing those subject-specific values. Especially in the rehabilitation and sports science where each subject can easily have quite different anthropometry and muscle condition due to disease, age or training history, it would be important to identify those parameters to take benefits correctly from the recent advances in computational musculoskeletal modeling. In this paper, Mass Distribution Identification to improve the joint torque estimation and Muscle Strength Identification to improve the muscle force estimation were performed combined with previously proposed methods in muscle tension optimization. This first result highlights that the reliable muscle force estimation could be extracted after these identifications. Fig. 4 shows the estimated muscle forces of Rectus Femoris, Vastus Lateralis and Vastus Medialis with different speeds (first two series are normal speed, second two are slow and last two are fast). The corresponding visualizations of estimated muscle tensions at the indicated time instant are depicted in the bottom. The proposed framework toward subject-specific musculoskeletal modeling would contribute to a patient-oriented computational rehabilitation [22].

6.1.5. Joint Angle Estimation with Inertial Sensors Calibrated by Kinect

Participants: Mitsuhiro Hayashibe, Antonio Padilha Lanari Bo (Univ. of Brasilia), Philippe Poignet.

In this work, we explore the combined use of inertial sensors and the Kinect for applications on rehabilitation robotics and assistive devices. In view of the deficiencies of each individual system, a new method based on Kalman Filtering was developed in order to perform online calibration of sensor errors automatically whenever measurements from Kinect are available. The method was evaluated on experiments involving healthy subjects performing multiple DOF tasks. Accelerometers and gyrometers are used to estimate joint angle, while the Kinect is used for initializing the inertial system and for enabling 3D visualization of the performed task as in Fig. 5 [32].

6.1.6. Investigation of fibre size stimulation selectivity using earthworm model

Participants: Pawel Maciejasz, Christine Azevedo Coste, David Andreu, David Guiraud.

Fibre type and diameter selective stimulation may allow to restore various motor and sensory functions of human body that have been lost due to disease or injury. For example in people unable to voluntarily empty the bladder, selective stimulation of small fibres within the ventral branch of the sacral nerve roots (S2-S4/5) would induce detrusor contraction and those cause bladder emptying closest to normal physiology. Currently, it is not possible to perform it in such a way, because stimulation of sacral nerve roots activates also bigger fibres innervating the urethral sphincter, which closest the outlet of the bladder.

Already many stimulation techniques have been proposed for fibre type and diameter selective stimulation. They were verified performing computer simulations and in some cases also by in vivo experiments on mammalian models. However, results of computer simulations still need to be confirmed by in vivo experiments, whereas experiments on mammalian models, due to high number of fibres within stimulated nerve, can be very...
Figure 4. Estimated muscle forces of Rectus Femoris, Vastus Lateralis and Vastus Medialis using the identified model in squat motion with 4kg load with different speeds (first two series are normal speed, second two are slow and last two are fast) (up). The corresponding visualization of estimated muscle tensions at the indicated time instant (bottom).

Figure 5. Angles estimated using inertial sensors in a sit-to-stand task.
complex to perform and obtained results difficult to interpret. As a result, it is still unclear which stimulation parameters may allow for selective stimulation of only particular group of fibers. Therefore we propose the earthworm (Lumbricus terrestris) as a model for selective stimulation. The earthworm has three giant nerve fibres, with two distinctly different conduction velocities and diameters. Therefore it is very easy to distinguish between fibres that are firing at the moment. As a consequence the selectivity of stimulation may be immediately verified without application of sophisticated signal processing and averaging techniques.

We have investigated influence of various pulse amplitudes and durations on the selectivity of stimulation. Using a simple experimental set-up [29] shown in the fig. 6 A, we were able to achieve selective activation of small (fig. 6 C) and big (fig. 6 D) fibers, as well as concurrent activation of both fibers (fig. 6 B) [28]. For that purpose we have used so called "anodal block" technique.

Based on the results of the above experiments, the recommendations of the optimal parameters for selective stimulation of nerve fibres will be prepared. Afterwards we are going to verified these recommendations in mammalian models (rats).

![Figure 6. A. The schematic representation of the stimulation ("-" - cathode, "+" - anode) and recording (R1, R2 and R3) sites during experiments on earthworms; B, C and D - examples of nerve responses recorded for various pulse amplitudes. It may be observed that although all fibres are activated under cathode (R1 recording site, first plot in each line), on the anode side (R2 and R3 recording sites, second and third plot in each line respectively) activation of all (B), only small (C) and only big (D) fibres could be achieved.]

6.1.7. Neural network based identification for time-variant dynamics

Participants: Zhan Li, Mitsuhiro Hayashibe, David Guiraud.

Due to high nonlinearity and time variance in muscle dynamics under FES, the identification of muscle model is complex task. The time-variation of muscle response may come from muscle fatigue, but also the electrode attachment condition. Along with such long-term time-variation, short term time-variation may be created by reflex effect. In addition, the characteristics of such variance even may change in time in an unpredicted way.
Reinforcement learning framework may be applied to bring the robustness in adaptive identification. Current work is focused on the usage of discrete-time recurrent neural network for model identification.

6.2. Function control and synthesis

6.2.1. Correction of drop-foot in post-stroke hemiplegic patients

**Participants:** Christine Azevedo Coste, Roger Pissard-Gibollet (SED INRIA), Fabien Jammes (INRIA RA), Jérôme Froger (Rehab. Centre, Grau du Roi, CHU Nîmes).

Hemiplegia is a condition where one side of the body is paretic or paralyzed; it is usually the consequence of a cerebro-vascular accident. One of the main consequences of hemiplegia is the drop-foot syndrome. Due to lack of controllability of muscles involved in flexing the ankle and toes, the foot drops downward and impedes the normal walking motion. Today, there are commercially available assistive systems that use surface electrodes to stimulate Tibialis Anterior (TA) muscle and prevent drop-foot. The efficiency of drop-foot stimulators depends on the timing of stimulation and functionality of dorsiflexion motion. Classically, available stimulators use footswitches to detect foot on/off events. These discrete events allow only for triggering the stimulation and/or playing with the duration of the stimulation pattern, but does not allow for precise online modification of the pattern itself. We have developed algorithms to monitor the ongoing walking cycle by observing the valid limb movements. In order to ensure legs coordination during walking, we propose a robust phase estimation method based on the observer of a nonlinear oscillator. We have modified a commercial stimulator, ODSTOCK, in order to be able to trigger it using our own wireless sensors and algorithms. Agreement from Nîmes CPP (ethical committee) was obtained in June 2010 to run tests on patients. The protocol comprises 1) the control algorithm triggering the stimulator based on signals issued from one wireless inertial sensor placed on healthy shank, 2) a sensor setup including inertial sensors placed on deficient shank and foot, one goniometer measuring deficient ankle angle, one EMG sensor placed on stimulated TA and one instrumented carpet (GAITRITE) (fig. 7). Several patients have been included in the study and data is being processed [15][14].

![Figure 7. Stroke patient study protocol description.](image)

6.2.2. eEMG Feedback Torque Control in FES

**Participants:** Mitsuhiro Hayashibe, Qin Zhang, Christine Azevedo Coste.
Electrical stimulation (ES) is one of the solutions for drop foot correction. Conventional ES systems deliver predefined stimulation pattern to the affected muscles. However, time-variant muscle response may influence the gait performance as they are difficult to be taken into account in advance. Therefore, closed-loop ES control is important to obtain desired gait in presence of muscle response variation. In this work, a dual predictive control, which consists of two nonlinear generalized predictive controllers, is proposed to track desired torque. The stimulated muscle dynamics are modeled by Hammerstein cascades, with one representing stimulation to activation, the other representing activation to torque. Ankle dorsiflexion torque and ES-evoked EMG of tibialis anterior were recorded experimentally for model identification. The control scheme is validated by following desired torque trajectories with the identified model. The results show that the stimulation pattern obtained from the dual predictive control can produce good torque tracking according to the current muscle condition as shown in Fig. 8. The updates of model parameters were switched off after certain instant for both the excitation and contraction model. Consequently, the model prediction in the control was only driven by the model input and the last model parameter estimates. The dual predictive controller can still generate suitable control signal to obtain desired torque trajectory [23].

![Figure 8. Torque reference (solid blue) and reproduced torque output by the proposed controller (dashed red). The updates of model parameters were switched off after 19.2s. Consequently, the model prediction in the control was only driven by the model input and the model parameter estimates at the time of 19.2s.](image)

6.2.3. FES assisted Sit-to-Stand

**Participants:** Jovana Jovic, Christine Azevedo Coste, Philippe Fraisse, Charles Fattal.

Standing up is a common daily activity and a prerequisite to standing or walking. This frequently executed task is one of the most biomechanically demanding activities. The ability to rise from a sitting to a standing position is very important for individuals with paraplegia in order to achieve minimal mobility and has functional and therapeutic benefits related to bone loading, joint extension, cardio-circulatory stimulation, and pressure sore prevention. One method which has been widely investigated is functional electrical stimulation (FES) of the lower extremities. The sit-to-stand method, which is widely used in clinical practice, involves open-loop stimulation of knee extensors activated by hand switches. This technique works adequately in many cases, however, in applying this strategy, stimulation starts without referencespect to the upper body movement. Hence, the whole-body motion is not optimal and requires a high velocity of the joints and large upper limb forces during the rising motion, which may cause both damage of joint tissues and shoulder complications.
We propose a "patient-driven" FES method that would coordinate motion of the trunk, which is under voluntary control of the patient, and motion of the lower limbs, which are under FES control. The proposed approach is based on the observation of trunk movement during rising motion and a detection algorithm, which triggers a pre-programmed stimulation pattern. Trunk acceleration was acquired by a single one-axis wireless accelerometer positioned on the subject's back. The detection algorithm consists of an online comparison of the movement acceleration of the ongoing motion with the reference pattern (a typical pattern characterizing the sit-to-stand transfer for each subject) using Pearson’s correlation coefficients \cite{25}. Experiments on paraplegic subjects are ongoing in rehabilitation center PROPARA. The experimental setup and a paraplegic subject of the experiment are presented in Fig. 9.

![Experimental setup.](image)

We have shown that in the cases where the acceleration and reference signal are similar, our algorithm is able to recognize sit-to-stand motion and to properly trigger leg stimulation at the desired instant. Also, we have shown that there is an influence of stimulation timing on applied hand forces during the motion. The best results were achieved for trials in which motion was similar to the one of the able-bodied subjects in terms of trunk motion and the beginning of the leg motion with respect to the trunk acceleration signal.

We also investigated dynamic optimization as a tool to improve FES assisted sit-to-stand transfers of paraplegic subjects. The objective would be to find optimal strategy for voluntary trunk movement, which would minimize hip, knee and ankle torques and demand minimal upper limb participation during the motion. Our results suggest paraplegic patients should bend their body forward in order to use linear momentum of the trunk in sit off phase. Figure 10 shows optimal coordination of ankle, knee, and hip angles during sit-to-stand motion \cite{26}, \cite{24}.

6.2.4. Signal-based segmentation of human locomotion using embedded sensor network

Participants: Maud Pasquier, Christine Azevedo Coste, Bernard Espiau, Christian Geny (CHU Montpellier), Fabien Jammes.

Last year, we introduced a simple approach to segment in homogeneous phases a long-duration record of locomotion data consisting of body segment acceleration and foot pressure information. We used a system based on a network of wireless nodes embedding various types of sensors \cite{3}. Two cases were considered: walk and run around an indoor running track \cite{35} and outdoor marathon \cite{34}. 
Figure 10. Optimization results for lower limb trajectories. Blue line is ankle angle, red line is knee angle and green line is hip angle. The dashed bar marks the beginning of sit off phase.

We now use this system as part of a study of mobility impairment caused by Parkinson’s disease (fig. 11). Freezing of gait (FOG) has been identified as one of the main contributors to gait disturbances in this disease. We introduce an ambulatory gait analysis method using body attached gyroscopes and accelerometers to detect the freezing of gait. One hand, we aim at proposing a FOG detection algorithm more robust because the existing algorithms were not able to detect the FOG without tremor. On the other hand, we would like to anticipate the freezing before it is installed in order to reduce the risk of falling.

Before and during a FOG, a patient tends to walk slowly with short strides and fast rhythm. The detection of an increase of frequency is not enough, because there exists similar variations during the initiation of gait or a voluntary acceleration. The association of an increase of the gait rhythm together with a decrease of stride length allows us to detect a FOG. The computation of correlation coefficient in a moving window allows us to estimate the rhythm of strides. We are also working on different methods to estimate the stride length using one or two IMU (3-axis gyroscope and 3-axis accelerometer).

A time-frequency representation permits to show an increase of fundamental frequency and a duplication before a FOG, Fig. 12. The variations of the fundamental frequency are already detected with the correlation. In the future works, we aim at characterizing these duplications and to propose an algorithm of automatic detection.

6.2.5. Awake surgery: How to optimize functional brain mapping by improving per-operative testing?

Participants: Cheikh Niang, Pom Charras, Stephane Argon, Christine Azevedo, Hugues Duffau, David Guiraud, François Bonnetblanc.

It is now possible to perform resections of slowgrowing tumors in awake patients. Using direct electrical stimulation (DES), real-time functional mapping of the brain can be used to prevent the resection of essential areas near the tumor. For now, simple clinical tests are performed on conscious patients and combined with DES in order to discriminate functional and non-functional areas invaded by the tumors. In this work we try to develop a simple device based on a simple technology to better quantify the performances of the patients during the surgery itself and give a real-time feedback to the neurosurgeon that will help to further guide the surgery.
Figure 11. nodes disposition on the patient.

Figure 12. FOG: Smoothed pseudo Wigner-Ville time-frequency distribution with causal kernel.
by improving the sensibility of the functional mapping. This procedure should also allow building a strong
database that should serve retrospectively to improve the surgical procedure and reinforce the neurosurgeons’
experience as well as to monitor the patients’ performances all along their life.

6.2.6. Closed-loop CoM based posture control in FES

Participants: Alejandro González, Mitsuhiro Hayashibe, Philippe Fraisse.

Center of Mass control has been used in humanoid robotics to create stable standing postures and movements.
By controlling the CoM position and acceleration, joint trajectories which respect to the ZMP stability criterion
can be generated. FES may be used to drive joint torques in order to maintain a standing posture within a closed
loop controller. Current work is focused on locating a human’s CoM by creating a statically equivalent serial
chain (SESC) model using widely accessible equipment, such as the Kinect camera and the Wii balance board.

6.3. Neuroprostheses

6.3.1. Stimulator calibration

Participants: Jérémie Salles, Fabien Soulier, Serge Bernard, Guy Cathébras.

![Stimulator architecture overview.](image)

In the context of the TIME project, one CAFE12-based stimulator will be used for chronic experiment in human.
During the validation of the stimulator, it appeared that we needed to improve both the linearity and the current
matching of the 12 channels. We thus define a calibration process consisting in:

- PCB modification: To take advantage of the 10 bits of the DAC (only 8 were used before for compatibility reasons). The modification give the FPGA access to the two latter bits. Moreover, test points were added between the ASIC and the output capacitors that now can be removed for the calibration phase.
- Digital interface modification: To allow a 16th current amplifying ratio (only 0-15 were enable). Improvements in the activation sequences of output current mirrors have also been carried on.
- Reference voltage and current tuning: The stimulator use several level of power supply and voltage references. Nominal values are:

\[
\begin{align*}
V_{hv} &= 16.0 \text{ V}, & V_{DD} &= 3.3 \text{ V}, & V_{hv2} &= 13.3 \text{ V}, \\
V_{ref P} &= 13.5 \text{ V}, & V_{ref N} &= 1.5 \text{ V}.
\end{align*}
\]
The DAC current reference is set to get a 5.46 mA maximum current at the stimulator output for ratio of 15. We have enabled modification of the biasing resistor in order to fine-tune this current reference.

- Raw data acquisition: Measurement of the 12 output currents are carried on independently with the following configuration:
  - all outputs configured as cathodes,
  - all ratios set to 16.

The measurement setup makes use of a characteristic analyzer (HP4156A) to maintain the voltage load to 7.5 V for all the DAC current values.

- Correction: The linearity and matching correction is specific to the association of a particular ASIC with a particular DAC. For human experiment, the configuration will be limited to common anode/controlled cathodes. A first-order linear regression is applied to the 12 raw current measurements. This gives gain and offset adjustments for each channel that are applied by a linear digital correction block (fig. 14). The DAC initial value (8-bit) is multiplied by the correction gain and summed to the correction offset (both channel-dependant), resulting in a 10-bit corrected command. At last, respective correction values are chosen and quantified to lower impact of these modifications to the precision and dynamic range of the stimulator output (no “lost” bit). Concerning the implementation, since the 3 most significant bits of the correction gain appear to be constant, it is possible to use channel-independent bit-shifts and a substractor to perform the 8 to 10-bit multiplication.

![Figure 14. Linear digital correction principle.](image)

The improvement in the matching of the 12 channels can be seen in figure 15. The results in terms of linearity are an integral non-linearity of ±2.5 LSB and a differential non-linearity of ±0.3 LSB.

### 6.3.2. Nerve Modelling for ENG recording

**Participants:** Olivier Rossel, Jonathan Coulombe, Fabien Soulier, Serge Bernard, Guy Cathébras.

In the context of FES, neural recording is one of the main issues, as the control requires information carried on afferent peripheral nerves. Because specific information are carried in different fascicles, we propose to realize a non-invasive and spatial-selective electrode. Last year, based on investigation on the topic of extracellular Action Potentials (AP), we proposed a new tripole design, where the tripolar output signal is the image of the activity in the close vicinity of this tripole, providing high spatial selectivity.

We showed however, that this high spatial selectivity is achieved at the expense of signal amplitude. This first result jeopardizes the feasibility of this kind of electrode since the signal amplitude appears to be on the same range of the expected noise. First, we propose to estimate the performance of the proposed electrode with a quantitative study of the electrode selectivity. Then, to conclude on the feasibility of this electrode, the SNR has to be determined. So with a more accurate model, we studied the sensitivity of the proposed tripole, allowing to determine precisely the amplitude level of the expected signal. Thus, the SNR can be estimated knowing the expected noise.
Figure 15. Mean gain (top) and worst case (bottom) before and after correction.
In short, the work of this year aims at characterizing the performances and evaluating the feasibility of this new multi-contact cuff electrode.

### 6.3.2.1. Selectivity

We proposed an electrode configuration inspired from the FINE electrode (figure 16) designed for the same purpose. The electrode is composed of many tripodes, placed around the nerve. This disposition is used for two electrode, state-of-the-art electrode A and the proposed electrode B. The unique difference between both electrode resides on the longitudinal inter-pole distance ($d_e$), which is respectively 5 mm for the electrode A and 0.375 mm for the electrode B.

![Figure 16. Electrodes A and B have the same shape but differ on the longitudinal inter-pole distance ($d_e$). Two fascicles are represented.](image)

The electrodes performances are evaluated based on simulations using a model of a nerve comprising multiple fascicles [38]. The Selectivity Index ($SI$) quantifies the ability to record and distinguish between different active fascicles in such a manner that $SI = 0$ corresponds to a case where an active fascicle yields identical signals at every recording site, while $SI = 1$ occurs when one recorded signal is different from every other. This $SI$ has to be presented according to the inter-fiber spacing.

The result of electrode selectivity are presented in the fig. 17. This figure shows that activity of two fascicles separated by as little as 1 mm can be distinguished for the proposed electrode (for this distance $SI$ for electrode B ($\approx 0.9$) is more than double that of electrode A ($< 0.4$)). The proposed electrode thus appears to be much more selective than the reference electrode.

### 6.3.2.2. Sensitivity

Using a more realistic model (inhomogeneous and anisotropic), we investigate the spatial properties of extracellular AP and that of the filtering done by the proposed tripode [37]. This allows us to represent the tripolar sensitivity. It was realized for the proposed tripole B and compared to a state-of-the-art tripole A 18. This sensitivity represents the amplitude of the tripolar output signal for a single unit action potential.

This figure shows that the classical tripole radial sensitivity is huge compared to that of the proposed electrode. This confirms the high spatial sensibility of the proposed tripole. We can also determine the expected amplitude, where the signal can reach 6 μV. Considering this amplitude and knowing that in natural case there will be superposition of action potentials, we can conclude that the signal amplitude could be higher than the expected noise (around 1 μV). So we can conclude positively to the feasibility of this kind of electrode.

### 6.3.3. Low-noise, low-power ENG amplifier design

**Participants:** Jonathan Coulombe, Olivier Rossel, Fabien Soulier, Serge Bernard, Guy Cathébras.

This year we proposed a method for enhancing the noise-power tradeoff of front-end amplifiers in parallel recording applications of analog signals with respect to a common reference. One example of application is shown in the Fig. 19 for spatial-selectivity ENG recordings.

The circuit architecture is based on a Shared-Input Amplifier (SIA), composed by shared-input transconductance amplifiers and a differential stage. Averaging null signals and subtracting the result from every signal reduce the noise because the correlated noise between parallel outputs is attenuated. It results significant supply current savings without noise penalty. One example is shown in the Fig. 20 for the specific case of two average of two null signals.
Figure 17. Selectivity index computed for random combinations of simulated fascicles, plotted as a function of the distance between each couple of fascicles.

Figure 18. Comparison between classical and proposed tripole sensitivity. The peak-to-peak amplitude of a single unit action potential is represented, measured by a classical tripole on the left and by the proposed tripole on the right. The tripoles are placed on the surface of a nerve of 300 µm radius.
Figure 19. Conceptual representation of a selective ENG recording system.

![Conceptual representation of a selective ENG recording system](image1)

Figure 20. SIA modified for the use of transconductance amplifiers in open-loop configuration for ENG recordings. And concept of parallel SIA with noise reduction using null output averaging and differential readout.

![Diagram of SIA modified for ENG recordings](image2)
Also, a method for reducing the remaining noise with little power penalty is possible. And it is possible to combine both methods, either noise level, total supply current, or both can be significantly reduced. The benefits of combining both methods and the related trade-offs was validated by simulations using models of a 0.35 µm BiCMOS process. So we have shown that the total supply current can be reduced by more than 50% that of a comparable system using conventional differential amplifiers with equivalent output noise. Alternatively, the noise can be reduced by approximately 35% with comparable power consumption.

This should enable low-noise recording of signals with significantly better efficiency than even the theoretical limit of any conventional differential amplifier. Future work will include circuit optimization and investigation of the impact of the architecture over other performances of the system, such as crosstalk, linearity, distortion, and channel mismatch. Implementation of the circuit for full characterization is expected to be completed in the near future.
5. New Results

5.1. Model Design

5.1.1. Sensitivity Analysis of Complex Biophysical Models

5.1.1.1. Background

Sensitivity analysis (SA) is a fundamental tool in the building, use and understanding of mathematical models [44]. Sampling-based approaches to uncertainty and sensitivity analysis are both effective and widely used [38]. For this purpose, Sobol’s method is a key one [47]. Since it is based on variance decomposition, the different types of sensitivity indices that it estimates can fulfill different objectives of sensitivity analysis: factor prioritization, factor fixing, variance cutting or factor mapping [37]. It is a very informative method but potentially computationally expensive [38]. Besides the first-order effects, Sobol’s method also aims at determining the levels of interaction between parameters [48]. In [46], the authors also devised a strategy for sensitivity analysis that could work for correlated input factors, based on the first-order and total-order index from variance decomposition.

5.1.1.2. Algorithm numerical implementation

Computational methods to evaluate Sobol indices sensitivity rely on Monte-Carlo sampling and re-sampling [47], [40]. For $k$ dimensional factor of model uncertainty, the $k$ first-order effects and the $k$ total-order effects are rather expensive to estimate, needing a number of model evaluations strictly depending upon $k$ [43]. Therefore, it is crucial to not only devise efficient computing techniques, in order to make best use of model evaluations [45], but also to have a good control of the estimation accuracy with respect to the number of samples.

With the objective of an efficient computational method for sensitivity analysis of functional-structural tree growth models, we proposed a new estimator based on Homma-Saltelli method to compute Sobol indices, which improves slightly their use of model evaluations thanks to a more balanced resampling strategy. This new estimator can be considered as an effort to improve the efficiency of SA methods for models.

We also derived a theoretical analysis of the error estimation for the sensitivity analysis for the studied class of Sobol’s estimators (it can be applied to all the three Sobol’s estimators mentioned in this paper) with respect to the sampling size and the number of model evaluations. An analytical test function is used to test the error estimation, and we obtained that the error estimation in this paper gives out a better ‘upper bound’ than the previous works related to this problem. This error estimation directly relates to the variance of the result, so it can also be used for checking the confidence interval, which is usually difficult to attain.

We derived a theoretical analysis of the error estimation for the sensitivity analysis for the studied class of Sobol’s estimators (it can be applied to all the three Sobol’s estimators mentioned in this paper) with respect to the sampling size and the number of model evaluations. An analytical test function is used to test the error estimation, and we obtained that the error estimation in this paper gives out a better ‘upper bound’ than the previous works related to this problem. This error estimation directly relates to the variance of the result, so it can also be used for checking the confidence interval, which is usually difficult to attain.

The result has been accepted to be published in J of Rel. Eng. and Sys. Safety. Based on the published result for first order index of Sobol’s, we also extended this method to the second order index computing which is very important for us to know the precise pairs parameters with interactions between them, with the objective of making best use of the input-output model evaluation matrices that involve in the main part of the sensitivity analysis computing cost. Besides the computing efficiency improvement, one side result we got from the algorithm for second order index is that it can also make the final index has smaller variance so that the result can be more reliable.
Besides Sobol’s method, we also tried Morris method to complete the aim of ‘screening’ parameter of sensitivity analysis.

5.1.1.3. Strategies for FSPM

Global sensitivity analysis (SA) has an important role to play in functional-structural plant growth modeling by assessing the different source of uncertainty help us to gain some insights inner the models so as to explain the behavior of them. Different FSPMs have different scales of model design, which leads to all types of diverse multi-biological processes.

To study specifically how global SA can help for FSPMs, SA was applied on a wide variety of functional-structural plant models, typically the 3 FSPMs: firstly a simple source-sink model of maize growth, is used to specifically study the process of carbon (C) allocation among expanding organs during plant growth, with simple plant structure, multi-stage and detailed observations, secondly the GreenLab model of tree growth (applied to poplar tree) characterized by the retroaction of plant functioning on its organogenesis [41], which describes tree structural plasticity in response to trophic competition, lastly a functional-structural model, NEMA [16], describing C and nitrogen (N) acquisition by a wheat plant as well as C and N distributions between plant organs after flowering. This model has the specificity to integrate physiological processes governing N economy within plants: root N uptake is modeled following the transport systems high affinity transport systems (HATS) and low affinity transport systems (LATS), and N is distributed between plant organs according to the turnover of the proteins associated to the photosynthetic apparatus. C assimilation is predicted from the N content of each photosynthetic organ. Consequently, this model is more mechanistic but also more complex than the two previous ones. Another objective is to explore an effective simulation design to help the sensitivity analysis for complicate models with several logically distinct but biological functioning interacted moduls.

All these SA result shadowed a light to the models for us to diagnosis the model behavior and will bring a big step for parameter estimation and experimental simplification in our modelling next.

5.1.2. A model for Cecropia sciadophylla under fluctuating environmental conditions

In collaboration with Patrick Heuret (INRA, JRU Ecofog, Kourou, French Guiana), we developed a tree growth model dedicated to Cecropia sciadophylla, a neotropical species from the genus Cecropia. These trees have interesting properties from a modeller’s point of view: they have a simple architecture, their number of phytomers remain limited even for old individuals, and most importantly, [39] and [49] have developed a methodology based on morphological observations to estimate tree age on C. obtusa and C. sciadophylla respectively. It is therefore possible to fully describe the tree structure and topology from morphological observations, which is very uncommon for trees: for most tree species, their high stature, complex structure, and long life span drastically increase the fieldwork required to collect data at the organ scale and hamper the development, calibration and validation of functional-structural tree growth models and their potential applications in the field of forest management.

We used datasets collected on 18 trees in 2007 and 2008 in French Guiana to develop and evaluate our model. Our objective was to analyse the influence of fluctuating environmental conditions on the dynamics of trophic competition within C. sciadophylla trees. We defined an integrated environmental factor that includes meteorological medium-frequency variations and a relative index representing the local site conditions for each plant. The meteorological variations were input from pluviometry data, that could be considered as the main fluctuating environmental stress under that tropical climate. The relative index was estimated based on inversion of our model using data from respectively 11 trees for model calibration (those measured in 2007) and 7 trees for model evaluation (those measured in 2008). This study provided a model that can be seen as a tool to disentangle the ontogenic variations (low-frequency trend) and the environmental variations (medium-frequency variation). One paper was accepted for publication [22].
5.1.3. Using model inversion to analyze the effects of inter-tree competition on four Pine trees grown under two contrasted density conditions

In collaboration with Guo Hong and Lei Xiangdong (Chinese Academy of Forestry, Beijing, China), we analyzed the characteristics of individual tree response to competition on source-sink balance through the calibration of the GreenLab model.

Four Chinese pine trees (Pinus tabulaeformis Carr.) were destructively measured in November 2009 from the nursery garden located in the Yuanyiqi forest farm, Beijing, China. Two 13-year-old trees (T1 and T2) were from a high density plantation (3500N/ha) and two 10-year-old trees (T3 and T4) were from a low density plantation (2000N/ha). We first examined the statistical differences in the tree morphologies and topologies. Significant differences were found for internode diameter, internode biomass and needle biomass between the two densities, but not for internode length. In a second step, we studied the ability of the GreenLab model to simulate the plasticity of pine trees grown under different densities. To fulfil these objectives, it was necessary to find a way to characterize the competition conditions of each tree. Given the inherent difficulty of identifying the most relevant experimental measurements for this characterization, we proposed to represent the effects of competition on the tree growth through a single tree-specific parameter of GreenLab, called characteristic surface area, and to estimate it for each tree by model inversion, together with the more classical endogenous species parameters. This will eventually allow us to examine whether the obtained value of this characteristic surface area could be correlated to other possible indicators of competition pressure. This could pave the way to the development of an individual-based stand growth model including the effects of a competition index.

One paper was submitted to Trees - Structure and Functions.

5.1.4. Coffee trees and genetics

In collaboration with Sylvie Sabatier (INRA, AMAP), Philippe de Reffye (CIRAD, AMAP) and Perla Hamon (IRD Montpellier), we studied the architectural and genetic diversities in 5 Coffea species, native from Madagascar. We explore two complementary methods: the genetic diversity using molecular markers (genomic- and/or EST-microsatellites) and the variability of adaptive traits between populations with different ecological niches. We focused on 5 Coffea species endemic to Madagascar, some of which are classified as critically endangered in the World Conservation Union(IUCN) Red List. For each species, architecture and genetic comparative analyses between individuals growing in situ (natural forest) and ex situ (common garden test) are being performed. In parallel, the same populations are analysed using the GreenLab model. These results will be used to study the potential links between the parameters of GreenLab and the allelic distribution in these populations. This is the subject of the PhD of Domohina Andrianasolo (CIRAD, Montpellier and FOFIFA, Antananarivo, Madagascar). This work was presented at the XVIII International Botanical Congress (IBC) [34].

5.1.5. Methods for tree crown analysis and application to young Eucalyptus

Based on the pioneer work on coffee trees of Philippe de Reffye, a stochastic model was developed to describe the topological development of trees. In the model, growth and branching processes are driven by the respective probabilities of activity, rest or death of apical and lateral buds. Because of its mathematical formulation, the model inversion can be done analytically which is rare and parameter values can be estimated from experimental data. The MATLAB softaware GLOUPS developped by Philippe de Reffye was used. We explored the feasibility of calibrating this stochastic model for eucalyptus, which presents the additional difficulty of a continuous growth with no marked endogenous cessation. Incomplete systems were also defined for the case, common with trees, of incomplete datasets. An adequate strategy was defined to sample measurements and applied to five eucalyptus trees (data collected by Pr Lei Xiangdong, Guo Hong and Diao Jun, Chinese Academy of Forestry, Beijing, China).

One paper was accepted for publication [20].

5.2. Model Evaluation and Parameter Estimation
5.2.1. Maximum Likelihood Estimation

In [18], a first approach for parameter estimation was introduced based on the assumption of an underlying deterministic model of biomass production and uncorrelated errors in the mass measurements of different types of organs in the plant structure. A novel idea is developed on the modeling plant growth in the framework of non-homogeneous hidden Markov models, for a certain class of plants with known organogenesis (structural development). Unknown parameters of the models are estimated via a stochastic variant of a generalised EM (Expectation-Maximization) algorithm where both steps (E-step, M-step) are non-explicit. For this reason, the E-step is approximated via a sequential Monte-Carlo procedure (sequential importance sampling with resampling) and the M-step is separated into two steps (Conditional-Maximization), where before applying a numerical maximization procedure (quasi-Newton type), a large subset of unknown parameters is updated explicitly conditioned on the other subset. The model is tested with real data and the results are satisfying. Further work is in progress, including MCMC techniques for parameter estimation (with the collaboration of Dr. Sonia Malefaki from the University of Patras, Greece) and Bayesian type estimation, see [33].

5.2.2. Convolution Particle Filter for parameter estimation

Although Kalman filter is applied to various fields and dominated for decades, it is limited by its assumptions of linearity. Particle filter, which combines Bayesian inference with Monte Carlo sequential sampling approach, is a method using different combinations of random variables sampled directly from the parameter space (or the state space) to estimate parameters and states of a complex system. These combinations, generally called particles, propagate by introducing new observations and provide updated posterior distributions by taking into account their weights. Meanwhile, a resampling procedure is used to prevent the degeneracy problem. Since classical filtering methods are generally not able to estimate the dynamical state vector along with the unknown parameters, the convolution particle filter is implemented based on convolution kernel approximation to meet the need while modelling with Markovian dynamical system.

Several tests are carried out to examine the performance of the Convolution Particle Filtering method [42], [36], and efforts are made to find the optimal perturbation parameters. The applications of the method rely on the Lotka-Volterra model and the sugar beet model. Since the quality of the estimations is limited by the number of the observations, the Conditional Iterative Bayesian Filtering method is applied. The principal is simply to use the posteriori distributions as the a priori information to re-perform over and over again the estimation algorithm and each time we introduce the same sequence of observations. This approach helps us to improve significantly the final estimation of the hidden states and the unknown parameters while testing with the virtual data. The bootstrapping method is implemented in order to compare with the results from different methods.

In the case of applications based on dynamical stochastic systems, two types of noise are introduced, one is involved in the modelization technique and the other is attached to the observation procedure. An alternation of deterministic parameter estimation and stochastic parameter estimation is proposed (in progress) which allows us to estimate these two kinds of parameters at the same time.

5.2.3. Modelling the inter-individual variability of organogenesis in sugar beet populations

Modelling the inter-individual variability in plant populations is a very important issue to enhance the predictive capacity of plant growth models at the field scale. In the case of sugar beet, this variability is well illustrated by the phyllochron (the thermal time elapsing between the appearance of two successive leaves): if the mean phyllochron remains very stable across seasons, there is a high heterogeneity among individuals. Likewise, seedling emergence may strongly vary within a population, potentially inducing important variations in individual plant productions.

A hierarchical segmented model was used to describe and study the variability of the dynamics of leaf appearance in sugar beet crops. The use of this nonlinear mixed model allows for a better handling of the heterogeneity in the plant population, and gives estimates of this variability: each model’s parameter is considered as a random variable, varying from one plant to another around a mean population value, with a given variance.
These mean population values and inter-individual variability can be used as input of functional-structural models, the main issue being then to compute the propagation of these sources of probabilistic uncertainty in the dynamic system of Greenlab.

5.3. Methods for the Applications

5.3.1. Optimization of Phenotyping based on a Parameter Selection Methodology

The model Cornflo is a functional plant growth model simulating Corn’s growth and yield. Based on it, the classification of environmental scenarios is researched in term of their influences to corn’s yield, and their parameter estimation capabilities for Cornflo parameters. The initial qualitative analysis of parameter estimation results shows that environmental scenarios’ classification benefit estimation accuracy and identifiability. Currently this project is researched from three aspects. Firstly, different clustering techniques are tested to find the most proper scenarios categories for parameter estimation. Secondly, the scenarios clusters are used for botanical experiments optimization, such as the selection of experimental locations. Lastly, parameter estimation is optimized and researched in a practical use for plant growth models.

5.3.2. Plant-Soil interactoin and Optimal Control of Irrigation

This work is performed in collaboration with JC Mailhol (Cemagref). Irrigation scheduling is an important issue for crop management, in a general context of limited water resources and increasing concern about agricultural productivity. Methods to optimize crop irrigation should take into account the impact of water stress on plant growth and the water balance in the plant-soil-atmosphere system. For this purpose, different plant-soil interaction models are proposed to simulate the functional plant growth. In particular, a compartment plant model is designed to integrate water stress impact on different main physiological processes of crop: biomass production, biomass allocation, and foliar senescence. This model is applied and calibrated for maize, in order to predict the harvest index according to the stress undergone by crop during its whole cycle. As for the optimal control problem of irrigation, it can be formulated by considering a price for the crop yield and for the water resource. Dynamic programming is then applied to the plant-soil system to determine an optimal irrigation strategy.
6. New Results

6.1. Network Economics

Participants: Pierre Coucheney, Hai Tran Hoang, Bruno Tuffin, Jean-Marc Vigne.

While pricing telecommunication networks was one of our main activities for the past few years, we are now dealing with the more general topic of network economics. We have tackled it from different sides: i) investigating how QoS or QoE can be related to users’ willingness to pay, ii) investigating the consequences and equilibrium due to competition among providers in different contexts, iii) studying the economic aspect of interdomain relationships, iv) looking at the economics of applications, for example adword auctions for search engines, v) investigating the economics of security in telecommunications, vi) studying the network neutrality issue.

On the first item, in [70], [29], we have studied how utility functions can be related to QoE recent research. Indeed, a logarithmic version of utility usually serves as the standard example due to its simplicity and mathematical tractability. We argue that there are much more (and better) reasons to consider logarithmic utilities as really paradigmatic, at least when it comes to characterizing user experience with specific telecommunication services. We justify this claim and demonstrate that, especially for Voice-over-IP and mobile broadband scenarios, there is increasing evidence that user experience and satisfaction follows logarithmic laws. Finally, we go even one step further and put these results into the broader context of the Weber-Fechner Law, a key principle in psychophysics describing the general relationship between the magnitude of a physical stimulus and its perceived intensity within the human sensory system.

A notable part of our activity has been related to competition among telecommunication providers, mainly within the framework of the ANR CAPTURES project. The goal is to improve most of the pricing models analysis which only deal with a single provider while competition (that is observed in the telecommunication industry) can drive to totally different outcomes. A general view of some of our results is summarized in [67]. A general model of competition in loss networks is described and analyzed in [22] as a two-levels game: at the smallest time scale, users’ demand is split among providers according to the Wardrop principle, depending on the access price and available QoS (depending itself on the level of demand at the provider), and at the largest time scale, providers play a pricing game, trying non-cooperatively to maximize their revenue. A striking result is that this game leads to the same outcome than if providers were cooperatively trying to maximize social welfare; the so-called price of anarchy is equal to one. An additional (higher) level of game is analyzed in [23] (but using another type of negative externality for users, based here on delay), at which providers play on the technologies to implement, based on the infrastructure and license (if any) costs, anticipating what would be the resulting price war outcome and revenue for given profiles of sets of technologies. This type of study may help a regulator to decide a licence cost, in order to drive the resulting Nash equilibrium to a better point in terms of social or user welfare. A specific situation we have analyzed is the case for a competitive market operated by a Mobile Network Operator (MNO) and a Mobile Virtual Network Operator (MVNO) [46]. The resource that is leased by the MNO to the MVNO is spectrum. MNO and MVNO compete posting subscription prices and the mobile users may choose to subscribe to one operator, or not to subscribe. The scenario is modeled by a three-level game comprising: a bargaining game, which models the spectrum leasing by the MNO; a competition game, which models the price competition between the MNO and the MVNO; and a subscription game, which models the subscription choice by the mobile users, and the outcome of which may be either not to subscribe, to subscribe to the MNO or to subscribe to the MVNO. We assess which conditions lead to an equilibrium where the competition does take place and the amount of the spectrum that should be leased to maximize user or social welfare.
Another important activity is around interdomain issues, with a network like the Internet being made of thousands of autonomous systems. Intermediate domains need some (economic in our case) incentives for forwarding the traffic of other domains. In [33], we have described the problem, provided a state of the art and highlighted the difficulties that must be solved. In [32], we have designed a decentralized algorithm based on double-sided auctions to allocate (and charge) the resource usage.

But network economics is not only about ISPs, it also deals with the application side. In order to make money many service providers base their revenue on advertisement. Search engines for example get revenue thanks to adword auctions, where commercial links are proposed and charged to advertisers as soon as the link is clicked through. Most search engines have chosen (or switched to) a revenue-based ranking and charging scheme instead of a bid-based one. In [53] we investigate the relevance of that scheme when advertisers’ valuation comes from a random distribution, showing that depending on the search engine’s click-through-rate, revenue-based does not always outperform bid-based in terms of revenue to the search engine. But in this adword auction context too, there exist very few works dealing with search engines in competition for advertisers. We have developed a two-level game where at the largest time scale search engines decide which allocation rule to implement, between revenue-based and bid-based; and at the lowest time-scale advertisers decide how to split their advertising budget between the two search engines, depending on the benefits this will bring to them. The game at the largest time scale is solved using backward induction, the search engines anticipating the reactions of advertisers [54], [52]. We describe the advertisers best strategies and show how to determine, depending on parameters, an equilibrium on the ranking rule strategy for search engines; this may explain Yahoo!’s move to switch from bid-based to revenue-based ranking to follow Google’s strategy.

We similarly have looked at the competition aspects linked to security. We have reviewed the interactions and strategies of attackers and defenders [68]. But we have also looked at the economics of network security, when network users can choose among different security solutions to protect their data, offered by competitive security providers [51]. The interactions among users are modeled as a noncooperative game, with a negative externality coming from the fact that attackers target popular systems to maximize their expected gain.

A new issue we are investigating is the network neutrality debate coming from the increasing asymmetry between Internet Service Providers (ISPs), mainly due to some prominent and resource consuming content providers which are usually connected to a single ISP. We have described and analyzed in [69] the respective arguments of neutrality proponents and opponents, and are currently completing the analysis of several promising game-theoretic models on this issue.

6.2. Dependability and extensions

Participants: Raymond Marie, Gerardo Rubino, Samira Saggadi, Bruno Tuffin.

We maintain a permanent research activity in different domains related to dependability, performability and vulnerability analysis of communication systems. Our focus is on evaluation techniques using both the Monte Carlo and the Quasi-Monte Carlo approaches. Monte Carlo (and Quasi-Monte Carlo) methods often represent the only available tool to solve complex problems in the area, and rare event simulation requires a special attention, in order to be able to efficiently analyze the model, that is, to be able to use good estimators having, in particular, a sufficiently small relative variance. Novel results in simulation can be decomposed into two subsets: results on rare event simulation, and those on Randomized Quasi-Monte Carlo methods.

The effectiveness of randomized quasi-Monte Carlo (RQMC) techniques is examined in [26] to estimate the integrals that express the discrete choice probabilities in a mixed logit model, for which no closed form formula is available. These models are used extensively in travel behavior research. We consider popular RQMC constructions, but our main emphasis is on randomly-shifted lattice rules, for which we study how to select the parameters as a function of the considered class of integrands. We compare the effectiveness of all these methods and of standard Monte Carlo (MC) to reduce both the variance and the bias when estimating the log-likelihood function at a given parameter value.
The main part of our activity in this simulation area in 2011 has been on rare event simulation though. The two major simulation families or rare event estimations are importance sampling and splitting. In [63], we have provided a recent view of those methods, while in [64] we have overviewed how the zero-variance importance sampling can be approximated in classical reliability problems.

The problem of estimating the probability that a given set of nodes is connected in a graph (or network) where each link is failed with a given probability has received a lot of attention from us in 2011. We have proposed in [21] a new Monte Carlo method, based on dynamic Importance Sampling. The method generates the link states one by one, using a sampling strategy that approximates an ideal zero-variance importance sampling scheme. The approximation is based on minimal cuts in subgraphs. In an asymptotic rare-event regime where failure probability becomes very small, we prove that the relative error of our estimator remains bounded, and even converges to 0 under additional conditions, when the unreliability of individual links converges to 0. The empirical performance of the new sampling scheme is illustrated by examples. The method is even sped up in [50] by applying series-parallel reductions at each step of the algorithm.

The same problem is also analyzed in [15] by novel method that exploits a generalized splitting (GS) algorithm. We show that the proposed GS algorithm can accurately estimate extremely small unreliabilities and we exhibit large examples where it performs much better than existing approaches. Remarkably, it is also flexible enough to dispense with the frequently made assumption of independent edge failures. In [17], another splitting approach is explored for the same problem, with very good results. It consists of a standard splitting procedure applied to the so-called Creation Process that can be associated with the initial static model. The paper discusses both a method for splitting this process, and an experimental analysis of the covering of the resulting estimator, showing its good behavior on different classes of test problems. Last, in [16], always for the same static reliability problem, we proposed a new procedure belonging to the RVR family (Recursive Variance Reduction) where a new estimator based both in computed minpaths and mincuts of the graph, together with series-parallel reductions, allows to obtain very good accuracy in many rare events situations.

Finally, a versatile Monte Carlo method for estimating multidimensional integrals, with applications to rare-event probability estimation is presented in [39], [75]. The method uses two distinct and popular Monte Carlo simulation techniques, namely Markov chain Monte Carlo (MCMC) and Importance Sampling, combined into a single algorithm. We show that for some illustrative and applied numerical examples the proposed Markov Chain Importance Sampling algorithm performs better than methods based solely on Importance Sampling or solely on MCMC.

Concerning the risk on spares for life-time maintenance purposes which is due to uncertainties on the mean up time, an extended version of a presentation made in 2010 has been published in [24].

6.3. Performance evaluation

Participants: Laura Aspirot, Raymond Marie, Gerardo Rubino, Bruno Sericola.

An important problem arising when dimensioning a P2P system is to understand the evolution of the peers’ population with time. The number of units being usually large, the standard stochastic models used to represent this kind of system (e.g. a Markovian stochastic process) are difficult to use in practice. Instead, it is popular today to move to deterministic continuous-state (fluid) models whose dynamics is governed by differential equations. It is then of interest to analyze the conditions under which the latter are the limit, in some sense, of the former. We started to develop this program in [36] by focusing on some popular models of P2P systems, and analyzed when and how the deterministic model is the limit of the stochastic one when the number of peers goes to infinity.

In [60], we continued to explore the concept of power of a queueing model proposed by Kleinrock in the 80s. Kleinrock’s idea was to build a metric combining two “competing” ones, the mean throughput and the mean response time, for the system in equilibrium. The power is defined as the ratio of normalized versions of those metrics. We discuss different ways of adapting this concept to more general queueing systems such as queueing networks. In this research line, [60] opens the way for a definition of efficiency, which is currently analyzed in the team.
In [30], we expose a clear methodology to analyze maximum level and hitting probabilities in a Markov driven fluid queue for various initial condition scenarios and in both cases of infinite and finite buffers. Step by step we build up our argument that finally leads to matrix differential Riccati equations for which there exists a unique solution. The power of the methodology resides in the simple probabilistic argument used that permits to obtain analytic solutions. We illustrate our results by a comprehensive fluid model that we solve exactly.

In [65], we analyze the transient behavior of a fluid queue driven by a general ergodic birth and death process using spectral theory in the Laplace transform domain. These results are applied to the stationary regime and to the busy period analysis of that fluid queue.

Finally, in [71] we present a global view of the performance evaluation area in computer and communication systems, an extended and reviewed version of a talk given in 2010.

6.4. Quantitative aspects of distributed systems

Participants: Bruno Sericola, Romaric Ludinard.

This work is a collaboration with the Inria team-project Asap. We proposed in [20] a fully decentralized algorithm to provide each of the nodes of a distributed system with a value reflecting its connectivity quality. Comparing these values between nodes, enables to have a local approximation of a global characteristic of the graph. Our algorithm relies on an anonymous probe visiting the network in an unbiased random fashion. Each node records the time elapsed between visits of the probe which is called the return time of the random walk. Computing the standard deviation of such return times enables to approximate the conductance of the graph. Typically, this information may be used by nodes to assess their position, and therefore the fact that they are critical, in a graph exhibiting low conductance.

We continue our collaboration with the Inria team-projects Adept and Ipso. It is well-known that peer-to-peer overlays networks can only survive Byzantine attacks if malicious nodes are not able to predict what will be the topology of the network for a given sequence of join and leave operations. In [13] and in [35], we investigate adversarial strategies by following specific games. Our analysis demonstrates first that an adversary can very quickly subvert DHT-based overlays by simply never triggering leave operations. We then show that when all nodes (honest and malicious ones) are imposed on a limited lifetime, the system eventually reaches a stationary regime where the ratio of polluted clusters is bounded, independently from the initial amount of corruption in the system. These results have been obtained using Markov models. In [14] and [34], we consider the behavior of a stochastic system composed of several identically distributed, but non independent, discrete-time absorbing Markov chains competing at each instant for a transition. The competition consists in determining at each instant, using a given probability distribution, the only Markov chain allowed to make a transition. We analyze the first time at which one of the Markov chains reaches its absorbing state. We obtain its distribution and its expectation and we propose an algorithm to compute these quantities. We also exhibit the asymptotic behavior of the system when the number of Markov chains goes to infinity. Actually, this problem comes from the analysis of large-scale distributed systems and we show how our results apply to this domain.

6.5. QoE (Quality of Experience)

Participants: Sebastián Basterrech, Yassine Hadjadj-Aoul, Sofiene Jelassi, Adlen Ksentini, Gerardo Rubino, Kamal Singh, César Viho.

We continue the development of the PSQA technology (Pseudo-Subjective Quality Assessment) in the area of Quality of Experience (QoE). PSQA is today a stable technology allowing to build measuring modules capable of quantifying the quality of a video or an audio sequence, as perceived by the user, when received through an IP network. It provides an accurate and efficiently computed evaluation of quality. Accuracy means that PSQA gives values close to those than can be obtained from a panel of human observers, under a controlled subjective testing experiment, following an appropriate standard (which depends on the type of sequence or application). Efficiency means that our measuring tool can work in real time, if necessary. Observe that perceived quality is the main component of QoE. PSQA works by analyzing the networking environment of the communication
and some the technical characteristics of the latter. It works without any need to the original sequence (as such, it belongs to the family of no-reference techniques).

It must be pointed out that a PSQA measuring or monitoring module is network dependent and application dependent. Basically, for each specific networking technology, application, service, the module must be built from scratch. But once built, it works automatically and very efficiently, allowing if necessary to use it in real time.

At the heart of the PSQA approach there is the statistical learning process necessary to develop measuring modules. So far we have been using Random Neural Networks (RNNs) as our learning tool (see [82] for a general description), but recently, we have started to explore other approaches. For instance, in the last ten years a new computational paradigm was presented under the name of Reservoir Computing (RC) [78] covering the main limitations in training time for recurrent neural networks while introducing no significant disadvantages. Two RC models have been developed independently and simultaneously under the name of Liquid State Machine (LSM) [81] and Echo State Networks (ESN) [78] and constitute today one of the basic paradigms for Recurrent Neural Networks modeling [79]. The main characteristic of the RC model is that it separates two parts: a static sub-structure called reservoir which involves the use of cycles in order to provide dynamic memory in the network, and a parametric part composed of a function such as a multiple linear regression or a classical single layer network. The reservoir can be seen as a dynamical system that expand the input stream in a space of states. The learning part of the model is the parametric one. In a recent collaboration with the Applied Computational Intelligence Research Unit, Artificial Neural Networks Group of the University of the West of Scotland during the first half of the year, we developed an algorithm based on a combination of topology preserving maps such as the Self-Organising Map [80] and the Scale Invariant Map [77] to improve the performance of RC models. The obtained results are presented in two papers: [37] and [38].

In [42] we developed a PSQA version for evaluating the perceived quality in the context of SVC video coding. The tool is based on the use of the RNN model. The main difficulties in defining this tool is regarding the relation between the SVC layers, since the enhanced layers require the information of the base layer in order to be decoded.

In [61], we developed a tool for evaluating the perceived quality of an application distributing streamed video using HTTP (and thus, TCP). The difficulties here are focused around the possible playout interruptions and the quality variations due to the use of adaptive bitrate techniques. Our procedure belongs to the no-reference family of learning ones, and it is also based on the use of the RNN tool.

In [41] we compared PSQA used for the video evaluation to other no-reference tools as well as two objective evaluation tools. We showed that PSQA outperforms the majority of the other tools, in terms of high correlation with human evaluation. This version will be used as the main metric for evaluating the QoE in the future internet architecture proposed by the FP7 Alicante project.

We have also been developing single-ended parametric-model speech-quality assessors of VoIP conversations over future networks. To do that, a careful identification and accurate characterization of quality-degrading factors over next-generation networks has been done. The recent progress and challenges for accurate assessment of voice quality over evolving VoIP systems has been detailed in the survey paper [19]. In [18], we study the perceived effects of packet loss processes, which are the principal source of quality degradation over IP networks. In reality, the perceived effect of a given packet loss process is highly related to the distribution of missing packets. Basically, the higher the burstiness of packet loss processes, the greater the perceived quality degradation. Recently, several assessors of speech quality sensitive to packet loss burstiness have been proposed in the literature. A comprehensive comparison study of bursty-packet-loss-aware artificial assessors has been conducted in [18]. An extended and more elaborated version has been published in [47].

Moreover, novel artificial quality assessors that consider transient loss of connectivity incurred by mobile users over mobile transport system have been developed. A paper describing our developed tools and performance results is under preparation. Recently, we started to work on new analytical models of packet losses and delays of packet-based voice conversations over wireless ad-hoc networks. The developed models will be used to design specialized artificial quality assessors of multimedia services over wireless ad-hoc networks. Moreover,
we are working on the enhancement of a voice quality assessor version of PSQA, by considering the features of removed speech signals.

6.6. Wireless networks

**Participants:** Nizar Bouabdallah, Yassine Hadjadj-Aoul, Adlen Ksentini, Raymond Marie, Bruno Sericola, César Viho.

We continue working on wireless networking. The focus mainly concerns wireless distribution of audio and video, which require strict Quality of Service (QoS) support.

In [27], we investigated the main challenges when the goal is to constitute an efficient Radio Resource Management (RRM) framework. The existing solutions of RRM were classified based on the considered decision-making technique. Moreover, we investigated in [28] how QoE can help for designing efficient RRM for wireless networks. A resource allocation mechanism is proposed in [62]. In [59] we proposed a novel network selection mechanism for heterogeneous wireless networks that take QoE into consideration for decision-making. The main idea is to use QoE of ongoing users in candidate networks as an indicator to select the best network for connection. Besides, in order to provide efficient interworking between the different access players, we first defined some issues related to the interworking operation between the satellite and terrestrial domains. We suggested some solutions and discussed their potential in [31].

We also investigated in [74] solutions that ensure the scalability of mobile networks, which are facing a rapid increase of data traffic. We devise methods that enable User Equipments, both in idle and active mode and while being on the move, to always have optimal Packet Data Network (PDN) connections (i.e., IP addresses) in such decentralized networks. We demonstrated the effectiveness of such approach in current mobile and wireless networks. In these systems, minimizing energy consumption is becoming more and more crucial. In [66], we devised a PID (Proportional Integral Derivative)-based controller permitting to reduce the amount of wasted energy by determining an optimal schedule between the sleep and wakeup periods of the wireless interface during the VoIP communication while keeping the perceived quality at the desired level.

Based on our previous research on proactive routing for wireless ad-hoc networks, we have published a book chapter in [73], focusing on modeling the resilience of routing information for ad hoc networks where topology information is uncertain.

We continue our collaboration with the Inria team-projects Pops (Lille), D-Net (Lyon), Reso (Lyon) and the NPA (Networks and Performance Analysis) research group of LIP6 (Paris) on fast self-stabilization in large scale wireless networks. In these systems, distributed self-organization is more convenient than centralized planification. Self-stabilization protocols are a useful technique to provide self-organization but their stabilizing time is related to the size of the network. In [25], we show that a clustering algorithm, known for its good robustness properties, is actually self-stabilizing. We propose several enhancements to the scheme in order to reduce the stabilization time and thus improved the stability in a dynamic environment. The key technique to these enhancements is a localized self-stabilizing algorithm for directed acyclic graph construction. We provide extensive studies (both theoretical and experimental) that show that our approach enables efficient yet adaptive clustering in wireless multihop networks.

6.7. Sensor networks

**Participants:** Nizar Bouabdallah, Sofiane Moad.

Wireless Sensor Networks (WSNs) are composed of tiny sensor nodes, which are capable of sensing and processing data from inaccessible environments and communicating them to the end-user for further analysis. WSNs are characterized by the limited capacity of their sensor node batteries, making energy efficiency a critical issue. Once a WSN is deployed, sensor nodes must self-organize and live as long as possible, based only on their initial energy stores. Consequently, techniques minimizing energy consumption are required to improve network lifetime. Our research on WSNs [72] revolves around two main directions: 1) clustering, and 2) radio diversity. Regarding clustering, we first developed a Connectivity Degree-Based Energy Efficient
6.8. Scalable Video Coding (SVC) transmission over IP and Broadcast networks

Participants: Majd Ghareeb, Adlen Ksentini, César Viho, Yassine Hadjadj-Aoul.

One of the multimedia market trends is audiovisual service (TV or VoD) anywhere, at any time. To support such service, a Video Service Provider has to manage, store, and distribute content towards multiple kinds and scales of terminals, and over different and transient access technologies to reach the end user. To solve such issues, video scalability seems to be the most relevant solution. It encodes the video in multiple separated layers, which enable a large number of users with heterogeneous capability to view any desired video stream, at anytime, and from anywhere. One of the most well known scalable standards is the Scalable Video Coding (SVC) extension of H.264/MPEG-4 AVC video compression. Our researches in this topic are related to how to optimize and enhance SVC transmission over IP and broadcast networks.

With the aim at keeping a high perceived video quality using SVC, MultiPath Video Streaming (MPVS) over Video Distribution Network (VDN) comes as a promising solution to overcome the limitations of the classical single path and IP-level video streaming approaches. In [45] and [43] we proposed different approaches that couple the three SVC scalability modes (Spatial, Temporal, SNR), with the path diversity provided by VDN. Our method adapts to both the heterogeneity of end-users using the scalable video coding as well as to network bandwidth fluctuations by observing the changes of the available bandwidth over the multiple overlay paths, and updating the streaming strategy accordingly. In [44] we enhanced the precedent solutions by using the PSQA-SVC version [42] in order to get the end-user feedback in terms of QoE, which helps adapting the streaming strategy. In [48] we designed a new protocol optimizing the energy consumption when transmitting video streams. We propose to exploit the SVC coding to adapt dynamically the received video quality to the instantaneous wireless nodes’ characteristics. This is achieved through determining the number of the transmitted/received enhancements layers of an SVC video based on the wireless node context.

In [49] we proposed to support SVC over DVBT2 networks, by associating the layering architecture of both technologies in order to tackle users mobility. This association allows mobile receivers with good physical channels to decode all the SVC layers and benefit from high video quality. Meanwhile, users with poor channel conditions can at least decode the base layer and benefit from acceptable video quality. Further, we introduced a novel QoE-based adaptive mechanism for SVC layers decoding. The proposed approach selects dynamically the number of layers to decode, at the receiver side, so as to maximize the users’ perceived quality. Thus, no feedbacks or signaling messages are needed to implement the proposed algorithm. This makes it compliant with unidirectional technologies such as DVB-T2.
6. New Results

6.1. Algorithmic study of linear functional systems

Participants: Alban Quadrat [correspondent], Thomas Cluzeau [ENSIL, Univ. Limoges].

In [77], [76], [97], it is shown that every linear functional system (e.g., PD systems, differential time-delay systems, difference systems) is equivalent to a linear functional system defined by an upper block-triangular matrix of functional operators: each diagonal block is respectively formed by a generating set of the elements of the system satisfying a purely \(i\)-codimensional system. Hence, the system can be integrated in cascade by successively solving (inhomogeneous) \(i\)-codimensional linear functional systems to get a Monge parametrization of its solution space [129] [89]. The results are based on an explicit construction of the grade/purity filtration of the module associated with the linear functional system. This new approach does not use involved spectral sequence arguments as is done in the literature of modern algebra [102], [103]. To our knowledge, the algorithm obtained in [77], [97] is the most efficient algorithm existing in the literature of non-commutative algebra. It was implemented in the PURITYFILTRATION package developed in Maple (see Section 5.7) and in the homalg package of GAP 4 (see Section 5.8).

Given a linear multidimensional system (e.g., ordinary/partial differential systems, differential time-delay systems, difference systems), Serre’s reduction aims at finding an equivalent linear multidimensional system which contains fewer equations and fewer unknowns. Finding Serre’s reduction of a linear multidimensional system can generally simplify the study of structural properties and of different numerical analysis issues, and it can sometimes help solving the linear multidimensional system in closed form. In [17], Serre’s reduction problem is studied for underdetermined linear systems of partial differential equations with either polynomial, formal power series or analytic coefficients and with holonomic adjoints in the sense of algebraic analysis [102], [103]. These linear partial differential systems are proved to be equivalent to a linear partial differential equation. In particular, an analytic linear ordinary differential system with at least one input is equivalent to a single ordinary differential equation. In the case of polynomial coefficients, we give an algorithm which computes the corresponding linear partial differential equation.

In [45], we give a complete constructive form of the classical Fitting’s lemma in module theory which studies the relation between equivalences of linear systems and isomorphisms of their associated finitely presented modules. The corresponding algorithms were implemented in the OREMORPHISMS package (see Section 5.5).

6.2. A new approach to classes of quasilinear PD systems

Participants: Alban Quadrat [correspondent], Thomas Cluzeau [ENSIL, Univ. Limoges], Daniel Robertz [Univ. Aachen].

Many partial differential systems appearing in mathematical physics, engineering sciences and mathematical biology are nonlinear. Unfortunately, algebraic analysis and \(D\)-module theory, which were successful for the algorithmic study of linear partial differential systems, cannot consider nonlinear PD systems. This project aims at developing a generalization of the algebraic analysis approach to certain classes of quasilinear partial differential systems appearing in mathematical physics and engineering sciences (e.g., Burgers’ equation, shallow water, Euler equations for an incompressible fluid, traffic flow, gas flow). In [44], we have shown how constructive methods of differential algebra and algebraic analysis could be combined to extend results obtained in [45] and [104] for linear PD systems and how they allowed us to compute conservation laws, internal symmetries and decompositions of the solution space of certain classes of quasilinear PD systems. The algorithms have been implemented in the JANETMORPHISMS package dedicated to this new approach (see Section 5.6).
6.3. Stabilization problems & Noncommutative geometry

Participant: Alban Quadrat [correspondent].

In [124], [123], [122], it was shown how the fractional representation approach to analysis and synthesis problems developed by Vidyasagar, Desoer, Callier, Francis, Zames..., could be recast into a modern algebraic analysis approach based on module theory (e.g., fractional ideals, algebraic lattices) and the theory of Banach algebras. This new approach successfully solved open questions in the literature. Basing ourselves on this new approach, we explain in [126] why the non-commutative geometry developed by Alain Connes is a natural framework for the study of stabilizing problems of infinite-dimensional systems. Using the 1-dimensional quantized calculus developed in non-commutative geometry and results obtained in [124], [123], [122], we show that every stabilizable system and their stabilizing controllers naturally admit geometric structures such as connections, curvatures, Chern classes... These results are the first steps toward the use of the natural geometry of the stabilizable systems and their stabilizing controllers in the study of the important $H_{\infty}$ and $H_2$-problems.

6.4. Stabilization of time-delay systems

Participants: Alban Quadrat [correspondent], Arnaud Quadrat [SAGEM, MASSY].

In [127], we study the stabilization problem of a linear system formed by a simple integrator and a time-delay. We show that the stabilizing controllers of such a system can be rewritten as the closed-loop system defined by the stabilizing controllers of the simple integrator and a distributed delay. This result is used to study tracking problems appearing in the study of inertially stabilized platforms for optical imaging systems.

6.5. Singular boundary problems

Participants: Georg Regensburger [correspondent], Anja Korporal [RICAM, Linz], Bruno Buchberger [RISC, Linz], Markus Rosenkranz [Univ. Kent].

In [55], we present results on algorithmic methods for singular boundary problems for linear ordinary differential equations. Moreover, the implementation of integro-differential operators and the corresponding algorithms for boundary problems in the computer algebra system Maple is discussed. The operations implemented for regular boundary problems include computing Green’s operators as well as composing and factoring boundary problems. For singular boundary problems, compatibility conditions and generalized Green’s operators can be computed. In [94], we give a survey and new results on our algebraic and symbolic approach to boundary problem developed over the last years. The construction of integro-differential operators and polynomials over an integro-differential algebra is described in detail along with a generic implementation of the corresponding canonical forms and algorithms.

6.6. Model of reaction networks

Participants: Georg Regensburger [correspondent], Stefan Müller [RICAM, Linz].

In a joint work, Stefan Müller and G. Regensburger propose a notion of generalized mass action systems that could serve as a more realistic model for reaction networks in intracellular environments; classical mass action systems capture chemical reaction networks in homogeneous and dilute solutions, see e.g. [111] and [114]. We show that several results of Chemical Reaction Network Theory carry over to the case of generalized mass action kinetics. Our main result essentially states that, if the sign vectors of the stoichiometric and the kinetic-order subspace coincide, there exists a unique positive complex balancing equilibrium in every stoichiometric compatibility class.

6.7. Ruin probabilities

Participants: Georg Regensburger [correspondent], Hansjörg Albrecher [Univ. Lausanne], Corina Constantinescu [Univ. Lausanne], Zbigniew Palmowski [Univ. Wrocław], Markus Rosenkranz [Univ. Kent].
In a cooperation with Hansjörg Albrecher, Corina Constantinescu (both University of Lausanne), Zbigniew Palmowski (University of Wroclaw), and Markus Rosenkranz (University of Kent), we developed a symbolic technique to obtain asymptotic expressions for ruin probabilities and discounted penalty functions in renewal insurance risk models when the premium income depends on the present surplus of the insurance portfolio. The analysis is based on boundary problems for linear ordinary differential equations with variable coefficients and the corresponding Green’s operators (integral operators), generalizing the approach from [99]. We obtain also closed-form solutions for more specific functions in the compound Poisson risk model.

6.8. Systems of linear ordinary integro-differential equations

Participants: Alban Quadrat, Georg Regensburger [correspondent].

A. Quadrat and G. Regensburger (in the frame of his grant) are working on a new approach for studying algebraic and algorithmic properties of systems of linear ordinary integro-differential equations with boundary conditions. In a recent series of papers, in particular, [100], [101], V. V. Bavula obtained numerous algebraic results for modules over the ring of integro-differential operators with polynomial coefficients using generalized Weyl algebras. We are interested in how far some of his approach can be made algorithmic and generalized to boundary problems. First results in this direction were presented at the Journées Nationales de Calcul Formel (JNCF 2011).

6.9. Stabilization of MIMO fractional systems with delays

Participants: Catherine Bonnet, Le Ha Vy Nguyen, Alban Quadrat.

In order to yield the set of all stabilizing controllers of a large class of MIMO fractional time-delay systems, we may look for coprime factorizations of the transfer function and their corresponding Bézout factors. As primary results, in considering $H_\infty$ stability, left coprime factorizations and left Bézout factors have been determined analytically from the transfer function. Then a particular stabilizing controller has been derived. We also proved the existence of right coprime factorizations.

6.10. Stability analysis of (fractional) delay systems of neutral type

Participants: Catherine Bonnet, André Fioravanti [UNICAMP], Le Ha Vy Nguyen.

The $H_\infty$-stability analysis of (fractional) delay systems of neutral type has been studied in [14]. It was shown that the chains of poles are asymptotic to vertical axes which position depend on the roots of a certain polynomial (easily determined from the given transfer function). In [14] the case of roots of multiplicity one was completely treated whereas the case of roots of multiplicity greater than one was considered only in the particular case of neutral systems whose transfer function is a product of transfer functions of neutral systems with one delay. This year, we have studied more deeply the case of roots of multiplicity greater than one for both, standard and fractional delay systems.

6.11. Matrix Norm Approach for Control of Linear Time-Delay Systems

Participants: Catherine Bonnet, André Fioravanti [UNICAMP], José Claudio Geromel [UNICAMP], Silviu Niculescu.

In [46], we have treated the time-delay linear systems control design in the framework of complete and partial information. We were able to find linear controllers that increase the first stability window imposing at the same time that the delay-free system is stable using some properties about the norms of the state-space matrices. Our method treated the design problem by numeric routines based on Linear Matrix Inequalities (LMI) arisen from classical linear time invariant system theory coupled together with a unidimensional search. Both the state and output feedback design, were solved.

6.12. Interval Observers

Participants: Frédéric Mazenc, Silviu Niculescu, Olivier Bernard [UNICAMP].
The technique, based on the notion of interval observer, is a recent state estimation technique, which offers the advantage of providing information on the current state of a system at any instant of time. The first interval observers were relying on the assumption that the system was cooperative or, roughly speaking, "almost" cooperative.

In the contribution [25], we have proved that, for any time-invariant exponentially stable linear system with additive disturbances, time-varying exponentially stable interval observers can be constructed. The technique of construction relies on the Jordan canonical form that any real matrix admits and on time-varying changes of coordinates for elementary Jordan blocks which lead to cooperative linear systems. We applied our to the case of linear systems with input and output that are detectable.

The paper [31] focused on the analysis and the design of families of interval observers for linear systems with a point-wise delay. First, we proved that classical interval observers for systems without delays are not robust with respect to the presence of delays, no matter how small delays are. Next, we have shown that, in general, for linear systems with delay, the classical interval observers endowed with a point-wise delay are unstable. A new type of design of interval observers enabling to circumvent these obstacles is proposed. It provides with framers that incorporate distributed delay terms. The proposed interval observers are assessed through a non-linear biotechnological model.

6.13. Partial Differential Equations

Participants: Frédéric Mazenc, Christophe Prieur [GIPSA Lab, CNRS].

In [33] and [65], for families of partial differential equations (PDEs) with particular stabilizing boundary conditions, we have constructed strict Lyapunov functions. The PDEs under consideration were parabolic and, in addition to the diffusion term, might contain a nonlinear source term plus a convection term. The boundary conditions were the classical Dirichlet conditions, or the Neumann boundary conditions or a periodic one. The constructions relied on the knowledge of weak Lyapunov functions for the nonlinear source term. The strict Lyapunov functions were used to prove asymptotic stability in the framework of an appropriate topology. Moreover, when an uncertainty is considered, our construction of a strict Lyapunov function made it possible to establish some robustness properties of Input-to-State Stability (ISS) type.

In [64], we have considered a family of time-varying hyperbolic systems of balance laws. The partial differential equations of this family can be stabilized by selecting suitable boundary conditions. For the stabilized systems, the classical technique of construction of Lyapunov functions provides with a function which is a weak Lyapunov function in some cases, but is not in others. We transform this function through a strictification approach which gives a time-varying strict Lyapunov function which allows us to establish asymptotic stability in the general case and a robustness property with respect to additive disturbances of Input-to-State Stability (ISS) type.

Participants: Frédéric Mazenc, Siviu Niculescu.

In the work [32], we propose a new approach for the stabilization of nonlinear time-varying forward-complete systems with delay in the input. This approach is a new reduction model approach, which relies on operators of a new type. It presents three advantages. First, the corresponding control laws do not include distributed terms. Second, it yields closed-loop systems with positive solutions that can be easily derived. Finally, the stabilized systems possess some robustness properties (for instance of ISS type) that can be estimated.

6.15. Backstepping with delay

Participants: Frédéric Mazenc, Siviu Niculescu, Mounir Bekaïk.
In the contributions [30] and [63], we revisited the problem of constructing globally asymptotically stabilizing control laws for nonlinear systems in feedback form with a known pointwise delay in the input. The result we obtained covers a family of systems wider than those studied in the literature and endows with control laws with a single delay, in contrast to those given in previous works which include two distinct pointwise delays or distributed delays. The strategy of design is based on the construction of an appropriate Lyapunov-Krasovskii functional. An illustrative example ends the paper.

6.16. Certifying good performance for adaptive systems
Participants: Frédéric Mazenc, Michael Malisoff [Louisiana State University].

The usual adaptive control problem is to design a controller that forces all trajectories of the system to track a prescribed trajectory, while keeping the estimator of the unknown constant parameter vector bounded. We studied the important and more difficult adaptive tracking and estimation problem of simultaneously (1) forcing the trajectories of the system to track a given trajectory and (2) identifying the parameter vector. This problem was known to be solvable when the regressor satisfies a persistency of excitation condition, but the known results did not provide a strict Lyapunov function for the augmented error dynamics and so could not certify good performance such as ISS with respect to uncertainty added to the controller.

Our main result from [118] covers adaptively controlled first-order nonlinear systems that satisfy the persistency of excitation condition and are affine in the unknown parameter vector. Our contribution consists in particular in constructing global strict Lyapunov functions for the augmented error dynamics. In [28], we extended [118] to adaptive tracking for nonlinear systems in feedback form with multiple inputs and unknown high-frequency gains multiplying the controllers. The control gains must be identified as part of the control objective. High-frequency gains are important for electric motors, flight dynamics, and robot manipulators. We used a persistency of excitation condition that again ensured tracking and parameter identification and led to the explicit construction of a global strict Lyapunov function for the closed loop augmented error dynamics. The strict Lyapunov function was key to proving integral ISS with respect to time varying uncertainties added to the unknown parameters.

6.17. Improved Model Predictive Control design
Participants: Sorin Olaru, Morten Hovd [NTNU, Trondheim, Norway].

New results [38] have been obtained toward the computation of feasible sets for linear model predictive control techniques, based on set relations and not on the conventional orthogonal projection. Further, the problem of computing suitable inner approximations of the feasible sets was considered. Such approximations are characterized by simpler polytopic representations, and preserve essential properties as convexity, positive invariance, inclusion of the set of expected initial states.

6.18. Particle Swarm Optimization for reduced order Hinf controllers with constraints handling
Participants: Guillaume Sandou, Gilles Duc [Supelec (E3S) Control Department], Mohamed Yagoubi [Ecole des Mines de Nante].

Efficient dedicated methods have been developed for Hinfinity controller synthesis. However, such methods require translating the design objectives using weighting filters, whose tuning is not easy; in addition they lead to high order controllers which have to be reduced. A particle swarm optimization method is used to solve both problems successively: after having optimized the filters according to the design specifications using a full order controller but no reformulation of the constraints, a reduced-order one is computed using the obtained filters. Experimental tests for a pendulum in the cart exhibit much than satisfactory results [95], [52]. In addition, the design of Hinfinity static output feedback has been done and tested using the Compleib library and exhibiting similar results to those obtained with the HIFOO solver [86].
6.19. Ant colony for symbolic regression  
Participants: Guillaume Sandou, Bianca Minodora Heiman.

The identification of systems is a key feature to get representative models and so to design efficient control laws. Numerous methods exist to identify the parameters of nonlinear systems when the global structure of the model is given. The problem appears to be much more difficult when this structure is unknown (symbolic regression). We introduce ant colony optimization (ACO) in solving the problem of non linear systems identification in the case of an unknown structure of the model [53]. Numerical results prove the viability of the approach.

6.20. Robust optimization for energy management  
Participants: Guillaume Sandou, Henri Borsenberger, Philippe Dessante [Supelec (E3S) Energy Department].

Many studies have considered the solution of Unit Commitment problems for the management of energy networks. In this field, earlier work addressed the problem in deterministic cases and in cases dealing with demand uncertainties. In this paper [15], the authors develop a method to deal with uncertainties related to the cost function. Indeed, such uncertainties often occur in energy networks (waste incinerator with a priori unknown waste amounts, cogeneration plant with uncertainty of the sold electricity price...). The corresponding optimization problems are large scale stochastic non-linear mixed integer problems. The developed solution method is a recourse based programming one. The main idea is to consider that amounts of energy to produce can be slightly adapted in real time, whereas the on/off statuses of units have to be decided very early in the management procedure. Results show that the proposed approach remains compatible with existing Unit Commitment programming methods and presents an obvious interest with reasonable computing loads.

6.21. Modeling and control of Acute Myeloid Leukemia  
Participants: José Luis Avila Alonso, Annabelle Ballesta [BANG project-team], Frédéric Bonnans [COMMANDS project-team], Catherine Bonnet, Jean Clairambault [BANG project-team], Xavier Dupuis [COMMANDS project-team], Pierre Hirsch [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Jean-Pierre Marie [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Faten Merhi [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris], Silviu Niculescu, Hitay Özbay [Bilkent University, Ankara, Turkey], Ruoping Tang [INSERM Paris (Team18 of UMR 872) Cordeliers Research Centre and St. Antoine Hospital, Paris].

In order to better take into account physiological phenomena as well as better understand the effect of the new anti-FLT3 therapy for AML, we have modified the model M. Adimy and F. Crauste in two ways [88]:
- we have introduced a modeling of quick self-renewal of cells in each stage of maturation.
- we have modeled each phase of the proliferating compartment (that is $G_1$, $S$, $G_2$ and $M$) separately. For the time being, only the $M$-phase is supposed to have a fixed time duration as it is well-known that the short time necessary to perform mitosis is hardly submitted to any variation.

In parallel to this modeling task, Faten Merhi and Annabelle Ballesta have performed experiments in order to identify parameters of the model. These experiments (which will continue in 2012) tend to show that we will converge to a patient-dependant model.

6.22. Chronic myelogenous leukemia  
Participants: Frédéric Mazenc, Siviu Niculescu, Peter Kim [Univ. of Sydney].
The paper \[26\] focuses on the stability analysis of a delay-differential system encountered in modeling immune dynamics during imatinib treatment for chronic myelogenous leukemia (CML). A simple algorithm is proposed for the analysis of delay effects on the stability. Such an algorithm takes advantage of the particular structure of the dynamical interconnections of the model. The analysis shows that the model yields three fixed points, two of which are always unstable and one of which is sometimes stable. The stable fixed point corresponds to an equilibrium solution in which the leukemia population is kept below the cytogenetic remission level. This result implies that, during imatinib treatment, the resulting anti-leukemia immune response can serve to control the leukemia population. However, the rate of approach to the stable fixed point is very slow, indicating that the immune response is largely ineffective at driving the leukemia population towards the stable fixed point. To extend the stability analysis with respect to the delay parameter, we conduct a global nonlinear analysis to demonstrate the existence of unbounded solutions. We provide sufficient conditions based on initial cell concentrations that guarantee unbounded solutions and comment on how these conditions can serve to predict whether imatinib treatment will result in a sustained remission based on a patient’s initial leukemia load and initial anti-leukemia $T$ cell concentration.

### 6.23. Control of a model of human heart

**Participants:** Frédéric Mazenc, Michael Malisoff [Louisiana State University], Marcio de Queiroz [Louisiana State University].

We worked on the control of human heart rate during exercise \[27\], which is a problem that has implications for the development of protocols for athletics, assessing physical fitness, weight management, and the prevention of heart failure. We provided new stabilization techniques, based on the notion of tracking, for a recently-proposed nonlinear model for human heart rate response that describes the central and peripheral local responses during and after treadmill exercise. The control we proposed respect the sign constraint imposed by the model and we proposed observers to cope with the case (important from a practical point of view) where some of the variables are not measured.

### 6.24. Marine Robotic Surveys

**Participants:** Frédéric Mazenc, Michael Malisoff [Louisiana State University], Fumin Zhang [Georgia Tech.].

The works \[24\], \[61\] was inspired by the recent Deepwater Horizon oil spill disaster. The goal was to develop and implement robotic surveying methods to evaluate the immediate and longer term environmental impacts of the oil spills. It was joint with Michael Malisoff from the LSU and a Georgia Tech robotics team led by Fumin Zhang. Robotic surveying methods provide a low cost and convenient way to collect data in marsh areas that are difficult to access by human based methods. We designed strict Lyapunov functions that made it possible to use ISS to quantify the robustness of collision avoiding curve tracking controllers under controller uncertainty. The controllers are designed to keep the robot a fixed distance from, but moving parallel to, a two dimensional curve. Four challenges in applying ISS to curve tracking are (a) the need to restrict the magnitudes of the uncertainty to keep the state in the state space and build a strict Lyapunov function, (b) the likelihood of time delays in the controllers in real time applications, (c) possible parameter uncertainty such as unknown control gains, and (d) generalizations to three dimensional curve tracking. We overcame challenge (a) by finding maximum bounds on the perturbations that maintain forward invariance of a nested family of hexagons that fill the state space and transforming a nonstrict Lyapunov function into a strict Lyapunov function on the full state space. To address challenge (b), we used a Lyapunov-Krasovskii approach from \[119\] to convert the strict Lyapunov function into a Lyapunov-Krasovskii functional. This led to an upper bound on the admissible controller delay that can be introduced into the controller while still maintaining ISS.
6. New Results

6.1. Fundamental results and algorithms: distributed planning

Participants: Eric Fabre, Loig Jézéquel.

A planning problem consists in organizing some actions in order to reach an objective. Formally, this is equivalent to finding a path from an initial state to a goal/marked state in a huge automaton. The latter is specified by a collection of resources, that may be available or not (which defines a state), and actions that consume and produce resources (which defines a transition). In the case of optimal planning, actions have a cost, and the objective is to find a path of minimal cost to the goal.

Our interest in this problem is threefold. First, it is naturally an instance of a concurrent system, given that actions have local effects on resources. Secondly, it is a weak form of an optimal control problem for a concurrent/distributed system. Finally, we are interested in distributed solutions to such problems, which is an active topic in the planning community under the name of “factored planning.”

Our previous contributions to the domain was the first optimal factored planning algorithm [61]. The main idea is to represent a planning problem as a network of interacting weighted automata, the objective being to jointly drive all of them to a target state, while minimizing the cost of their joint trajectory. We have developed and tested [68] a distributed algorithm to solve this problem, based on a weighted automata calculus, and that takes the shape of a message passing procedure. Components perform local computations, exchange messages with their neighbors, in an asynchronous manner, and the procedure converges to the path that each component should follow. The optimal global plan is thus given as a tuple of (compatible) local plans, i.e. a partial order of actions.

In 2011, we have extended this framework in two directions. In terms of modelling, first. In most planning problems, some actions consume/produce resources, but also are enabled by the presence of other resources, that they only read but not consume. We have proposed to model this feature under the form of networks of automata with read arcs. Interactions then take the form of synchronous actions, as previously, but also the form of readings: a component may only be allowed to fire some local transition if another component is in a specific state. Our distributed planning approach has then been extended to this new model of distributed systems [38].

The second improvement is algorithmic. So far, our distributed optimal planning algorithm computes all possible distributed plans, in a factored form. This contrasts with the philosophy of planning algorithms, that look for one plan only, and organize the computations to quickly reach the best plan. In other words, most planning algorithms are based on a common ground known as the A-star algorithm, a depth-first search procedure in a graph, guided by a heuristic function that estimates the remaining cost to reach the goal. We have developed a truly distributed version of this algorithm, to perform a search on a product graph. Each component runs an A-star procedure to find a path to its goal, taking into account the costs of its neighbors in order to guarantee that all components converge to local plans that are compatible and jointly optimal.

6.2. Fundamental results and algorithms: communication with messages and scenarios

Participants: Loïc Hélouët, Rouwaida Abdallah, Claude Jard, Blaise Genest.

In this paragraph, we collect our fundamental results regarding the models and algorithms we use for communicating systems, and in particular, scenarios.
A major challenge with models communicating with messages (e.g., scenarios) is to exhibit good classes of models allowing users to specify easily complex distributed systems while preserving the decidability of some key problems, such as diagnosis, equality and intersection. Furthermore, when these problems are decidable for the designed models, the second challenge is to design algorithms to keep the complexity low enough to allow implementation in real cases.

This year, we have considered analysis for a timed extension of scenarios called Time-constrained MSCs and implementation techniques that take scenarios as an input model and output an equivalent distributed implementation.

The first part of our work is the study of Time-Constrained MSC graphs (TC-MSGS for short). Time-constrained MSCs (TC-MSCs) are simply MSCs decorated with constraints on the respective occurrence dates of events. The semantics of a TC-MSC $T$ is a dated MSC, that is a MSC where events are associated with an occurrence date. For a given TC-MSC, there can be an infinite set $L(T)$ of dated MSCs satisfying its constraints. Note however that some time-constraints in a TC-MSC may not be satisfiable, and hence $L(T)$ can simply be empty. TC-MSCs can be extended by composition mechanisms such as TC-MSC graphs. TC-MSC graphs are simply automata labeled by TC-MSC. Each path $\rho$ of a TC-MSC $G$ is associated with a TC-MSC $T_\rho$ obtained by concatenation of TC-MSC along $\rho$. The language $L(G) = \bigcup_{\rho \text{ path of } G} L(T_\rho)$ of a TC-MSC Graph is then the union of all dated MSCs associated to paths of $G$. Because of inconsistent timing constraints, some path may have no possible realization (i.e., $L(T_\rho = \emptyset$). One can even design a MSC Graph $G$ such that $L(G) = \emptyset$ - such TC-MSC graph is clearly inconsistent-. It has been shown [64] that checking whether $L(G) = \emptyset$ is an undecidable problem in general, but can be decided for the restricted subclass of regular TC-MSC graphs (that have the expressive power of event-count timed automata). We have proposed two restrictions allowing for the decision of emptiness. The first one is $K$-drift boundedness, which imposes for a fixed integer $K$ that for every $T_\rho$ there exists one dated realization such that for every pair of events $e, f$ appearing in the same transition of $G$, the dates of $e$ and $f$ differ by at most $K$. We have shown that $K$-drift boundedness is decidable in a symbolic and efficient way, and that for $K$-drift bounded TC-MSC graphs, emptiness is decidable [52]. This extends decidability results beyond regular specifications. The second restriction is $K$-non-zenoness, which imposes that for a fixed $K$, for every path $\rho$ of $G$, there exists one realization such that at every date $d$, at most $K$ events occur between date $d$ and $d + 1$. When a TC-MSC graph is $A$-drift-bounded and $B$-non-zeno, then $L(G)$ has a regular set of representants, which opens the way for more involved model-checking applications [51].

The second part of our work is the study of realistic implementation of scenarios. The main idea is to propose distributed implementation (communicating state machines) of High-level MSCs that do not contain deadlocks, and behave exactly as the original specification. It is well known that a simple projection of a HMSC on each of its process to obtain communicating finite state machines results in an implementation with more behaviors than the original specification. An implementation of a HMSC $H$ is considered as consistent if and only if it exhibits the same prefix closed set of behaviors as $H$. We have studied how such projection with additional local controllers allows the distributed synthesized behavior to remain consistent with the original specification. This work has been implemented in our scenario prototype (see the Software section). As usually for scenarios, the synthesis algorithm works for a particular syntactic class of scenarios, namely the class of local HMSCs. Roughly speaking, in local HMSC, a decision to behave according to a scenario or another is always taken by a single participant. The deciding process need not be the same at each choice. This class is a sensible restriction of HMSCs, as distributed choices can not be implemented without additional synchronization among processes [53].

Last, we have extended existing results on diagnosis from scenarios [15]. We have shown that when a distributed implementation is instrumented with software probes that publish their observations while the system is running, and when the system is modeled as a High-level MSC, then diagnosis can be expressed as a new HMSC the executions of which are all explanations of the observation. The construction of diagnosis can be performed offline or online, and we have considered the conditions under which online diagnosis can run with finite memory.
6.3. Fundamental results and algorithms: timed models

**Participants:** Claude Jard, Aurore Junier, Akshay Sundararaman.

Our works in that subject concern Time Petri Nets (TPNs) and Network Calculus. With TPNs, we are particularly interested in symbolic unfoldings (extended with parameters). Possible applications are supervision of distributed timed systems [8] and testing of concurrent systems (work done in collaboration with Stefan Haar, INRIA-LSV in Cachan).

The article [26] was made during the internship of the master degree of Aurore Junier under the supervision of Anne Bouillard (ENS Paris). It uses a (min, plus)-algebra to define a worst-case delay bound for networks where flows have fixed priorities.

After that, we studied a well-known problem: detection of congestion and failure in networks. The idea was to find an efficient and deterministic method that is very reactive and takes little memory space. Such a method does not exist for now and is an important issue for Alcatel-Lucent. We achieved a solution that solves this problem based on the analysis of flows behaviour. This work is part of the work done within the Alcatel-Lucent-Inria joint lab and a patent is being established.

We are also studying the way buffers of routers can increase. The objective is to find a method that can detect if sizes of buffers can dangerously increase on a defined topology. We start by looking at Link State Advertisements (LSA) in the OSPF protocol. We represent the topology and a part of the protocol by a Time Petri Net and try to infer parameters ensuring stability.

6.4. Fundamental results and algorithms: dynamic epistemic logic

**Participants:** Guillaume Aucher, François Schwarzentruber.

Dynamic Epistemic Logic (DEL) deals with the representation and the study of knowledge and belief change in a multi-agent setting. The core representative task of this logical framework can be split up in three parts: 1/ the initial global state of the distributed system, 2/ an event occurring in this system, 3/ a product update taking as argument these two representations and yielding a new representation of the new global state of the distributed system. Therefore, we can express uniformly within the DEL framework epistemic statements about:

(i) what is true about an initial state
(ii) what is true about an event occurring in this initial state
(iii) what is true about the resulting state after the event has occurred.

We axiomatized within the DEL framework what we can infer about (iii) given (i) and (ii), what we can infer about (ii) given (i) and (iii), and what we can infer about (i) given (ii) and (iii). Given three logical formulas $\phi$, $\phi'$ and $\phi''$ describing respectively (i), (ii) and (iii), we also showed how to build three formulas that capture respectively all the information which can be inferred about (iii) from $\phi$ and $\phi'$, all the information which can be inferred about (ii) from $\phi$ and $\phi''$, and all the information which can be inferred about (i) from $\phi'$ and $\phi''$. We showed how our results extend to other modal logics than the minimal modal logic $K$. These results are to appear in [9] and [10]. In [19], we also provided a tableau method deciding whether such inferences are valid. We implemented it in LOTRECscheme and showed that this decision problem is NEXPTIME-complete. This work contributes to the proof theory and the study of the computational complexity of DEL which have rather been neglected so far.

Application to fault localization in IMS network (see the UNIVERSELF project) has started. The various agents involved in an IMS network (clients, assistance, administrators...) have a partial view of the network and so need to communicate their partial knowledge of the network to each other in order to localize the fault in the network (each communication having possibly a different cost). One of the main problems is to determine which communication should occur and which agent should be queried so that the fault is eventually localized. This problem can naturally be expressed in the DEL framework. We have shown how the initial state of an IMS network representing the knowledge of each agent can be represented by a particular kind of epistemic
model (i) and how the desired state where the fault is localized can be expressed by a logical formula (iii). The problem amounts to determining which communication or sequence of communications should occur (ii) so that one passes from the initial epistemic model (i) to another epistemic model where the fault is localized (iii), and also to determine if such a communication or sequence of communications is possible. We have focused so far on the case of a single communication, but we plan to extend it to a sequence of communications. Further theoretical work still needs to be done to address the issue of sequential communication.

In parallel to this work, we also axiomatized different notions of knowledge and belief which are defined by means of a ‘sphere’ semantics. This work is the result of an invited contribution and is to appear in [48].

6.5. Fundamental results and algorithms: statistical model checking

Participants: Sean Sedwards, Cyrille Jégourel, Axel Legay.

Our work on statistical model checking (SMC) avoids an explicit representation of the state space by building a statistical model of the executions of a system and giving results within confidence bounds. The key challenges of this approach are to reduce the length (simulation steps and cpu time) and number of simulation traces necessary to achieve a result with given confidence. Rare properties pose a particular problem in this respect, since they are not only difficult to observe but their probability is difficult to bound. A further goal is to make a tool where the choice of modelling language and logic are flexible.

We have developed the prototype of a compact, modular and efficient SMC platform which we have named PLASMA (PLatform for Statistical Model checking Algorithms). PLASMA incorporates an efficient discrete event simulation algorithm and features an importance sampling engine that can reduce the necessary number of simulation runs when properties are rare. We have found that PLASMA performs significantly better than PRISM (the de facto reference probabilistic model checker) when used in a similar mode: PLASMA’s simulation algorithm scales with a lower order and can handle much larger models. When using importance sampling, PLASMA’s performance with rare properties is even better.

6.6. Fundamental results and algorithms: quantitative model checking and quantitative specification Theories

Participants: Uli Fahrenberg, Axel Legay.

Model checking of systems deals with the question whether a given model of a computer system satisfies the properties one might want to require of it. This is a well-established and successful approach to formal verification of safety-critical computer systems.

When the models of the systems contain quantitative information, the model checking problem becomes complicated by the fact that in most cases, quantitative properties of the systems do not need to be satisfied exactly. Indeed, the model or the properties might be subject to measurement error, or probabilistic information might only be an approximation. In this case, it is of little use to know whether or not a model satisfies a specification precisely; what is needed instead is a notion of satisfaction distance: a measure which can assess to which extent a quantitative model satisfies a quantitative specification.

In other words, what is needed is a notion of satisfaction which is robust in the sense that small deviations in the model or the specification only lead to small changes in the outcome of the model checking question. We have published work on such distances in the papers [37], [34].

For more elaborate reasoning about distributed systems or systems-of-systems, an important role is played by specification theories. Such systems are often far too complex to reason about, or model-check, as a whole, and additionally they might be composed of a large number of components which are implemented by different vendors. Hence one needs methods for compositional reasoning, which allow to infer properties of a system from properties of its components, and for incremental design, which allow to synthesize and refine specifications in a step-wise manner.
Such specification theories are by now well-established e.g. in the incarnations of interface theories and modal transition systems. Additionally to defining a formalism for describing and model-checking specifications, they provide notions of refinement of specifications, logical conjunction of specifications, and structural composition and quotient.

When the models and specifications contain quantitative information, all the above notions need to be made robust. One needs to introduce a quantitative version of refinement, and the operations on specifications need to be continuous with respect to refinement distance: compositions of specifications with small refinement distance need themselves to have small refinement distance. We have published work on these issues in the papers [21], [35]; additionally, two other papers within this research area are currently under submission.

6.7. Specific studies: Web services orchestrations

Participants: Ajay Kattepur, Albert Benveniste, Claude Jard.

Web services orchestrations and choreographies refer to the composition of several Web services to perform a co-ordinated, typically more complex task. We decided to base our study on a simple and clean formalism for WS orchestrations, namely the Orc formalism proposed by Jayadev Misra and William Cook [71].

Main challenges related to Web services QoS (Quality of Service) include: 1/ To model and quantify the QoS of a service. 2/ To establish a relation between the QoS of queried Web services and that of the orchestration (contract composition); 3/ To monitor and detect the breaching of a QoS contract, possibly leading to a reconfiguration of the orchestration. Typically, the QoS of a service is modeled by a contract (or Service Level Agreement, SLA) between the provider and consumer of a given service. To account for variability, in previous years, we proposed soft probabilistic contracts specified as probabilistic distributions involving the different QoS parameters; we studied contract composition for such contracts; we developed probabilistic QoS contract monitoring; and we studied the monotonicity of orchestrations; an orchestration is monotonic if a called service improves its performance, then so does the overall orchestration.

This year, in the framework of the Associated Team FOSSA with the University of Texas at Austin (John Thywissen (PhD), Jayadev Misra and William Cook), we have extended our approach to general QoS parameters, i.e., beyond response time. We now encompass composite parameters, which are thus only partially, not totally, ordered. We have developed a general algebra to capture how QoS parameters are transformed while traversing the orchestration and we have extended our study of monotonicity. Finally, we have developed corresponding contract composition procedures. John Thywissen (from UT Austin) and Ajay Kattepur have started extending the Orc language and execution engine to support QoS according to our theory. This extension mainly consists in 1/ providing a rich type system to declare QoS domains and related algebra, and 2/ providing a new operator for Orc that allows for selecting competing returns from different sites on the basis of their QoS. A journal paper is under revision.

A key task in extending Orc for QoS was to extend the Orc engine so that causalities between the different site calls are made explicit at run time while execution progresses. This benefits from our previous work on Orc semantics, but a new set of rules has been proposed to generate causalities in an efficient way, by covering new features of the language. This is joint work of Claude Jard, Ajay Kattepur and John Thywissen from Austin. A publication is in preparation.

Besides this main line of work, other topics have been addressed by Ajay Kattepur as part of his thesis.

- In [41], we study variability of composite services. We model variability as a feature diagram (FD) that captures all valid configurations of its orchestration. Then, we apply pair-wise testing to sample the set of all possible configurations to obtain a concise subset. Finally, we test the composite service for selected pairwise configurations for a variety of QoS metrics such as response time, data quality, and availability. Using two case studies, Car crash crisis management and e-Health management, we demonstrate that pairwise generation effectively samples the full range of QoS variations in a dynamic orchestration. The pairwise sampling technique eliminates over 99% redundancy in configurations, while still calling all atomic services at least once.
• Web services orchestrations conventionally employ exhaustive comparison of runtime quality of service (QoS) metrics for decision making. The ability to incorporate more complex mathematical packages is needed, especially in case of workflows for resource allocation and queuing systems. By modeling such optimization routines as service calls within orchestration specifications, techniques such as linear programming can be conveniently invoked by non-specialist workflow designers. Leveraging on previously developed QoS theory, we propose the use of a high-level flexible query procedure for embedding optimizations in languages such as Orc. The Optima site provides an extension to the sorting and pruning operations currently employed in Orc. Further, the lack of an objective technique for consolidating QoS metrics is a problem in identifying suitable cost functions. We use the analytical hierarchy process (AHP) to generate a total ordering of QoS metrics across various domains. With constructs for ensuring consistency over subjective judgements, the AHP provides a suitable technique for producing objective cost functions. Using the Dell Supply Chain example, we demonstrate the feasibility of decision making through optimization routines, specially when the control flow is QoS dependent. This work was published in [39].

• With web services quality of service (QoS) modeled as random variables, the accuracy of sampled values for precise service level agreements (SLAs) come into question. Samples with lower spread are more accurate for calculating contractual obligations, which is typically not the case for web services QoS. Moreover, the extreme values in case of heavy-tailed distributions (e.g., 99.99 percentile) are seldom observed through limited sampling schemes. To improve the accuracy of contracts, we propose the use of variance reduction techniques such as importance sampling. We demonstrate this for contracts involving demand and refuel operations within the Dell supply chain example. Using measured values, efficient forecasting of future deviation of contracts may also be performed. A consequence of this is a more precise definition of sampling, measurement and variance tolerance in SLA declarations. This work was published in [40].

6.8. Specific studies: active documents and web services

Participants: Albert Benveniste, Loïc Hélouët, Benoît Masson.

Active Documents have been introduced by the GEMO team at INRIA Futurs, headed by Serge Abiteboul, mainly through the language Active XML (or AXML for short). AXML is an extension of XML which allows to enrich documents with service calls or sc’s for short. These sc’s point to web services that, when triggered, access other documents; this materialization of sc’s produces in turn AXML code that is included in the calling document. One therefore speaks of dynamic or intentional documents. In the past years, we have collaborated with the GEMO team to study a distributed version of their language.

This year, we have addressed the problem of distributed documents from a different point of view. Starting from our knowledge of distributed active XML (DAXML), we have first proposed a Petri Net semantics for a subset of DAXML [43], and then considered compositionality issues [54]. Compositionality in services can be addressed in several ways: first one have to ensure that modules that provide services an modules that use them agree on the data that they exchange. This notion is called composability of modules. However, composability does not ensure that a service always terminates (i.e., it returns a result to the caller) when it is invoked with appropriate data. Composability plus termination of services is called compatibility. We have shown that under some restrictions on the recursion in active documents, on the data; and upon the assumption that services use positive guards, composability is decidable. This work has also helped us isolate the core idea behind active documents, and propose a model for them called Docnets. Docnets are dynamic Petri nets which places are typed, which transitions are guarded computable type transformations, and which can receive new tokens from their environment. Docnet modules compose well, and if their closure by type transformation is finite, their compatibility is decidable. This work led to a publication [43].

Within the context of the DST associated team, we have proposed a new model, that combines arbitrary numbers of finite workflows, hence allowing for the definition of sessions. Sessions is a central paradigm in web-based systems. As messages exchange between two sites need not follow the same route over the net, a site can not rely on the identity of machines to uniquely define a transaction. This unique identification is
essential, as commercial site, for instance, need to manage several interactions at a given time. The current

trend, as in BPEL, is to associate a unique identifier to each session. Modeling realistic session hence often

forces to include session counters, and hence render most of properties undecidable. The session formalism

studied in 2011 can be seen as a mix of BPEL and ORC elements, but was designed to keep several properties
decidable. The strength of this formalism is to allow designing systems that use sessions without the obligation
to provide identifiers. The formalism has the expressive power of reset Petri nets for which coverability is
decidable. This is sufficient to decide whether a set of agent can be found in some bad configuration during
the lifetime of a system. This joint work with Ph. Darondeau from the S4 Team, and with M. Mukund from
the Chennai Mathematical Institute led to a publication in the ATVA conference [28].

Our last work on Web-services was the development of an experimental platform. During his post-doc, Benoît
Masson has designed a distributed Active XML engine, which can be distributed over a network. We have
built a lightweight experimentation platform, made of four linux machines, that run DAXML services and
communicate with one another. Simultaneously, R. Abdallah has designed a synthesis tool to generate REST
services from High-level Message Sequence Charts. These services were successfully tested on the platform.

6.9. Specific studies: security and privacy

Participants: Guillaume Aucher, Blaise Genest.

We have worked on three parallel lines of research related to security and privacy. The first line deals with
problems of delegation and revocation in distributed systems. The second line deals with problems of
compliance of a system with respect to a privacy regulation expressed in a language combining epistemic,
deontic and dynamic modalities. The third line tackles the minimal information needed at runtime to e.g.
break in a (stochastic) system.

6.9.1. Delegation and revocation in distributed systems

Together with Steve Barker from King’s College London, Guido Boella from the University of Torino, Valerio
Genovese and Leon van der Torre from the University of Luxembourg, we defined a (sound and complete)
propositional dynamic logic to specify and reason about delegation and revocation schemes in distributed
systems. This logic describes formally a family of delegation and revocation models that are based on the work
of [65]. We extended our logic to accommodate an epistemic interpretation of trust. What emerges from this
work is a rich framework of formally well-defined delegation and revocation schemes that accommodates an
important trust component. In particular, we showed how to automatically reason about whether an agent is
authorized to do an operation on an object and about the authorization policy resulting from the execution
of a sequence of actions. We used our logical framework to give a formal account of eight different types of
revocation schemes informally introduced in previous literature. This work is published in [18].

6.9.2. Privacy policy with modal logic: the dynamic turn

As explained in Section 6.4, we want to define a logical language to specify privacy policies which is
close to the natural language. In general, privacy policies can be defined either in terms of permitted and
forbidden knowledge, or in terms of permitted and forbidden actions. For example, it may be forbidden to
know the medical data of a person, or it may be forbidden to disclose these data. Implementing a privacy
policy based on permitted and forbidden actions is relatively easy, since we can add a filter on the system
checking the outgoing messages. Such a filter is an example of a security monitor. If the system attempts
to send a forbidden message, then the security monitor blocks the sending of that message. However, the
price to pay for this relatively straightforward implementation is that it is difficult to decide which actions are
permitted or forbidden so that a piece of information is not disclose. We are therefore interested in privacy
policies expressed in terms of permitted and forbidden knowledge. Expressing a privacy policy in terms of
permitted and forbidden knowledge is relatively easy, since it lists the situations, where, typically, it may
not be permitted to know some sensitive information. Implementing a privacy policy based on permitted and
forbidden knowledge is quite difficult, since the system has to reason about the relation between permitted
knowledge and actions. The challenge is that the exchange of messages changes the knowledge, and the
security monitor therefore needs to reason about these changes. This inference problem is already non trivial with a static privacy policy, and becomes challenging when privacy policies can change over time. Together with Guido Boella and Leon van der Torre, we therefore introduced a dynamic modal logic that permits not only to reason about permitted and forbidden knowledge to derive the permitted actions, but also to represent explicitly the declarative privacy policies together with their dynamics. The logic can be used to check both regulatory and behavioral compliance, respectively by checking that the permissions and obligations set up by the security monitor of an organization are not in conflict with the privacy policies, and by checking that these obligations are indeed enforced. We also showed that the complexity of the model checking problem is quadratic in the size of the model and the formula and provided the corresponding model-checking algorithms. This work is published in [11].

6.9.3. Minimal information needed

Together with Nathalie Bertrand from Vertecs, we tackle the problem of the minimal information a user needs at runtime to achieve a simple goal, modeled as reaching an objective with probability one [25]. The natural question is then to minimize the additional information the user needs to fulfill her objective. This optimization question gives rise to two different problems, whether we consider to minimize the worst case cost, or the average cost. On the one hand, concerning the worst case cost, we show that efficient techniques from the model checking community can be adapted to compute the optimal worst case cost and give optimal strategies for the users. On the other hand, we show that the optimal average price (a question typically considered in the AI community) cannot be computed in general, nor can it be approximated in polynomial time even up to a large approximation factor. Following this negative results, we investigate with P.S. Thiagarajan’s group at NUS, Singapore basic algorithms of the AI community to infer the exact probability in (compact) stochastic systems. We proposed in [45] a simple parametrized extension of the usual Factored Frontier algorithm in order to choose the desired accuracy of the algorithm, at the cost of additional but manageable computations. We showed its benefit when dealing with biological pathways.

6.10. Specific studies: network maintenance

Participants: Eric Fabre, Carole Hounkonnou.

This work represents part of our activities within the research group “High Manageability,” supported by the common lab of Alcatel-Lucent Bell Labs (ALBLF) and INRIA. It concerns a methodology for the graceful shut down and restart of routers in OSPF networks, one of the core protocols of IP networks. A methodology has been proposed to safely switch off the software layer of a router while still maintaining this router in the forwarding plane: the router still forwards packets, but is not able to adapt its routing table to changes in network conditions or topology. Nevertheless, it is possible to check whether this frozen router is harmless or can cause packet losses, through a centralized or distributed algorithm. And if ever it puts the network at risk, minimal patches can be set up temporarily until the router comes back to normal activity. This avoids running twice a global OSPF update at all nodes (once for shutdown of the equipment, one for restart). There is a patent project on this activity, that we don’t detail more here.

6.11. Specific studies: network and service diagnosis

Participants: Eric Fabre, Carole Hounkonnou.

This work represents part of our activities within the research group “High Manageability,” supported by the common lab of Alcatel-Lucent Bell Labs (ALBLF) and INRIA. It is also supported by the UniverSelf EU integrated project, and conducted in relation with Orange Labs.

The objective is to develop a framework for the joint diagnosis of networks and of the supported services. We are aiming at a model-based approach, in order to tailor the methods to a given network instance and to follow its evolution. We also aim at active diagnosis methods, that collect and reason on alarms provided by the network, but that can also trigger tests or the collection of new observations in order to refine a current diagnosis.
In 2011, the main effort was dedicated to a key and difficult part of this approach: the definition of a methodology for self-modelling. This consists in automatically building a model of the monitored system, by instantiating generic network elements. There are several difficulties to address:

- The model must capture several layers, from the physical architecture up to the service architecture and its protocols. As a case-study, we have chosen VoIP services on an IMS network, deployed over a wired IP network.
- The model should be hierarchical, to allow for multiscale reasoning, and to reflect the intrinsic hierarchical nature of the managed network.
- The model should be generic, i.e. obtained by assembling component instances coming from a reduced set of patterns, just like a text is obtained by assembling words.
- The model should be adaptive, to capture the evolving part of the network (e.g. introduction of new elements) but also its intrinsically dynamic nature (e.g. opened/closed connections).
- The model should display the hierarchical dependency of resources, specifically the fact that lower-level resources are assembled to provide a support to a higher level resource or functionality.
- The model should allow progressive discovery and refinement: for a matter of size, it is not possible to first build a model of the complete network and then monitor it; one must adopt an approach where the model is build on-line, and where the construction is guided by the progress of the diagnosis algorithms.

The first elements of a methodology achieving these objectives have been designed in 2011. The next efforts will aim at refining the grammar of this model, for our specific case study, and at developing the dedicated diagnosis algorithms. For the latter, we envision a new setting of hierarchical and generic Bayesian networks, in order to capture the dependencies between network elements at different granularities.
6. New Results

6.1. Exposure to diffusion in dynamic networks

In many contexts, complex networks are subject to diffusion phenomenon, like spreading of epidemics in human groups or the diffusion of information in social networks. Often, the underlying network is dynamic, that is, its links change along time. Clearly, the dynamics of links has an influence on the diffusion phenomenon taking place over the network. A first step to understand these relationship is to determine which nodes of the dynamic network are more likely to be reached by a diffusion process. We designed new notions of exposure in order to do it, based either on contacts, paths or flows in a dynamic network. In particular, the notion of dynamic flow, which we introduced, has given interesting preliminary results. We computed the exposition scores of nodes of real world dynamic networks and showed that it is correlated to the likelihood of nodes to be affected by a diffusion in the classical SI model.

6.2. Aggregation of temporal graph series

A very natural and extensively used way to represent a dynamic network, where links change along time, is to build a graph series : the series of snapshots of the network taken at different time of its evolution. The way to do so is to aggregate all the contact information on a time window into a single graph : that is, we put an edge between u and v in the graph if they are in contact at least once during the considered time window. Doing so for disjoint windows of equal length which cover the whole period of study, we obtain a series of graphs representing the dynamics of the network. A question remain : how one should choose the length of the aggregation window? The problem is critical since depending on the choice made, the properties of the dynamic network are different and the conclusion derived from its analysis may change. We design a systematic method to estimate the maximum possible aggregation length. Up to our knowledge, this is the first method addressing the problem. It is based on activity rate of dynamic paths in the dynamics. On a dynamic path, only some time steps are used to move within the network. When the aggregation time is short, the activity rate of paths is close to zero and it tends to 1 when this time grow until the whole period of experiments. Between the two behaviors, we showed that there is a phase transition that we interpret as the moment when the properties of the dynamics are distorted because of the too long aggregation time.

6.3. Characterizing changes in dynamic networks

Very often, dynamic networks are described as time series of graphs. Many works focus on analyzing or capturing into models the properties of the graphs of the series. This approach has a clear limitation : it looses the relationships between the different graphs of the series, which however contain a key information on the dynamics. In order to get more insight in the relationships between the graphs of the series, we analyzed the structure of we call the difference graphs. The difference graph of two consecutive graphs $G_1, G_2$ of the series is the graph whose edge set is the symmetric difference of the edge sets of $G_1$ and $G_2$. In other words, this is exactly the graph of the pairs whose adjacency relationship changed from $G_1$ to $G_2$. We showed that the structure of difference graphs is very particular : their edges are concentrated around a small number of vertices. This shows that the changes between two graphs of the series are not spread everywhere in the network, but are due to changes of the neighborhood of only a small number of nodes of the network. We could show this fact by computing a graph parameter called Minimum Vertex Cover (MVC), which is NP-complete to compute. Using a preprocessing step, we could compute the exact value of this parameter for all difference graphs of real world series. We obtained that the value of the MVC on difference graphs is very small compared to the expected value on a random graph with same density. We also showed that the most common models of dynamic networks do not capture this property of concentration of edges in the difference graphs of the series. Our result shed light on the way dynamic networks evolve and open the way to significant improvement of existing models.
6.4. Community detection: dynamic and overlapping

Overlapping community detection is a popular topic in complex networks. Comparing to disjoint community structure, overlapping community structure is more reasonable to describe networks at a macroscopic level. Overlaps shared by communities play an important role in combining different communities. We propose two different approaches to detect overlaps: fuzzy community detection and overlapping community detection. The former estimates membership degree of node belonging to community, and the latter allows node to be shared by communities. In this paper, a fuzzy detection and a clique optimization are introduced. Experimental studies in synthetic networks show fuzzy detection yields meaningful information in stability and hierarchy of communities. And clique optimization is efficient in capturing overlapping nodes. Applications in real networks whose community structure is not well-known find that overlapping clusters found by our fuzzy detection can provide different views than general overlapping nodes to characterize overlaps.

Although community detection has drawn tremendous amount of attention across the sciences in the past decades, no formal consensus has been reached on the very nature of what qualifies a community as such. We take an orthogonal approach by introducing a novel point of view to the problem of overlapping communities. Instead of quantifying the quality of a set of communities, we choose to focus on the intrinsic community-ness of one given set of nodes. To do so, we propose a general metric on graphs, the cohesion, based on counting triangles and inspired by well established sociological considerations. The model has been validated through a large-scale online experiment called Fellows in which users were able to compute their social groups on Facebook and rate the quality of the obtained groups. By observing those ratings in relation to the cohesion we assess that the cohesion is a strong indicator of users subjective perception of the community-ness of a set of people.

6.5. Cross-Layer Optimization for Software Layer to Physical Device layer Mapping

We develop a generic method for mapping software state machines used in protocol stacks and communication layers directly to hardware communication devices using their specifications. The proposed method can handle power modes and timing constraints imposed by hardware devices in order to optimize the software code running on top of the device. This property allows the use of the hardware device in its lowest power consumption mode while making sure that real time constraints are met. To validate the merit of the proposed method, the generated code and power consumption gain, we evaluate the optimizations that can be done on a BMAC medium access control layer used in wireless sensor networks using a large scale experimental testbed. The results show that an average energy consumption gain of up to 60% at the radio level can be achieved.
DOLPHIN Project-Team

6. New Results

6.1. Generalizing dual-feasible functions to the multi-dimensional case
Participant: F. Clautiaux.

Dual-feasible functions have been used in the past to compute lower bounds and valid inequalities for different combinatorial optimization and integer programming problems. Until now, all the dual-feasible functions proposed in the literature were 1-dimensional functions. We extended the principles of dual-feasible functions to the m-dimensional case by introducing the concept of vector packing dual-feasible function. We explored the theoretical properties of these functions in depth, and we proposed general schemes for generating some instances of these functions. Additionally, we proposed and analyzed different new families of vector packing dual-feasible functions. All the proposed approaches were tested extensively using benchmark instances of the 2-dimensional vector packing problem. Our computational results show that these functions can approximate very efficiently the best known lower bounds for this problem and improve significantly the convergence of branch-and-bound algorithms.

6.2. Aggregation algorithms for network flow mathematical models
Participant: F. Clautiaux.

We designed a general framework for solving very large network flow mathematical models that use a pseudo-polynomial number of variables. It is based on an initial aggregation of the vertices of the model and its iterative refinement using different optimization techniques. This led to large improvements for a special case of vehicle routing problem. Several theoretical questions regarding convergence, worst-case analysis and approximation algorithms are raised by our work and are now under study.

6.3. New Price Setting models in the Energy Field
Participant: L. Brotcorne.

The electricity supply industry is facing in many countries a restructuring process towards deregulation and competition. In that context classical marginal cost based approaches based on estimation of cost production function and demand functions are not well-suited anymore. Indeed, the energy prices have to be defined not only to retrieve the production costs but also in order to take into account the consumer behavior. Consumers make their choice of service, or of energy provider in order to minimize their disutility values. Failing to recognize that may lead to tremendous lack on revenues. In order to capture this hierarchical decision process where a leader (the energy provider) takes explicitly into account the reaction of a follower (the consumers) in his decision process (see for example [1]) the energy pricing problems addressed in this subject have been modeled as bilevel programs.

6.4. Bi-level formulation for a Long-Distance Freight Transportation Problem
Participants: M. Diaby, L. Brotcorne, E.-G. Talbi.

A company wants to convey different types of products from origin i to points of destination j. It can deliver the goods itself or hire a transport company, and subcontract part of the application. The transport company must offer attractive prices while aiming to maximize its profit. The aim of this problem is to determine rates that allow the carrier to maximize its revenues and remain affordable for the customer. The problem is modeled as a bilevel program at the first level, the carrier (leader) wants to maximize its revenues; at the second level, the client (follower) aims to minimize its expenses. A primal dual heuristic has been proposed to solve the problem.
6.5. Advances in Parallel Metaheuristics on GPU

**Participants:** Thé Van Luong, Nouredine Melab, El-Ghazali Talbi.

Nowadays, GPU computing has recently been revealed effective to deal with time-intensive problems. This new emerging technology is believed to be extremely useful to speed up many complex algorithms. One of the major issues for metaheuristics is to rethink existing parallel models and programming paradigms to allow their deployment on GPU accelerators. Generally speaking, the major issues we have to deal with are: the distribution of data processing between CPU and GPU, the thread synchronization, the optimization of data transfer between the different memories, the memory capacity constraints, etc. The contribution of our work is to deal with such issues for the redesign of parallel models of metaheuristics to allow solving of large scale optimization problems on GPU architectures. Our objective is to rethink the existing parallel models and to enable their deployment on GPUs.

Thereby, the new results involve a new generic guideline for building efficient parallel metaheuristics on GPU (e.g. tabu search, iterated local search, island model for evolutionary algorithms, pareto local search or multi-start algorithms). Our challenge is to come out with the GPU-based design of the whole hierarchy of parallel models. In this purpose, very efficient approaches are proposed for CPU-GPU data transfer optimization, thread control, mapping of solutions to GPU threads or memory management. These approaches have been exhaustively experimented using eleven optimization problems and six GPU configurations. Compared to a CPU-based execution, experiments report up to 80-fold acceleration for large combinatorial problems and up to 2000-fold speed-up for a continuous problem. The different works related to our work have been accepted in a dozen of publications, including the IEEE Transactions on Computers journal.

6.6. Parallel Evolutionary Algorithms for Energy-Aware Scheduling

**Participants:** Y. Kessaci, M. Mezmaz, N. Melab, E.-G. Talbi, D. Tuyttens.

In the last decades, energy becomes an increasingly important issue in computing and embedded systems. In computing systems, minimizing energy consumption can significantly reduce the amount of energy bills. The demand for computing systems steadily increases and the cost of energy continues to rise. In embedded systems, reducing the use of energy allows to extend the autonomy of these systems. In addition, the reduction of energy decreases greenhouse gas emissions. Therefore, many researches are carried out to develop new methods in order to consume less energy. In this work, we propose an overview of the main methods used to reduce the energy consumption in computing and embedded systems.

As a use case and to give an example of a method, this work describes our new parallel bi-objective hybrid genetic algorithm that takes into account the completion time and the energy consumption. In terms of energy consumption, the obtained results show that our approach outperforms previous scheduling methods by a significant margin. In terms of completion time, the obtained schedules are also shorter than those of other algorithms.

6.7. A Parallel Bi-objective Hybrid Metaheuristic for Energy-Aware Scheduling for Cloud Computing Systems

In this work, we investigate the problem of scheduling precedence-constrained parallel applications on heterogeneous computing systems (HCSs) like cloud computing infrastructures. This kind of applications was studied and used in many research works. Most of these works propose algorithms to minimize the completion time (makespan) without paying much attention to energy consumption. We propose a new parallel bi-objective hybrid genetic algorithm that takes into account, not only makespan, but also energy consumption. We particularly focus on the island parallel model and the multi-start parallel model. Our new method is based on dynamic voltage scaling (DVS) to minimize energy consumption. In terms of energy consumption, the obtained results show that our approach outperforms previous scheduling methods by a significant margin. In terms of completion time, the obtained schedules are also shorter than those of other algorithms. Furthermore, our study demonstrates the potential of DVS.
6.8. A Pareto-based GA for Scheduling HPC Applications on Distributed Cloud Infrastructures

**Participants:** N. Melab, E.-G. Talbi.

Reducing energy consumption is an increasingly important issue in cloud computing, more specifically when dealing with High Performance Computing (HPC). Minimizing energy consumption can significantly reduce the amount of energy bills and then increase the provider’s profit. In addition, the reduction of energy decreases greenhouse gas emissions. Therefore, many researches are carried out to develop new methods in order to consume less energy. In this work, we present a multi-objective genetic algorithm (MO-GA) that optimizes the energy consumption, \( CO_2 \) emissions and the generated profit of a geographically distributed cloud computing infrastructure. We also propose a greedy heuristic that aims to maximize the number of scheduled applications in order to compare it with the MO-GA. The two approaches have been experimented using realistic workload traces from Feitelson’s PWA Parallel Workload Archive. The results show that MO-GA outperforms the greedy heuristic by a significant margin in terms of energy consumption and \( CO_2 \) emissions. In addition, MO-GA is also proved to be slightly better in terms of profit while scheduling more applications.

6.9. An Hybrid Multiobjective Method to solve Biclustering of Microarray Data

**Participants:** L. Jourdan, K. Seridia, E.-G. Talbi.

In this work, we propose an multi-objective genetic algorithm (NSGA-II) with a heuristic to solve the biclustering problem of micro-array data. Due to the huge size of the datasets, we propose a new representation based on a string of integers and the associated operators. Experimental results on real data set show that our approach can find significant biclusters of high quality.

6.10. Flexibility and dynamic optimization

**Participants:** L. Jourdan, M. Khouadjia, E.-G. Talbi.

In this work we propose a new method that explicitly searches for routes that are flexible enough to allow easy adaptation after a new order has arrived. For that we propose a measure of flexibility, and show that better solutions can be obtained when the "planning horizon" for all subproblems is modified to take the flexibility of solutions into account.

6.11. Indicator-based Multi-objective Local Search

**Participant:** A. Liefooghe.

In the last few years, a significant number of multi-objective metaheuristics have been proposed in the literature in order to address real-world problems. Local search methods play a major role in many of these metaheuristic procedures. We adapt a recent and popular indicator-based selection method in order to define a population-based multi-objective local search. The proposed algorithm is designed in order to be easily adaptable, parameter independent and to have a high convergence rate. The capacity of our algorithm to reach these goals is evaluated on a large bunch of experiments. Three combinatorial optimization problems are investigated: a flow-shop scheduling problem, a ring star problem and a nurse scheduling problem. The experiments show that our algorithm can be applied with success to different types of multi-objective optimization problems and that it outperforms some classical metaheuristics. Furthermore, the parameter sensitivity analysis enables us to provide some useful guidelines about how to set the main parameters.

6.12. Connectedness and Local Search for Bi-objective Knapsack Problems

**Participant:** A. Liefooghe.
In [33], we report an experimental study on a given structural property of connectedness of the set of Pareto-optimal solutions for two variants of the bi-objective knapsack problem. A local search algorithm that explores this property is then proposed and its performance is compared against exact algorithms in terms of running time and number of optimal solutions found. The experimental results indicate that this simple local search algorithm is able to find a representative set of Pareto-optimal solutions in most of the cases, and in much less time than exact approaches.

6.13. Set-based Multiobjective Fitness Landscapes

Participants: S. Verel, A. Liefooghe, C. Dhaenens.

Fitness landscape analysis aims to understand the geometry of a given optimization problem in order to design more efficient search algorithms. However, there is a very little knowledge on the landscape of multiobjective problems. In [43], we consider multiobjective optimization as a set problem. Then, we give a general definition of set-based multiobjective fitness landscapes. An experimental set-based fitness landscape analysis is conducted on the multiobjective NK-landscapes with objective correlation. The aim is to adapt and to enhance the comprehensive design of set-based multi-objective search approaches, motivated by an a priori analysis of the corresponding set problem properties. Our experimental study shows that tools from single-objective fitness landscapes can directly be extended for analyzing set-based multiobjective search approaches. The relevant features of multimodality and ruggedness has been highlighted for this particular class of problems.

Participants: S. Verel, A. Liefooghe, L. Jourdan, C. Dhaenens.

The structure of the search space explains the behavior of multiobjective search algorithms, and helps to design well-performing approaches. In this work, we analyze the properties of multiobjective combinatorial search spaces, and we pay a particular attention to the correlation between the objective functions. To do so, we extend the multiobjective NK-landscapes in order to take the objective correlation into account. We study the co-influence of the problem dimension, the degree of non-linearity, the number of objectives, and the objective correlation on the structure of the Pareto optimal set, in terms of cardinality and number of supported solutions [45], as well as on the number of Pareto local optima [46]. This work concludes with guidelines for the design of multiobjective local search algorithms, based on the main fitness landscape features. All our results show that no expectation on the performance of multiobjective local search algorithms can be drawn without taking the problem properties into account very precisely. Indeed, it has now become clear that the number of objectives is one of the key issue to explain a problem complexity, but we also pointed out that the objective correlation is at least as important. Multiobjective fitness landscape analysis plays a central role to explain the performance of local search algorithms, and to design more efficient methods, that suit better the problem features.

6.15. On the Neutrality of Combinatorial Optimization Problem to Design an Efficient Neutrality-based Local Search

Participants: M.-E. Marmion, C. Dhaenens, L. Jourdan, A. Liefooghe, S. Verel.

In the context of the permutation flowshop scheduling problem, a deep landscape analysis focused on the neutrality property has been driven [hal-00550356]. This analysis characterizes the neutral networks of the local optima in order to make propositions about the way to exploit it in algorithms. Hence, NILS has been designed in order to exploit the neutrality of local optima [hal-00563459]. As soon as a local optimum is found, the search is allowed to move to equivalent neighbors. Moreover, NILS gets only one parameter that controls the number of solutions allowed to be visited with the same fitness value. NILS has been tested on flowshop and has shown promising results.
6.16. Guiding the Search over Neutral Networks

Participants: M.-E. Marmion, C. Dhaenens, L. Jourdan, A. Liefooghe, S. Verel.

In a context of neutrality, VEGAS was designed to escape from neutral networks based on the evolvability of solutions, and on a multi-armed bandit by selecting the more promising solution from the neutral network [hal-00579990]. Its main feature is to consider the whole evaluated solutions of a neutral network rather than the last accepted solution as classical methods. VEGAS was tested on NKq-landscapes (problems built to present neutral properties) and results show the importance of considering the whole identified solutions from the neutral network and of guiding the search explicitly.

6.17. DAMS: Distributed Adaptive Metaheuristic Selection

Participants: B. Derbel, S. Verel.

In this work, we design a new Distributed Adaptive Metaheuristic Selection (DAMS) scheme. DAMS is dedicated to adaptive optimization in distributed environments. Given a set of metaheuristics, the goal of DAMS is to coordinate their local execution on distributed nodes in order to optimize the global performance of the distributed system. DAMS is based on three-layer architecture allowing nodes to decide distributively what local information to communicate, and what metaheuristic to apply while the optimization process is in progress. Within this context, we specialize DAMS by describing a particular instantiation called Select Best and Mutate (SBM). Its is a simple, yet efficient, adaptive distributed algorithm using an exploitation component allowing nodes to select the metaheuristic with the best locally observed performance, and an exploration component allowing nodes to detect the metaheuristic with the actual best performance. SBM features are analyzed from both a parallel and an adaptive point of view, and its efficiency is demonstrated through experimentations and comparisons with other adaptive strategies (sequential and distributed).

6.18. A Method to Combine Combinatorial Optimization and Statistics to Mine High-Throughput Genotyping Data

Participants: J. Hamon, C. Dhaenens, J. Jacques.

In collaboration with Gènes Diffusion, we are interested in high-throughput genotyping data in order to select a subset of genes explaining a trait of interest. We suggest to study these high-throughput data combining combinatorial optimization and statistical methods. A first method based on an ILS (Iterated Local Search) and using a statistical criterion to calculate the fitness was suggested and compared with classical statistical approaches.

Participants: J. Jacques, L. Jourdan, C. Dhaenens.

This work focuses on helping clinical trials investigators to screen more patients. First, we performed an analysis of clinical trial business and medical data available in French hospitals. We carried on several expert interviews. Then we developed a model to this problem as an association rules mining problem. After a statistical study of rule interestingness measures, we proposed an improvement of this model as a multi-objective combinatorial optimization problem.

6.20. Reducing Thread Divergence in GPU-based B&B Applied to the Flow-shop Problem

Participants: I. Chakroun, A. Bendjoudi, N. Melab.
Branch-and-Bound (B&B) algorithms are attractive methods for solving to optimality combinatorial optimization problems. Nevertheless, they are time-intensive when dealing with large problem instances. Therefore, several parallel B&B strategies based on large computer clusters and grids have been proposed in the literature. However, to the best of our knowledge no contribution has been proposed for designing B&B algorithms on GPUs (Graphic Processing Units). Because of their tremendous computing power and remarkable cost efficiency, GPUs have been recently revealed as a powerful way to achieve high performance on long-running scientific applications. In this research work, we propose to revisit the design and implementation of B&B algorithms on GPU. We focus on the parallel evaluation of the bounds since preliminary experiments performed on the Flow-Shop scheduling problem (FSP) have shown that the bounding operation consumes over 98% of the execution time of the B&B algorithm. To deal with thread divergence reduction issue caused by the bounding operation a code refactoring approach have been proposed.

6.21. Fitness Landscapes: Local Optima Network

Participant: S. Vérel.

A new methodology to study the structure of the configuration spaces of hard combinatorial problems. It consists in building the network that has as nodes the locally optimal configurations and as edges the weighted oriented transitions between their basins of attraction. We apply the approach to the detection of communities in the optima networks produced by two different classes of instances of a hard combinatorial optimization problem: the quadratic assignment problem (QAP). We provide evidence indicating that the two problem instance classes give rise to very different configuration spaces. For the so-called real-like class, the networks possess a clear modular structure, while the optima networks belonging to the class of random uniform instances are less well partitionable into clusters.
6. New Results

6.1. Modelling of Erythroblastic Islands (red blood cell production)

The production of red blood cells, erythropoiesis, occurs in the bone marrow, where immature erythroid cells differentiate and produce red blood cells. Differentiation and maturation of immature red blood cells occurs in very specific spatial structures called erythroblastic islands. They consist of a macrophage (big white blood cell) surrounded by immature cells and providing them with survival factors. Using a hybrid model, made of a discrete model describing cell-cell interactions and accounting for spatial interactions, and a continuous model describing intracellular protein regulation (deciding for cell fate), we showed the importance of the central macrophage in the erythroblastic island, in order to prevent unstable islands leading either to cell populations extinction or excessive proliferation. This result is actually under review (Journal of Theoretical Biology), partial results have been already published (Math. Model. Nat. Phenom.)

6.2. Modelling of the CD8 T cell Immune Response

The CD8 immune response is a specific immune response triggered by the organism when the innate response is unable to fight a pathogen. We proposed a new model of the CD8 T cell immune response based on the description of feedback controls exerted by the cytotoxic CD8 T cell population on the pathogen and the population itself. This model, a system of ordinary and age-structured partial differential equations, allows to describe a classical response, characterized by a cellular expansion following the pathogen-mediated activation, then a contraction phase and the generation of memory CD8 T cells. Moreover, we showed the global asymptotic stability of this system corresponding to the elimination of the virus. This situation is expected and describes for instance what is observed with the flu virus. We are now confronting the model to experimental data being generated by Jacqueline Marvel’s team in Lyon (immunology team). The analysis of the model and the first results have been published in Journal of Biological Systems

6.3. Particle Dynamics Methods of Blood Flow Simulations

Various particle methods are widely used to model dynamics of complex media. In our work molecular dynamics and dissipative particles dynamics are applied to model blood flows composed of plasma and erythrocytes. The properties of the homogeneous particle fluid are studied. Capillary flows with erythrocytes are investigated.

6.4. Periodic linear cell cycle models

Several results on periodic linear cell cycle models were obtained in collaboration with Frederique Billy (Inria Bang), Jean Clairambault (Inria Bang), Olivier Fercoq (Inria Maxplus), Stéphane Gaubert (Inria Maxplus) and Thomas Ouillon (Ensta). Those results are currently in revision (minor modifications requested). It deals with the property of the growth rate in such models. Several aspects are discussed, among wich: effect of the variability of the division process on the growth rate, fitting coefficients to data obtained by FUCCI methodology and optimization procedure for the growth rate.

6.5. Relaxed cross diffusion models

A general well posedness result for relaxed cross diffusion models was obtained by members of our team in collaboration with Michel Pierre and Guillaume Rolland (IRMAR, Rennes). A paper in this subject has been submitted.
6. New Results

6.1. Diagnosis of large scale discrete event systems

Participants: Marie-Odile Cordier, Christine Largouët, Sophie Robin, Laurence Rozé, Yulong Zhao.

The problem we deal with is monitoring complex and large discrete-event systems (DES) such as an orchestration of web services or a fleet of mobile phones. Two approaches have been studied. The first one consists in representing the system model as a discrete-event system by an automaton. In this case, the diagnostic task consists in determining the trajectories (a sequence of states and events) compatible with the sequence of observations. From these trajectories, it is then easy to determine (identify and localize) the possible faults. In the second approach, the model consists in a set of predefined characteristic patterns. We use temporal patterns, called chronicles, represented by a set of temporally constrained events. The diagnostic task consists in recognizing these patterns by analyzing the flow of observed events.

More recently, we started research on interacting with large-scale systems in a decision-oriented way. Scenario patterns were defined for exploring complex systems, based on the use of model-checking techniques.

6.1.1. Distributed monitoring with chronicles - Interleaving diagnosis and repair - Making web services more adaptive

Our work addresses the problem of maintaining the quality of service (QoS) of an orchestration of Web services (WS), which can be affected by exogenous events (i.e., faults). The main challenge in dealing with this problem is that typically the service where a failure is detected is not the one where a fault has occurred: faults have cascade effects on the whole orchestration of services. We have proposed a novel methodology to treat the problem that is not based on Web service (re)composition, but on an adaptive re-execution of the original orchestration. The re-execution process is driven by an orchestrator Manager that takes advantage of an abstract representation of the whole orchestration and may call a diagnostic module to localize the source of the detected failure. It is in charge of deciding the service activities whose results can be reused and may be skipped, and those that must be re-executed. A paper has been submitted to the CAISE conference.

6.1.2. Scenario patterns for exploring qualitative ecosystems

Our work aims at giving means of exploring complex systems, in our case ecosystems. We proposed to transform environmental questions about future evolution of ecosystems into formalized queries that can be submitted to a simulation model. The system behavior is represented as a discrete event system described by a set of interacting timed automata, the global model corresponding to their composition on shared events. To query the model, we have defined high-level generic patterns associated to the most usual types of scenarios. These patterns are then translated into temporal logic formula. The answer is computed thanks to model-checking techniques that are efficient for analyzing large-scale systems. Five generic patterns have been defined using TCTL (Timed Computation Tree Logic): WhichStates, WhichDate, Whichstates, Stability, Safety. Three of them have been implemented using the model-checker UPPAAL.

The approach has been experimented on a marine ecosystem under fishing pressure. The model describes the trophodynamic interactions between fish trophic groups as well as interactions with the fishery activities and with an environmental context. A paper has been accepted for publication by the Environmental Modelling Software Journal [4].

We extended the approach to deal with “How to” queries. As before, we rely on a qualitative model in the form of timed automata and use model-checking tools to answer queries. We have recently proposed two approaches to answer questions such as “How to avoid a given situation?” (safety query). The first one exploits controller synthesis and the second one is a “generate and test” approach. We compared these two approaches in the context of an application that motivates this work, i.e the management of a marine ecosystem and the evaluation of fishery management policies. The results have been accepted for publication in [14].
6.2. Machine learning for model acquisition

Participants: Thomas Guyet, René Quiniou.

Model acquisition is an important issue for model-based diagnosis, especially as modeling dynamic systems. We investigate machine learning methods for temporal data recorded by sensors or spatial data resulting from simulation processes. We also investigate efficient methods for storing and accessing large volume of simulations data. Our main interest is extracting knowledge, especially sequential and temporal patterns or prediction rules, from static or dynamic data (data streams). We are particularly interested in mining temporal patterns with numerical information and in incremental mining from sequences recorded by sensors.

6.2.1. Mining temporal patterns with numerical information

We are interested in mining interval-based temporal patterns from event sequences where each event is associated with a type and time interval. Temporal patterns are sets of constrained interval-based events. This year, we have been working on improving the formal setting of the approach as well as its efficiency [8]. We have introduced the notion of $\epsilon$-covering of temporal patterns over sequences to cope with the dual nature, symbolic and numerical, of temporal patterns. The parameter $\epsilon$ specifies the tightness of the similarity used for matching patterns and sequences. It complements the parameter $\sigma$ representing the minimal support which is used to prune candidate patterns. The $\epsilon$-similar occurrences of some pattern, precisely their associated temporal intervals, are classified to characterize the different classes of numerical temporal intervals that correspond to different patterns sharing the same symbolic part. This process have been embedded in two sequential pattern mining algorithms, GSP and PrefixSpan, and we have compared their performance.

6.2.2. Incremental sequential mining

We investigate the problem of mining and maintaining frequent sequences in a window sliding on a stream of itemsets. We propose in [11] a complete and correct incremental algorithm based on a tree representation of frequent sequences inspired by PSP [52] and a method for counting the minimal occurrences of a sequence. Instead of the frequency, to a node representing a pattern is associated the set of occurrences of this pattern. The algorithm updates efficiently the tree representation of frequent sequences and their occurrences by means of two operations on the tree: deletion of the itemset at the beginning of the window (obsolete data) and addition of an itemset at the end of the window (new data). Experiments were conducted on simulated data and on real data of instantaneous power consumption.

6.2.3. Multiscale segmentation of satellite image time series

Satellite images allow the acquisition of large-scale ground vegetation. Images are available along several years with a high acquisition frequency (1 image every two weeks). Such data are called satellite image time series (SITS). In [9], we present a method to segment an image through the characterization of the evolution of a vegetation index (NDVI) on two scales: annual and multi-year. We test this method to segment Senegal SITS and compare our method to a direct classification of time series. The results show that our method using two time scales better differentiates regions in the median zone of Senegal and locates fine interesting areas (cities, forests, agricultural areas).

6.3. Decision aiding with models and simulation data

Participants: Tassadit Bouadi, Marie-Odile Cordier, Véronique Masson, Florimond Ployette, René Quiniou, Karima Sedki.

Models can be very useful for decision aiding as they can be used to play different plausible scenarios for generating the data representing future states of the modeled process. However, the volume of simulation data may be very huge. Thus, efficient tools must be investigated in order to store the simulation data, to focus on relevant parts of the data and to extract interesting knowledge from these data.
6.3.1. Exploring models thanks to scenarios: a generic framework

In the framework of the APPEAU project (see 8.2.1), that ended in December 2010, a paper, describing a generic framework for scenario exercises using models applied to water-resource management, has been written during 2011 in cooperation with all the partners and submitted to Environmental Modelling and Software. It is currently under revision.

6.3.2. A datawarehouse for simulation data

The ACASSYA project aims at providing experts or stakeholders or farmers with a tool to evaluate the impact of agricultural practices on water quality. As the simulations of the deep model TNT2 are time-consuming and generate huge data, we have proposed to store these simulation results in a datawarehouse and to extract relevant information, such as prediction rules, from the stored data. We have devised a general architecture for agro-environmental data on top of the framework Pentaho. An article presenting the principles of this architecture as well as a set of realistic scenarios and their transformation into OLAP queries has been submitted to Compag (Computers and Electronics in Agriculture).

6.3.3. Efficient computation of skyline queries in an interactive context

Skyline queries retrieve from a database the objects that optimizes multiple criteria, related to user preferences for example, or objects that are the best compromises satisfying these criteria. When data are huge such objects may shed light on interesting parts of the dataset. However, computing the skylines (i.e. retrieving the skyline points) may be time consuming because of many dominance tests. This is, especially the case in an interactive setting such as querying a data cube in the context of a datawarehouse. We have worked on how to answer efficiently to skyline queries by the materialization of precomputed skyline queries related to dynamic user preferences. An article has been submitted to the conference SIGMOD 2012.

6.3.4. Influence Diagrams for Multi-Criteria Decision-Making

For multi-criteria decision-making problems, we propose in [6] a model based on influence diagrams able to handle uncertainty, represent interdependencies among the different decision variables and facilitate communication between the decision-maker and the analyst. The model makes it possible to take into account the alternatives described by an attribute set, the decision-maker’s characteristics and preferences, and other information (e.g., internal or external factors) that influence the decision. Modeling the decision problem in terms of influence diagrams requires a lot of work to gather expert knowledge. However, once the model is built, it can be easily and efficiently used for different instances of the decision problem. In fact, using our model simply requires entering some basic information, such as the values of internal or external factors and the decision-maker’s characteristics.

6.3.5. Recommending actions from classification rules

In the framework of the SACADEAU project (see 8.2.1), a paper dedicated to building recommendation actions for a given situation, from the set of classification rules, learnt from simulation results, has been published in the KAIS journal [7].

6.4. Causal reasoning and influence diagrams

Participants: Philippe Besnard, Louis Bonneau de Beaufort, Marie-Odile Cordier, Yves Moinard, Karima Sedki.

This work stems on [23], [24], [25], [26], [27] and, for the logic programming translation, on [53], [54]. It is related to diagnosis (observed symptoms explained by faults).

The previously existing proposals were ad-hoc or, as in [29], [41], they were too close to standard logic in order to make a satisfactory diagnosis. Our proposal starts from a restricted first order logic (of the Datalog kind: no function symbols) and introduces causal formulas, built on causal atoms such as (α causes β) intended to mean: “α causes β”. The system is described thanks to these causal formulas, classical formulas, and taxonomy atoms such as (α IS_A β) (α is of kind β).
The system produces explanation atoms of the kind ($\alpha$ explains $\beta$ if possible $\{\gamma_1, \cdots, \gamma_n\}$), meaning that $\beta$ can be explained by $\alpha$ if all the $\gamma_i$'s are possible together in the context of the given data.

This year, we have improved our logic programming translation in ASP. The aim is to improve efficiency and also reduce the work of the programmer, taking advantage of the declarative aspect of this type of programming. We have applied some of these improvements to two classic riddles, in order to illustrate the power and limitations of current answer set programming systems, and we proposed a few improvements which could make the present systems yet easier to use [12], [13].

We are starting a work with some similarities to automatize the treatment of cognitive maps. The aim is to extract relevant information from these maps, which means: building a graph formalism for representing mixed causal and influence relations, and defining a framework (argumentation theory is a good candidate) to aggregate the graphs and provide inference rules in order to infer new information and relations. This work is done in the framework of the RADE2BREST project, involving Agrocampus Ouest and CNRS (GEOMER/LETG), funded by “Ministère de l’Ecologie”. The goal of this project is to model shellfish fishing in order to assess the impact of management pollution scenarios on the Rade de Brest. The cognitive maps result from interviews with fishermen.

---

1This project is not mentioned in section 8.1 because DREAM is not a partner of this project.
5. New Results

5.1. Dynamic World Perception and Evolution Prediction

5.1.1. Environment modeling and sensor data acquisition

An overall architecture of our environment-modeling module with the inputs from heterogenous sensors is shown in Fig. 6. The combined use of two lidars and stereo-vision helps mitigate uncertainty and allows for detection of partially occluded objects. The data processing includes the computation of probabilistic occupancy grids for each sensor and their subsequent fusion with the Bayesian Occupancy Filter (BOF). The output of the module is an estimation of the position, velocity and associated uncertainty of each observed object, which are used as input to the risk assessment module.

![Figure 6. Architecture of the environment modeling module.](image)

This architecture is implemented on our experimental platform, a Lexus LS600h car shown in Fig. 7. The vehicle is equipped with a variety of sensors including two IBEO Lux lidars placed toward the edges of the front bumper, a TYZX stereo camera situated behind the windshield, and an Xsens MTi-G inertial sensor with GPS.

The stereo camera baseline is 22 cm, with a field of view of 62°. Camera resolution is 512x320 pixels with a focal length of 410 pixels. Each lidar provides four layers of up to 200 impacts with a sampling period of 20 ms. The angular range is 100°, and the angular resolution is 0.5°. The on-board computer is equipped with 8GB of RAM, an Intel Xeon 3.4 GHz processor and an NVIDIA GeForce GTX 480 for GPU. The observed region is 40 m long by 40 m wide, with a maximum height of 2 m. Cell size of the occupancy grids is 0.2x0.2 m.
Figure 7. Lexus LS600h car equipped with two IBEO Lux lidars, a TYZX stereo camera, and an Xsens MTi-G inertial sensor with GPS.

The Lexus experimental platform provides to acquire sensor data in real traffic environments: eight layers of laser scans, stereo images, IMU data (accelerations), velocity, GPS position, steering angle. The experiments are conducted in various road environments (country roads, downtown and highway), at different time of the day, with various driving situations (light traffic, dense traffic, traffic jams). The datasets are acquired online and are used for testing of our sensor fusion and risk assessment algorithms.

5.1.2. Bayesian fusion of visual and telemetric information

Participants: Igor Paromtchik, Christian Laugier, Mathias Perrollaz, Amaury Nègre.

5.1.2.1. Concept of BOF and obstacle detection in occupancy grids

Obstacle detection is a widely explored domain of mobile robotics. It presents a particular interest for the intelligent vehicle community, as it is an essential building block for Advanced Driver Assistance Systems (ADAS). In the ANR project LOVe (Logiciel d’Observation de Vulnerables) and ArosDyn project, the e-Motion team proposed to perform obstacle detection within the occupancy grid framework. In order to work efficiently with occupancy grids, we have previously developed a probabilistic framework with the Bayesian Occupancy Filter (BOF) \[ 40 \] \[ 88 \] (patent 0552736 (2005) ), which provides filtering, data fusion, and velocity estimation capabilities while allowing for parallel computation. The Fast Clustering and Tracking Algorithm (FCTA) \[ 73 \] is then used to identify and track individual objects. The BOF is designed with the intent of its implementation in hardware as a system-on-chip. Like other grid based approaches, the BOF framework performs sensor fusion at the cell level \[ 40 \]. The BOF evaluates probabilities of both cell occupancy and cell velocity for each cell in a four-dimensional spatio-temporal grid. The monitoring of traffic scenes includes detection and tracking of objects by the FCTA \[ 73 \].

Fig. 8 shows examples of occupancy grid mapping with the proposed approach. The arrows indicate the pedestrian, the car, and the bicycle, which appear in the camera images and the occupancy grids. Because the accuracy of stereo-vision tends to become poor at large distance, the corresponding grid has been attenuated beyond 20 m and the system is tuned to give more confidence to the lidars than to the stereo-vision. One of advantages of sensor fusion is a larger viewfield so that the vehicles overtaking the ego-vehicle (they are not seen in the camera images) are correctly mapped on the resulting BOF grid. Moreover, the sensor fusion as well as the Bayesian estimation provide to filter out the laser impacts with the road surface, e.g. right lidar in Fig. 8.

Note that a large number of dynamic objects in the traffic scenes may lead to a failure of object-based fusion because of a large number of association hypotheses. The grid-based approach allows us to avoid the object association problem for sensor fusion.

5.1.2.2. Disparity space approach for a vision based occupancy grid

To use sensors in the BOF framework, it is essential to develop an associated probabilistic sensor model that takes into consideration the uncertainty over measurements. In 2009, we proposed such a sensor model for stereo-vision \[79\]. The originality of the approach relied on the decision to work in the disparity space, instead of the classical Cartesian space. In 2010, we improved our sensor model, in order to mimic some features of the sensor models used for range finders. Particularly, we worked on managing visible/occluded areas of the scene \[81\], and on including the information from the road/obstacle segmentation of the disparity image \[80\]. Our approach was also designed to allow highly parallel computation of the occupancy grid. A. Nègre implemented the approach on GPU using NVIDIA CUDA to enhance the performance. The complete processing of the stereo data can now be done in 6 ms, while more than 150 ms were necessary with the CPU implementation. The complete approach for occupancy grid computation using stereovision is described in \[30\].

Figure 9 shows an example of the occupancy grid computed by our new approach. We can observe that most objects are detected (light color), even if partially occluded (e.g. the sign on the right). Information from the road surface is also taken into consideration (dark areas). Moreover, similar to a laser scanner, it appears that regions in front of objects are seen as partially unoccupied, while less information is available behind obstacles (occupancy probability is closer to 0.5).

In 2011, we focused on including the approach into the risk estimation framework on our Lexus experimental platform. We implemented a demonstration to estimate a distance measurement to the closer object situated in the future trajectory of the vehicle. The future trajectory is estimated either by using a lane detection algorithm (in the highway) or by combining velocity and steering information of the vehicle. Figure 10 shows the HMI displayed in the car while driving.

5.1.2.3. Processing of multi-layer telemetric data in probabilistic framework

Participants: Mathias Perrollaz, Juan-David Adarve, Alexandros Makris.
Figure 9. Example of an occupancy grid computed with our new approach. a) the left image from a stereo pair. b) the occupancy grid computed in the u-disparity plane, and c) the corresponding grid mapped into cartesian space. Light colors correspond to areas with a high probability of occupancy, while dark colors are for low occupancy probability.

The occupancy grid computation based on a laser scanner uses the classical independent beam sensor model [90]. Since our vehicle is equipped with two four-layers laser scanners, it is necessary to merge the data from the multiple layers. In the original BOF framework, the fusion was performed through the classical Bayesian Fusion methodology. As shown in figure 11, this method causes problems of misdetection when some beams go over an object. In 2011, we proposed and implemented another approach. The fusion is now obtained through a weighted sum of the the occupancy grids provided by each layer. The weight of each layer is obtained by computing a confidence grid. This confidence depends both on the inclination of the layer and on the possible occlusions. The new approach provides a more precise description of the environment.

5.1.3. Sensor Fusion and parameters estimation

Participants: Agostino Martinelli, Chiara Troiani.

This is the follow up of the research activity started in 2009, when a self-calibration problem for a wheeled robot has been investigated. The main results achieved during that year were published in [69], [71], and [70]. This calibration problem allows us to introduce a general framework able to deal with any estimation problem. This framework is based on a new theoretical concept, the concept of continuous symmetry. Detecting the continuous symmetries of a given system has a very practical importance. It allows us to detect an observable state whose components are non linear functions of the original non observable state. The general theory has been developed during the last two years. Preliminary results have been published in 2010 [72] and a more complete version of these results, which include several extensions, has been published on Transaction on Robotics, in 2011 [9].

In 2011, this general framework has been extensively applied to investigate the problem of the fusion of visual and inertial data in the framework of the European project sFly. Special emphasis has been devoted to the structure from motion problem (SfM) when fusing these data. This problem has particular interest and has been investigated by many disciplines, both in the framework of computer science ([35], [54], [56], [87] and references therein) and in the framework of neuroscience and vision perception ([67], [95] and references therein). Even though prior work has answered the question of which are the observable
Figure 10. a) segmentation of the environment with the stereo-vision algorithm. Blue areas belong to the road surface, while red areas belong to the obstacles. b) HMI shown in the car during the demonstration of risk estimation. The trajectory is estimated by considering the velocity and steering angle of the ego vehicle. Here the car in front is not considered as dangerous because it is more than 2 seconds ahead. c-d) Another example, on the highway. For this example, the trajectory is estimated by considering the road markings.
Figure 11. Occupancy grid computed after fusion of eight layers of laser data. Above: with the previous approach, some objects are not correctly represented (e.g. the barrier on the left). Below: with the new approach, the description is more precise.
modes, i.e. the states that can be determined by fusing visual and inertial measurements [35], [54], [56], the questions of how to compute these states in the absence of a prior, and of how many solutions are possible, were still unanswered. During 2011, we have derived, for the first time, a closed form solution to the SfM problem in this case, allowing the determination of the observable modes without the need for any prior knowledge. The proposed solution analytically expresses all the observable modes in terms of the visual and inertial measurements acquired during a given (short) time-interval allowing the determination of all the observable modes without the need for any prior knowledge. Additionally, we have shown that this problem can have a unique solution or two distinct solutions or infinite solutions depending on the trajectory, on the number of point-features and on the number of monocular images where the same point-features are seen. Our results are relevant in all the applications which need to solve the structure from motion problem with low-cost sensors and which do not demand any infrastructure. Typical examples are the emergent fields of space robotics [77], humanoid robotics and unmanned aerial navigation in urban-like environments [93], where the use of the GPS is often forbidden. Furthermore, our results could play an important role in neuroscience by providing a new insight on the process of vestibular and visual integration. To this regard, we remind the reader that the influence of extra retinal cues in depth perception has extensively been investigated in the last decades. In the case when this extra retinal cue is the motion parallax induced by self-motion relative to a stationary environment, the scale factor is provided by the head velocity [65], [66]. The vast majority of these studies, consider the case when the head motion is active [38], [94]. This prevents the possibility to understand the contribution of the vestibular signals because of efference copy generated by active self movement. However, a very recent study investigates this problem by performing trials with passive head movements [43]. The conclusion of this study is that the combination of retinal image with vestibular signals can provide rudimentary ability to depth perception. Our findings could provide a new insight to this problem of depth perception since by combining retinal image with vestibular signals it is possible to determine the scale factor even without any knowledge about the initial speed. New trials would be necessary in order to verify whether a mechanism reproducing our closed form solution is present in humans and/or in other animals (especially the ones without binocular vision). Our findings also show that it is possible to easily distinguish linear acceleration from gravity. Specifically, our closed form solution perform this determination by a very simple matrix inversion. This problem has also been considered in neuroscience [75], [31]. Our results could provide a new insight to this problem since they clearly characterize the conditions (type of motion, features layout) under which this determination can be performed.

Our results have been published in three conference papers [14], [11], [15] and have been accepted for publication in transactions on robotics (a version is currently available as a technical report, [29]).

In parallel to this theoretical activity an experimental activity has started in order to experimentally validate our findings in the near future and to deploy our technologies to industrial partners. To this regard, a contact with the company Delta Drone in Grenoble has been established and a valorization contract with a SME in the field of civil drone applications is currently in preparation.

5.1.4. Analysis of dynamic scenes for collision risk assessment

The grid-based environment representation is used for dynamic scene analysis in the Arosdyn project [78]. The original idea behind the risk estimation approach developed in the e-Motion team consists in considering the possible behaviors of the vehicles in the scene. Indeed, with the classical TTC(time to collision)-based approach, the risk is estimated based on the prediction of the trajectory, considering the current state of the objects. This is only valid for very short term predictions, and in some cases it can result in a over-estimation of the collision risk. Understanding the intention of the other participants of the road scene allows a longer term, more precise prediction of trajectories.

Our approach is divided into two steps: behavior recognition and behavior realization. The behavior recognition aims at estimating the probability for a vehicle to perform one of its feasible behaviors. The behaviors are semantic representations of driving maneuvers (e.g. turn left, turn right, go straight, ...). The probability
distribution over possible behaviors is obtained by inference using layered HMMs. Driving behavior realization is modeled as Gaussian Process (GP). This model allows us to obtain the probability distribution over the physical realization of the vehicle motion (i.e. trajectories) by assuming a usual driving, for a given behavior.

Finally, a complete probabilistic model of the possible future motion of the vehicle is given by the probability distribution over driving behaviors, and by the realization of these behaviors. The risk calculation is performed by sampling of the paths from the corresponding GP: The fraction of the samples in collision gives the risk of collision.

In 2011, we conducted some early experiments on sensor fusion, using real data acquired with our Lexus experimental vehicle [16]. Moreover, the global framework of the Arosdyn project has been presented in [8].

5.1.5. Recognition for intelligent vehicles

We developed a generic object class recognition method. The method uses local image features and follows the part based detection approach. The state-of-the-art visual object class recognition systems operate with local descriptors and codebook representation of the objects. Various local features (e.g. gradient maps, edges) are used to create the descriptors. Then kernel based classifiers are commonly employed to classify the detected features in one of several object classes [32] [45]. The recognition of vehicles or pedestrians from sensors mounted on a moving platform is achieved by different approaches using various types of sensors, e.g. stereo camera, laser [51] [44]. The approaches that perform data fusion from various sensors have proven to be the more robust in a variety of road conditions [86].

This work focuses on the development of an object class recognition system which follows the part based detection approach [64]. The system fuses intensity and depth information in a probabilistic framework. To train the system for a specific object class, a database of annotated with bounding boxes images of the class objects is required. Therefore, extending the system to recognize different object classes is straightforward. We apply our method to the problem of detecting vehicles by means of on-board sensors. Initially, depth information is used to find regions of interest. Additionally, the depth of each local feature is used to weight its contribution to the posterior of the object position in the corresponding scale. The votes are then accumulated in a 3d space-scale space and the possible detections are the local maxima in that space. Figure 12 presents the steps of our approach.
The novelty of our approach is the fusion of depth and intensity information to form a probabilistic part-based detector. Using depth information is beneficial for the robustness of the approach, because we avoid including many noisy detections resulting from false matches between features of different scales. The method is tested with stereo video sequences captured in an urban environment. Fig. 13 shows some example detections. The proposed method detects side-views of cars in various scales, in cases with partial occlusions, and under significant background clutter.

![Figure 13. Car-side detection examples. True and false positive detections are represented by red and yellow bounding boxes respectively.](image)

(a) Cars in different scales with significant background clutter and significant occlusions are detected. (b) Precise detection of the un-occluded vehicle, whereas a vehicle that is heavily occluded in the left is not detected. (c) Difficult detection of a vehicle which is far and partially occluded and a false detection in the region between the road surface and the trees. (d) Detection with partial occlusion. (e) Partial detection of a taller than normal vehicle (on the left). The training dataset does not contain vehicles of this type. (f) Successful detection of a partially occluded car and a false positive arising from a bus and a van. Training separate detectors for these type of vehicles as well will help to avoid these false alarms.

5.1.6. Context-aware Bayesian estimation of risk at road intersections for cooperative vehicles

**Participants:** Stéphanie Lefèvre, Christian Laugier.

The work developed in this PhD is done in collaboration with Renault (CIFRE thesis) and concerns safety applications for cooperative vehicles.

In a few years, car manufacturers will start equipping vehicles with V2X communication devices, which will allow vehicles to share information with other vehicles and with roadside units using a dedicated communication channel. This new sensor on the car opens a whole new world of possibilities for Advanced Driver Assistance Systems (ADAS). In particular, the fact that the vehicle is able to “see” a car before it even enters the field-of-view of the driver allows for a better assistance in the tasks of perceiving, analyzing, predicting, and estimating the risk of a situation.

Early in the PhD we identified safety applications at road intersections as a relevant application domain for V2X technologies. The variety and complexity of scenes at road intersections makes reasoning and interpretation particularly difficult. On the other hand, intersections are a location of many accidents (they represent up to 50% of accidents in some countries), therefore reducing the accident rates in these areas would
have a considerable impact of global traffic safety. We also identified the key issues (and challenges) to be 1) situation understanding and 2) risk assessment, to be carried out from incomplete models and uncertain data. The focus of the year 2010 was on the first of these two problems. We developed a Bayesian Network that could estimate a driver’s intended exit lane at an intersection based on the current state of the vehicle (position, orientation, turn signal state) and on contextual information extracted from the digital map. The idea was to use the information on the geometry of the road network and on the connectivity between lanes to build a statistical model of the relationship between the position and turn signal of a vehicle and the driver’s intended exit lane. Initial results of this work were published in IEEE CIVTS’11 [12], then in IEEE IV’11 [13] with a more thorough evaluation.

The objective of the work conducted in 2011 was twofold:

1. Extend the initial system: add some filtering and take into account the priority rules.
2. Estimate the risk of a situation, based on the estimated behavior/intention of the drivers in the scene.

We proposed a probabilistic motion model for vehicles approaching and traversing an intersection that incorporates some knowledge about how the context (i.e. the traffic rules, the presence of other vehicles, the geometry and topology of the intersection) influences vehicle behavior. The distinctive features of our algorithm are:

- The explicit use of priority rules
  Priority rules are explicitly taken into account in the motion model: the necessity for a driver to stop and/or yield to another vehicle at an intersection is estimated, jointly with the driver’s intention to comply. This allows for a flexible and computationally inexpensive computation of risk. Flexible because depending on the final application one can decide to compute different types of risk, e.g. the probability that a specific vehicle is a violator, or the probability that a crash will occur between two vehicles, or the risk of a specific maneuver for a vehicle. Inexpensive because these can be computed without performing trajectory prediction for the vehicles in the scene.

- The assumption that drivers generally respect traffic rules
  Instead of making the classical assumption that vehicles’ trajectories are independent, we model their mutual influences by introducing a prior knowledge that drivers generally respect priority rules. The motion model therefore takes into account the priority rules and the presence of other vehicles to better interpret correctly a vehicle’s behavior. The advantages are twofold. Firstly, we are able to better estimate the maneuver intention of the drivers, which means our situation assessment capabilities are improved. Secondly, risk is estimated with a higher sensitivity. We avoid risk overestimation while still being able to detect dangerous situations as well as the conventional, more conservative, methods.

This reasoning is implemented using a Bayesian filter which estimates the hidden variables M (maneuver intention), D (distance to intersection), H (intention to stop) and H’ (necessity to halt) jointly for all the vehicles in the scene, using the position, speed and heading information shared between the vehicles via V2X communication. Inference on the hidden variables is carried out by a particle filter. The algorithm was described in an INRIA research report [27]. In this report we showed by reasoning on theoretical scenarios that our assumption that drivers tend to respect priority rules should lead to improved situation assessment and risk assessment (see Fig. 14).

Recently, data has been collected at an intersection using the Renault demonstrator vehicles, so that our algorithm can be tested on real data. Preliminary results seem to confirm that the intuitions described in the research report were correct. A Graphical User Interface is in the process of being developed so that demonstrations of the system can be carried out live in the Renault demonstrator vehicles (see Fig. 15).

5.2. Human Centered Navigation in the physical world
Figure 14. Illustration of a scenario where the advantage of taking into account the interactions between vehicles for maneuver prediction is obvious for ADAS applications. The behavior of the red vehicle is interpreted differently depending on whether or not the interactions with the green vehicle are considered.

Figure 15. Graphical User Interface for warning a driver of a violation of priority rules at an intersection (the violator vehicle is displayed in red).
5.2.1. Goal oriented risk based navigation in dynamic uncertain environment

**Participants:** Anne Spalanzani, Jorge Rios-Martinez, Amaury Nègre, Arturo Escobedo-Cabello, Christian Laugier.

Navigation in large dynamic spaces has been addressed often using deterministic representations, fast updating and reactive avoidance strategies. However, probabilistic representations are much more informative and their use in mapping and prediction methods improves the quality of obtained results.

Since 2008 we have proposed a new concept to integrate a probabilistic collision risk function linking planning and navigation methods with the perception and the prediction of the dynamic environments [47]. Moving obstacles are supposed to move along typical motion patterns represented by Gaussian Processes or Growing HMM. The likelihood of the obstacles’ future trajectory and the probability of occupation are used to compute the risk of collision. The proposed planning algorithm, call Risk-RRT, is a sampling-based partial planner guided by the risk of collision. Results concerning this work were published in [48] [49] [50].

In 2011, our algorithms were integrated into an embedded software architecture for social aware navigation (see fig. 16). For this purpose we started to migrate our algorithms to a new experimental platform. Moreover, we adapted the code to the open source software called ROS (Robot Operating systems) which offers tools to develop robot applications based in state of the art algorithms. Particularly, localization and visualization tools have been used. We have linked the control of our robotic wheelchair, the Risk-RRT planning and the social filter modules described in 5.2.2 into the framework ROS as shown in figure 16. The main objective was to increase the visibility of our approach and develop common libraries with research groups in robotics. In 2011, in the scope of the AEN PAL project, we started a collaboration with the EPI Arobas and complementary developments have been put on the INRIA forge.

![Figure 16. Architecture for the social navigation system in ROS](image)

Next two sections are conducted under the French project PAL “Personally Assisted Living” with a goal to enhance the quality of living by providing more autonomy in the daily activities of the disabled.

5.2.2. Social conventions based navigation

**Participants:** Jorge Rios-Martinez, Anne Spalanzani, Christian Laugier.

---

2 Willow Garage Inc., [http://www.ros.org](http://www.ros.org)
The objectives of this work are to integrate the notion of comfort in the classical safe navigation methods. If one consider that the navigation system transports a person, the integration of social conventions in the navigation strategy starts to be crucial. In this work, we propose to integrate the notions of personal space and interaction between people. We propose to enrich the knowledge the robot has, with a representation of the social conventions. The robot must take into consideration interactions to avoid groups of people (even if passing through the group is the “best” path for a conventional planning algorithm), or to join a group with a behavior close to the one of a human. To understand the behaviors of interaction between humans and the management of space, the works developed in the area of sociology to define some concepts as Personal space, o-space and F-formations are used.

- **Personal Space**
  
  In [53], Hall describes the use of space between humans, he observed the existence of some rules that conducted people to keep distances from others. He proposed a classification of the space around a person (its Personal Space) in social interaction in four zones:
  
  - the public zone \( > 3.6 \text{m} \),
  - the social zone \( > 1.2 \text{m} \)
  - the personal zone \( > 0.45 \text{m} \)
  - the intimate zone \( < 0.45 \text{m} \)

  This is a useful tool for a robot to understand the intentions of the humans. It is well known that these measures are not stricts and that they change depending on age, culture and type of relationship but the categories proposed explain very well reactions like the uncomfortable sense of a stranger invading your intimate zone or the perception of somebody looking social interaction because he is entering to your social zone.

- **F-formation**

  ![Examples of F-formations](image)

  *Figure 17. Examples of F-formations: (a) Vis-a-vis, (b) L-Shape, (c) C-Shape.*

  In [57], Kendon observed that people interacting in groups follow some spatial patterns of arrangement. When people are executing some activity they claim an amount of space related to that activity, this space is respected by other people and Kendon referred it as individual’s transactional segment. This transactional segment can vary depending on body size, posture, position and orientation during the activity. Moreover the groups can establish a joint or shared transactional segment and only the intervenants have permitted access to it, they protect it and others tend to respect it. The o-space is that shared transactional segment. A F-formation system is the spatial-orientation arrangement that people create, share and maintain around their o-space. We can see in fig. (17) three examples of F-formations.

The first stage in order to achieve an integration of social concepts with robot navigation was to include estimations of the risk of disturbing personal space and interaction space in the general risk estimation. A strategy to detect interactions in the environment based in the velocity, position and orientation of humans was implemented.
In fig. 18 we observe the results of the proposed integration, the robot (green rectangle) can use the detections of conversations (light ellipses) between humans (blue circles) for adding more risk to paths that invade the space of conversations. When a conversation is detected, a bi-dimensional Gaussian $G$ is created to represent the interaction space, also called o-space, the center of this space is approximated by taking into account the participants’ poses. Then, $G$ is used to obtain an estimation of risk of disturbing by passing around the conversation. The navigation strategy is based on the Risk-RRT algorithm. Details of this approach were published in [18].

5.2.3. Autonomous Wheelchair for the Elderly People’s Assistance

**Participants:** Arturo Escobedo-Cabello, Anne Spalanzani, Christian Laugier.

The elderly and the disabled are expected to benefit from the new technologies in the field of autonomous navigation robotics. Normal users of electric wheelchairs will also benefit from the development of more automatic functionalities bringing an extra driving comfort, especially during delicate maneuvers such as narrow door passages. This contribution is similar to the installation of driving assistance on a car. A simple improvement of the classical powered wheelchair can often diminish several difficulties of control.

Comfort defined as a state of ease and satisfaction of bodily wants, with freedom from pain and anxiety, has recently emerged as a design goal in autonomous navigation systems. Designers are becoming more aware of the importance of the user when scheming solution algorithms. The idea of comfort is especially important in the case of wheelchairs where the occupants are weak as result of their age or disease.

For any robot that is designed to transport people, the trajectory should be smooth and correspond to the user’s understanding as much as possible. Since human interpretation of the environment often differs from a robot’s interpretation, the decisions taken by the system might seem incomprehensible to a human observer. For example an autonomous vehicle could refuse to move forward due to some obstacle, while a human user would easily be able to move its way through. This undesirable behaviors may prove irritating and with time may lead to users stopping from using the system.

In 2011 we set up a robotic wheelchair as a trial platform. The wheelchair is a differential drive robot equipped with a SICK LMS-200 lidar to get 2D range information from the environment, odometry sensors, and a velocity controller we have also added a kinect sensor in order to perform some in the field of social
interactions. Some basic functions can be executed including the mapping of the environment using a Rao-Blackwellized Particle Filter [52], localization using an Adaptive Monte Carlo Localization approach (AMCL) [91], global planning using an A* algorithm [60] and local reactive planning using the Dynamic Window Algorithm [46].

Alongside we started working with the kinect sensor to detect and track people. Using the given tracking information, the wheelchair is able to follow a human located in front of it. This behavior is aimed to bring assistance not only to the user but also to the caregiver by allowing him to move without pushing the wheelchair. The technical implementation of the related approaches has been done on the basis of the ROS middleware due to easy integration with other opensourse robotics software which benefit sharing and testing developed software.

In 2012 we shall focus on the estimation of the user intentions by learning models of behavior. We’ll then use these models to propose an adaptive autonomous navigation method that best answer the user needs.

### 5.2.4. Multi-Robot Distributed Control under Environmental Constraints

**Participants:** Agostino Martinelli, Alessandro Renzaglia.

This research has been carried out in the framework of the European project sFly. In recent years it is revealed more and more the importance of using multi-robot systems for security application, otherwise impossible to be performed by a single robot.

The main problem approached is the optimal surveillance coverage of an unknown and complex environment, i.e. finding the optimal deployment for the robots and the way to safely reach such configuration. The solution for the 2D case without obstacles is already known in literature [39]. On the other hand, for the non-convex case, it is still a difficult problem. In [84] we firstly proposed a possible strategy based on a combination of the repulsive potential field method and the Voronoi partition. Then, in the last two years we have mainly approached the coverage problem by using a new stochastic optimization method. This work is in collaboration with professor Elias Kosmatopoulos, from CERTH (Thessaloniki), and professor Lefteris Doitsidis, from TUC (Crete), partners in the sFly project.

The Kosmatopoulos’s group has proposed a new adaptive stochastic optimization algorithm for a general class of multi-robot passive and active sensing applications [59], [58]. This method possesses the capability of being able to efficiently handle optimization problems for which an analytical form of the function to be optimized is unknown, but the function is available for measurement at each iteration of the algorithm employed to optimize it. As a result, it perfectly suits for multi-robot optimal coverage in non-convex environments, where the analytical form of the function to be optimized is unknown but the function is available for measurement (through the robots’ sensors) for each multi-robot configuration.

The main results obtained for the 2D case by using this method has been published in [85], [83]. We assume the robots are equipped with global positioning capabilities and visual sensors able to monitor the surrounding environment. The goal is to maximize the area monitored by the team, by identifying the best configuration of the team members. Moreover, in 2011, a distributed version of the algorithm was presented in [17]. In multi-robot systems, a distributed approach is desirable for several fundamental reasons. The most important are failure of the central station and limited communication capabilities. The proposed approach has the following key advantages with respect to previous works:

- it can solve the problem in a distributed way;
- it does not require any a priori knowledge on the environment;
- it works in any given environment, without the necessity to make any kind of assumption about its topology;
- it can incorporate any kind of constraints, for instance regarding a possible existing threshold on the maximum distance on the monitored region, or a limited visibility angle;
- it does not require a knowledge about these constraints since they are learnt during the task execution;
- its complexity is low allowing real time implementations.
Figure 19. (a) Wheelchair used in the emotion team, (b) Two people being tracked using the kinect and the map of the environment done by the wheelchair.
The previous approach has been also extended for the more important and realistic 3D case. Working in collaboration with the ETHZ (Zurich), some simulations using real data, which were collected with the use of a miniature quadrotor helicopter specially designed for the needs of the European project sFly, have been performed (see fig. 20). This work has lead to two joint publications with CERTH and TUC: one conference paper to present (CDC2011) and one journal papers under review, and two joint publications with CERTH, TUC and ETHZ: one conference paper ([10]) and one journal papers under review.

In 2011, this approach has been combined with human aware navigation technics presented in section 5.2.5.

Figure 20. Cooperative surveillance coverage with a team of four robots. The surface to monitor is created using the real data collected by the helicopters. Blue triangles show the final positions, which are provided by the CAO algorithm.

In the next months, the algorithm will be implemented on real MAVs for the final demo of the project. This demo will include experimentation both in indoor and outdoor complex environments.

Finally, a new collaboration with professor Kosmatopoulos has recently begun. The objective of this work is to develop a new efficient and scalable algorithm for multi-robot active control to perform cooperative simultaneous localization and mapping (CSLAM) and target tracking. The main idea is to use a convex optimization algorithm based on Semi-Definite Programming and Sum-of-Squares polynomials. Preliminary simulation results are very promising and a journal paper is under preparation.

5.2.5. Exploring stochastic optimization method to navigate between humans

Suppose that we have a robot navigating in an unknown and complex environment where people are moving and interacting. In such scenario the respect of the humans’ comfort becomes an important goal to achieve. The discomfort concept could be very general but we focus on the one mentioned before, i.e., the discomfort caused by disturbing one interaction or a personal space of humans. The approach here is to minimize the discomfort while the robot is navigating. As we cannot measure directly the value of discomfort, we can
infer it by modeling the concepts presented before using simple equations and after by applying a method of optimization. We propose to exploit a new stochastic and adaptive optimization algorithm (CAO) [59]. This method is very useful in particular when the analytical expression of the optimization function is unknown but numerical values are available for any state configuration. Furthermore, the proposed method can easily incorporate any dynamical and environmental constraints. To validate the performance of the proposed solution, several simulation results are provided.

In fig. 21 the model for discomfort function is shown together with robot navigation. At each step the robot randomly generate configurations in the environment and selects the one that takes it closer to the goal while minimizing values for the discomfort function of humans in the environment, this is repeated until goal is reached. Several executions of proposed approach in different scenarios can be observed in fig. 22

The details of this approach have been submitted to ICRA2012.

5.3. Bayesian Modelling of Sensorimotor Systems and Behaviors

Results proposed in this section were done in collaboration with the LPPA collège de France.

5.3.1. Bayesian programming applied to a multi-player video games

Participants: Gabriel Synnaeve, Pierre Bessière.

The problem addressed in this work is the autonomous replacement of a human player. It is the continuation of last year’s work on the same topic as well as a follow-up of previous E-Motion Ph.D Ronan Le Hy [61]. This year, we focused on real-time strategy (RTS) games, in which the players have to build an economy, advance technology, produce and control an army to kill the opponents. From a research point of view, multi-player games are interesting because they stand for a good in-between of the real world and simulations. The world is finite and simulated (no sensors problems) but we didn’t wrote the simulation and the other players are humans (or advanced robots in the case of AI competitions).
This year’s research work focused on plan recognition from noisy and incomplete observations. Previous plan recognition works in multiplayer games were mainly based on planning and case-based reasoning (CBR) [92], [68], [55], [76] or HMMs [41]. CBR allows for taking domain knowledge into account easily while not dealing efficiently with uncertainty/incompleteness of information, HMMs deal with uncertainty quite well but domain knowledge is harder to structure. We found different ways to decompose the joint $P(Observation_{1:N}, Plan_{1:M})$ which allows for tractable and robust inference. For instance with the help of intermediate variables which can be derived from domain knowledge (as we did) or found automatically (e.g. cross-validation on a HMM). Particularly, we were able to structure dependencies between domain knowledge extracted variables using coherence variables. We then learn the parameters of such joint distributions from data. Supervised (labeled), and semi-supervised learning (when we label automatically from clustering) have led to a publication at CIG (IEEE) 2011 [19] and unsupervised learning (using only raw game data) led to a publication at AIIDE (AAAI) 2011 [20].

On top of the research/evaluation implementation, we also implemented it in our StarCraft: Broodwar’s bot implementation BroodwarBotQ. With this bot, we took part in AIIDE and CIG conferences AI tournaments placing respectively 9th (out of 18) and 4th (out of 10). We also published last year’s result on multiple units control in real-time engagements (see [23] at CIG (IEEE) 2011 [21]. As optimal micro-management is almost always intractable (P-space) in real situations, we considered each unit as a Bayesian sensory motor robot which makes a fusion of its sensory inputs about the world, the enemy units, but also its allies (without explicit communication for less complexity) and higher level directions. So the units only take short term decision on where to go and who to attack, higher level planning is done at a squad (and then army) level and given as a sensory input. Results in micro-management tournaments are state of the art. In the more general case, they could be improved by reinforcement learning of the models parameters.
We are now working on concurrent goals resources attribution, still in the context of incomplete knowledge about the opponent. We are also working on correlating low-level observations (effects) and high-level inferences (causes) about the enemy strategy to be able to predict its future behavior.

5.3.2. Bayesian modelling to implement and compare different theories of speech communication

Participants: Raphael Laurent, Pierre Bessière, Julien Diard, Jean-Luc Schwartz.

A central issue in speech science concerns the nature of representations and processes involved in communication. The search for phoneme or syllable specific invariants led to three major sets of approaches: motor, auditory and perceptuo-motor theories, which have been widely argued for and against. The debate appears to be stagnating. This work is based on the belief that mathematical modeling of these theories could provide breakthroughs. More precisely, it is proposed that casting these theories into a single, unified mathematical
framework would be the most efficient way of comparing the theories and their properties in a systematic manner.

Bayesian modeling provides a mathematical framework that precisely allows such comparisons. The same tool, namely probabilities, can be used both for defining the models and for comparing them. Moreover, the use of a unified framework implies that common hypotheses would have common mathematical translations. This helps toward more principled studies of the competing theories.

Following this integrative approach, the motor, auditory and perceptuo-motor theories are thus cast into one unifying Bayesian framework in which they all appear as instances of various questions asked to one probabilistic communication model. This allows to compare these theories through quantitative testing in various paradigms. The work is aimed at understanding the differences in the predictions given by the different theories, and from these predictions to suggest experiments involving human subjects.

The model was used first to work on purely theoretical simulations aimed at studying with diverse paradigms the decrease in the performances predicted by the different theories due to communication noise. It was then used to work on plosive syllables production and perception, thanks to VLAM, a vocal tract simulation tool, which allows to map articulatory parameters to acoustic signals.
6. New Results

6.1. Graph Based Knowledge Representation

6.1.1. Knowledge Graph Abstract Machine

Participants: Olivier Corby, Catherine Faron-Zucker, Fabien Gandon.

KGRAM (Knowledge Graph Abstract Machine) is a generic interpreter for W3C SPARQL Query Language that operates not only on RDF graphs but on labelled graphs. The interpreter interacts with the target graph through proxies that implement an interface: Producer enumerates edges from the target graph, Evaluator evaluates filters and Matcher takes entailments into account.

This year, work have been done to leverage KGRAM up to SPARQL 1.1 Query Language & Update. It implements most of current version of the recommendation, except the service statement. It passes almost all W3C SPARQL 1.1 test cases.

In addition, the Corese Semantic Web Factory has been redesigned and modularized into release 3.0 entirely based on KGRAM interfaces and proxies. Corese 3.0 is a new lightweight RDF/S implementation with SPARQL 1.1. We ported the former Inference Rule engines (forward and backward engines) onto Corese 3.0. We also ported former SPARQL extensions: approximate search based on ontological distance, SQL and XPath in SPARQL 1.1, edge enumeration and length of Property Path, pragmas.

This new version is already used in several applications among which: cartography at IGN [28], design constraint modeling at CSTB [35], technological watch in ISICIL ANR project. It is also used in several PhD Theses in the team. A list of applications can be found on Corese Web site6.

6.1.2. Semantic Web Graph Visualization

Participants: Olivier Corby, Nicolas Delaforge, Erwan Demairy, Fabien Gandon [contact].

Thanks to an INRIA grant (ADT), we design and develop a Semantic Web Gephi Plugin. This plugin is coupling Corese and the Gephi Open Graph Visualization Platform to provide a framework to query and visualize RDF data taking into account their schemas. See the web pages7.

6.1.3. Semantic Social Network Analysis

Participants: Guillaume Erétéo, Fabien Gandon.

The PhD thesis of Guillaume Erétéo [14] in the context of the ANR project ISICIL allowed us to analyze the characteristics of the heterogeneous social networks that emerge from the use of web-based social applications, with an original contribution that leverages Social Network Analysis with Semantic Web frameworks. Social Network Analysis (SNA) proposes graph algorithms to characterize the structure of a social network and its strategic positions.

Semantic Web frameworks allow representing and exchanging knowledge across web applications with a rich typed graph model (RDF), a query language (SPARQL) and schema definition frameworks (RDFS and OWL). In this thesis, we merged both models in order to go beyond the mining of the link structure of social graphs by integrating two approaches: (1) semantic processing of the network typing and (2) emerging knowledge of online activities.

---

6 http://www-sop.inria.fr/teams/edelweiss/software/corese/
8 https://gforge.inria.fr/projects/segviz-public/
In particular we investigated how (1) to bring online social data to ontology-based representations, (2) to conduct a social network analysis that takes advantage of the rich semantics of such representations, and (3) to semantically detect and label communities of online social networks and social tagging activities.

This work was published at [15], [14].

6.1.4. Index Summarizing the Content of RDF Triple Stores

Participants: Adrien Basse, Fabien Gandon, Isabelle Mirbel.

We are interested in designing an architecture to support the distribution of a SPARQL query on a small and fixed number of RDF repositories. To do so, the key stage is to characterize the content of the base of each server in order to be able to predict if a server could contribute or not to the answer of a query. In the context of the PhD Thesis of Adrien Basse we propose an algorithm to extract a compact representation of the content of an RDF store. We improved the canonical representation of RDF graphs based on DFS code proposed in the literature by providing a join operator to reduce the number of generated redundant patterns.

6.1.5. Rules for the Web of Data

Participants: Oumy Seye, Olivier Corby.

In the context of this PhD thesis, the focus is on Rules for the Web of data. We are interested in integrating Rule Interchange Format (RIF) - W3C recommendation for exchanging rules on Web - to others W3C technologies. The aim of this year is to study the integration possibilities of RIF-BLD into semantic Web technologies. RIF-BLD is the dialect of RIF for logic-based systems. Firstly, we have studied the state of the art. Secondly we improved the RIF-BLD parser for presentation syntax and XML syntax. As RIF-BLD can be used with RDF data and OWL ontologies, it is interesting to consider RIF inferences in queries on RDF graph structure. That is why we finally study the integration of RIF-BLD into the Corese Semantic Web engine. In this last step, we have implemented the mapping of abstract syntax tree of RIF-BLD to abstract syntax tree of SPARQL. Thus, we can now execute logic inferences of RIF-BLD in the backward engine of Corese.

We have a paper accepted at EGC 2012 presenting RIF2SPARQL [44], a translation of RIF-BLD statements in SPARQL to perform the logical inferences of RIF-BLD on the Corese Semantic Web Factory. These inferences are implemented in backward chaining approach. We have designed and implemented the mapping of RIF-BLD to SPARQL.

6.1.6. Collaborative Management of Interlingual Knowledge

Participants: Maxime Lefrançois, Fabien Gandon.

We are interested in bridging the gap between the world of natural language and the world of the Semantic Web, in particular to support multilingual access to the Web of Data and management of interlingual knowledge bases. We introduce the ULiS approach, that aims at designing a pivot-based NLP technique called Universal Linguistic System, using Semantic Web formalisms, and being compliant with the Meaning-Text theory. Through ULiS, a user could interact with an Interlingual Knowledge base (IKB) in controlled natural language. Linguistic resources themselves (e.g. dictionary, grammar) are part of a specific IKB, thus, actors may enhance them (i.e. the model of the controlled natural language), through requests in controlled natural language (e.g., add a new lexical units, add grammar rules).

In [30] we proposed a novel approach to define Interlingual Lexical Units classes in the Interlingual Lexical Ontology so that they support the projection of their lexicographic definition on themselves using the OWL formalism. This approach is compliant with the Meaning-Text Theory.

In [31], [40] we introduced three basic interaction scenario for ULiS and we proposed and overviewed the layered architecture of ULiS: meta-ontology, ontology, facts; and ontology, interlingual knowledge, situational knowledge.

We have started a collaboration with the RELIEF project that deals with the construction of a French Lexical Network (Alain Polguère, CNRS-ATILF).
6.1.7. Reuse of Data Analytics Contents and Processes

Participants: Corentin Follenfant, Fabien Gandon, Olivier Corby.

Industrial Business Intelligence (BI) proposes tools and methods to perform data analysis over heterogeneous enterprise sources. They allow one to harvest, federate, cleanse, annotate, query, organize and visualize data in order to support decision making with human-readable documents such as reports, dashboards, mobile visualizations. Such processes currently require expertise in technical domains like relational modeling in order to produce relevant content.

Users willing to do so without following the learning curve have to reuse existing content to create new one, and need to be guided throughout the workflow. Recommender systems can contribute to easing their progression, but most of them will operate inside walled garden for specific tasks instead of assisting the user throughout his workflow.

Semantic Web tools allow us to provide a common ground for modeling the different operations that compose BI workflows with RDFS vocabularies, capturing usage of the underlying transformations operators within document repositories with RDF graphs, and enabling further composition and reuse of BI operations to achieve new analysis. We introduced with [38] an extension of the RDF Data Cube vocabulary\(^9\) to describe these operations as flexible services that are composed by matching multidimensional data structures interfaces, and validated this model on a production repository containing 900 BI documents decomposed into 8000 documents snippets.

The underlying sequence of operations specific to each snippet was then extracted into a unique RDF graph. Aggregate SPARQL queries allow us to compute basic usage statistics for BI operations that can feed recommender systems such as BI workflows wizards. Besides refining the proposed model, next steps include evaluating the technical usability of SPARQL property paths patterns for data lineage and to identify frequent patterns in sequences of BI operations.

This PhD Thesis is done with a CIFRE industrial grant from SAP Research.

6.2. Interaction Design

6.2.1. Question Answering over Linked Data

Participant: Elena Cabrio.

While an increasing amount of semantic data is being published on the Web, the crucial issue of how typical Web users can access this body of knowledge comes to light. This PostDoc project focuses on the development of methods for a flexible mapping between questions in natural language, and data objects. The main purpose is to allow an end user to submit a query to an RDF triple store in English and get results in the same language, masking the complexity of SPARQL expressions and RDFS/OWL inferences involved in the resolution, but at the same time profiting from the expressive power of these standards. In particular, we address the problem of automatic identification of the relevant relations in Question Answering (QA), to capture the context in which the requests should be interpreted, to be able to determine the constraints on the database query.

We aim at investigating the applicability of the Textual Entailment\(^10\) (TE) approach, recently proposed as a general framework for applied semantics, where linguistic objects are mapped by means of semantic inferences at a textual level \([55]\). According to such framework, entailment relations can be detected between an input question and a set of relational patterns that represent possible lexicalizations of the relations of interest. Such relations, collected in a pattern repository, can be associated to a SPARQL query to the database. A TE system should therefore first try to establish an entailment relation between an input question and each of the relations in the pattern repository. Then, the SPARQL queries associated to the relations for which the entailed patterns have been found are composed in a single query to the database.

Since this PostDoc research work has just started, our early efforts were directed toward the study of the state of the art on QA over Linked Data. We are currently carrying out a feasibility study on the extraction of the relational patterns from Wikipedia (as the source of free text) and the use of DBpedia\textsuperscript{11} as a linked data resource. For the experimental part, we are considering energy and environment as the reference scenario.

\subsection*{6.2.2. Mobile Access to the Web of Data}
\textbf{Participants:} Luca Costabello, Fabien Gandon.

This thesis, directed by F. Gandon and I. Herman (CWI and Semantic Web Activity Lead at W3C) deals with accessing the Web of Data from mobile environments. The first year addressed the multi-faceted relationship between ubiquitous consumption of Linked Data and mobile context. More specifically, focus has been put on RDF adaptive representation and on context-aware SPARQL endpoints access control.

When accessed from devices immersed into ubiquitous environments, RDF resources must be properly adapted to the mobile context in which the consumption is performed. A domain-independent, lightweight vocabulary for displaying Web of Data resources in mobile environments has been designed (PRISSMA, Presentation of Resources for Interoperable Semantic and Shareable Mobile Adaptability [36]). The vocabulary is the first step towards an adaptive rendering engine for RDF data coupled with a declarative framework to share and re-use presentation information for context-adaptable user interfaces for Linked Data.

Another line of research regards the role of mobile context in restricting access to the Web of Data. Ubiquitous connectivity enables new scenarios in consuming Linked Data and access control in such pervasive environments must not ignore the mobile context in which RDF consumption takes place, as uncontrolled access in given situations may be undesired by data providers. The work led to enhance the access control framework for SPARQL endpoints proposed by teammate Serena Villata (see 6.2.3) with the notion of mobile context provided by PRISSMA.

\subsection*{6.2.3. Access Control for the Web of Data}
\textbf{Participant:} Serena Villata.

This research activity is mainly focussed on the field of Knowledge Representation. First, we have proposed a new access control model for the Web of Data and the Social Web. In particular, we have introduced the S4AC ontology\textsuperscript{12} where the meaning of the access policies and their components is defined. This access control model proposes, also, a contextual evaluation of the accessors’ information. This model has been applied both to the world of Linked Data and to the world of social networks. This research activity has been addressed in the context of the DataLift ANR project [21], [20].

Second, we have continued a research activity in the area of argumentation theory. In this context, we are exploring the use of argumentation theory for modeling trust in those systems which deal with incomplete knowledge, and for providing explanations about the agents’ choices [22], [19], [23], [25].

\subsection*{6.2.4. ISICIL}
\textbf{Participants:} Nicolas Delaforge, Fabien Gandon.

As the leading team of the ISICIL project, we have developed many software components (client-side and server-side) to enrich the ISICIL platform. First, the whole server mechanism was redesigned, in order to improve the server performance, to strengthen and modularize the framework as well. Many semantic REST services were added (activity stream, syndication, subscription/notification, graphs and charts visualizations).

In collaboration with Erwan Demairy, in charge of the SegViz ADT, a Gephi-ISICIL connector was implemented, allowing ISICIL users to visualize the results of their SPARQL queries directly into a dynamic graph. A demo of this work was presented during the ISICIL public seminarium in September. Furthermore, projects such as Datalift and ISICIL had brought out the need of an access control model for the Web of Data. For this purpose, we designed the S4AC model and ontology and we realized a prototype to evaluate it based on the ISICIL dataset Figure 4.

\textsuperscript{11} http://dbpedia.org

\textsuperscript{12} http://ns.inria.fr/s4ac/
Since the Philoweb conference in 2010, a workshop dedicated to *philosophical engineering* was attached to the French IC conference in Chambery. We presented there the advancement of a brand new bookmark model called *Webmarks* which semantically models the user interest on a web resource (Figure 5 & 6). A long paper on this work was accepted in the EGC 2012 conference and will be published in the RNTI journal (Hermann editions) [27].

We also collaborate with the I3S team in a task of *semantization* of a commercial wiki, called Mindtouch. This wiki is enhanced with semantic description of its content (Figure 7), its users are part of the ISICIL social network and their activities on the wiki are reported on the metadata server. This tool represents the editorial layer of the software bundle developed to improve the business intelligence tasks. This work was also accepted as a long paper in the EGC 2012 conference [26].

### 6.2.5. Models and Methods for Representing and Identifying Groups of Individuals and Their Activities

#### 6.2.5.1. Models and Methods for Representing and Identifying "Collective Personas"

**Participant:** Alain Giboin.

**Context of the work:** ISICIL project.

As opposed to Individual Personas (which are user models represented as specific, realistic humans), Collective personas are models representing specific, realistic groups of people as such (e.g., teams, communities). Collective personas are aimed to design groupware more closely adapted to groups. In 2010, we updated our review of the existing methods for elaborating collective personas. This year, we published the updated review [17].
Figure 5. Webmark GUI
Figure 6. Webmark Model
Figure 7. SweetDeki Resource Model
6.2.5.2. Models and methods for Representing and Identifying Relationships between Individuals

Participants: Alain Giboin, Neji Bouchiba.

Context of the work: AVISICIL project, in collaboration with researchers from the Kewi team (I3S, UNS) and from the Laboratoire de Psychologie Cognitive et Sociale (UNS) who are involved in affective computing design projects (designing systems intended to help elderly people maintain their relationships, or autistic children to build relationships with others).

Digital technologies have been claimed to contribute to prevent elderly people from social isolation or loss of social ties. For example, ubiquitous computing, online social networking and affective computing have been reported to facilitate social interaction \[64\] or to enhance social connectedness \[61\] among the elderly. Participating to a project aimed to design a system for recognizing, through various sensors, the affective states (emotions) that indicate a loss or maintenance of social ties, we conducted a social ergonomic study to provide elements of design and evaluation of such a system. Noting that depressive states are among the most significant signs of an actual or potential loss of social ties (see, e.g., \[65\]), we focused the study in particular on: (a) the models describing the depressive states and the process of their recognition, and the links between these states and the state of social ties; (b) the sensors that can contribute to this recognition. In order to evaluate our solution (so-called GeREmo) with the elderly, we also identified, from an analysis of existing studies on the acceptability of digital technologies, criteria for assessing the acceptability of the GeREmo solution \[50\].

6.2.6. Comparing and Bridging Models of Shared Representations and Representation Sharing Processes

Participant: Alain Giboin.

Context of the work: GDR CNRS Psycho Ergo, Groupe thématique Coopération homme-homme et Coopération homme-machine. Action de recherche RefCom (Référentiel commun), co-led by Pascal Salembier (UTT).

Sharing representations or shared representations are often claimed to be a key factor for a collaboration to succeed. The notions of shared representations and representation sharing processes are examined in the research literature from several points of view; this variety of viewpoints gave rise to different conceptualizations, which are referred to using such terms as Common Frame of Reference, Mutual Intelligibility, Shared Context, Team/Situation Awareness, etc. In 2010, in order to achieve mutual intelligibility between researchers working on such conceptualizations, we elaborated and asked participants to the RefCom joint research action to test and apply a grid for collaboratively comparing and bridging the conceptualizations (see Edelweiss activity report 2010 \[13\]). This year, we analyzed and reported the results of the test and application of the grid \[39\]. This resulted in a revision of the grid.

6.2.7. Frameworks for taking pragmatic dimensions of ontologies into account

Participant: Alain Giboin.

Context of the work: Follow-up to the Palette European project. This work was done in collaboration with the Centre de Recherche sur l’Instrumentation, la Formation et l’Apprentissage, ULg (Belgium).

When designing ontologies, ontologists (i.e., knowledge engineers specialized in ontology engineering) most often focus on the semantic dimensions of ontologies (such as expressiveness, level of granularity, etc.). Pragmatic dimensions, i.e. dimensions related to the context of use (including the purpose) of the ontologies, are often neglected whereas they are critical to users: ontologies indeed are used in context. In brief, pragmatic dimensions are not taken seriously into account when engineering ontologies but they have to.

\[13\] http://raweb.inria.fr/rapportsactivite/RA2010/edelweiss/
We developed a framework to analyze the way we attempted, in the context of the Palette EU project, to contextualize the ontologies underlying a set of semantic knowledge services dedicated to communities of practice. The framework was derived from the Ontology Framework elaborated by members of the Ontology Engineering community during the Ontology Summit 2007 [62]. Both frameworks define a series of "pragmatic dimensions" of ontologies. Because our derived framework did not cover all possible dimensions, we complemented it, by relying on existing work from the Ontology Engineering community in general, and from the Pragmatic Web community in particular [16].

6.2.8. Explanation of Semantic Web Query Results

Participants: Rakebul Hasan, Fabien Gandon, Olivier Corby.

This PhD thesis, directed by Fabien Gandon and Olivier Corby, aims at opening the query-solving mechanism to the users, and handling and explaining the distribution of a query over several sources on the Semantic Web. This work is part of the Kolfow ANR project.

The current Semantic Web search engines are not able to explain how a given query result is obtained or why it has failed to obtain a result. The goal of opening the query-solving mechanism is to enable the Semantic Web query engines to explain the query solving process taking into account the inferences used to obtain the results for a given query. In addition, explanation of the performance indicators of the query-solving process contributes to the understanding of the resolution process. These performance indicators can be effectively used to help in formulating queries by suggesting alternative queries based on the history of the performance of the query-solving process. Another focus of this thesis is on how the distribution of the queries can be performed over the distributed sources and how explanation can be used to better understand the queries and their results over the distributed sources.

In the early stage of this thesis, our current focus is on explaining the Semantic Web query results taking the inferences into account. We are working on justification of results for SPARQL query with RDFS entailment. Our next focus will be on the different abstractions of these justifications with different degree of details and different types of presentations depending on different level of user expertise.

6.2.9. Pervasive Sociality through Social Objects

Participants: Nicolas Marie, Fabien Gandon.

The work is related to semantic spreading activation algorithm, from idea to first results and visualization. Spreading activation is a method for searching semantic networks by labeling a set of initial nodes with weights (called activation), propagating (spreading) that activation out to other nodes linked to the source nodes and iterating propagation. Previously, at the end of 2010, we designed an ontology called OCSO [41]. This ontology aims at describing in a structured format social objects (content augmented by social functionalities independently of its nature: video, place, text, etc.) and corresponding social activity. Then, the need of powerful and semantic sensitive algorithm to process such data led us to follow the track of semantic spreading activation.

Two posters were published at IC [42] and Web Science [43] presenting OCSO model and research axis about semantic spreading activation. A state of the art about exploitation of semantics in spreading activation and its position in the general context of this algorithm family was written. Then a formal proposition was made and algorithm development started leading to first experimental results. The state of the art, the formal proposition and early results were published at the Social Objects workshop [41]. The end of the year was mainly focused about results visualization through Gephi and knowledge acquisition on algorithm and its behavior through multiple tests.

5. New Results

5.1. Polychrony as open-source toolset

Participants: Loïc Besnard, Thierry Gautier, Paul Le Guernic.

A major event for us is that the open-source distribution of the Polychrony toolset has been effective since Summer 2011. The Polychrony toolset is described in Section 4.1. Following the considered part of the software, the distribution is made with the GPL V2 or EPL license. One of the objectives of this opening is to make possible a distribution of the software “by apartment” corresponding to a given functionality or to a group of functionalities, for users or developers that would be interested by only a given part of the whole software. To make this possible, a deep restructuration of the whole software has been undertaken. This takes several forms:

- One is related to the polychronous semantics and the transformations that are applied by a compilation process. A typical example is that of the representation type of the Data Control Graph (DCG), for which different levels of representation are distinguished. Some of them are based on the level of representation of the clock hierarchy.
  - The \textsc{DCGBasic} level is the general type. The DCG represents a program with all dependencies set. Clocks are represented as signals of event type.
  - The \textsc{DCGPoly} level is the subtype of \textsc{DCGBasic} such that the clock hierarchy in the DCG is the result of the clock calculus. Specific clocks such as \textit{tick} are created, but the clock hierarchy, in the general case, has several roots.
  - The \textsc{DCGEndo} level is the subtype of \textsc{DCGPoly} such that the clock hierarchy in the DCG is a tree (it is provided with a single root which is \textit{tick}). The program is endochronous.
  - The \textsc{DCGBool} level is the subtype of \textsc{DCGEndo} such that all clock expressions are boolean extractions. Clocks are represented as Boolean signals (no event type is used). Boolean signals representing clocks have themselves clocks represented as Boolean signals (the clock hierarchy still exists).
  - The \textsc{DCGSeq} level is the subtype of \textsc{DCGBool} such that all nodes of the graph are statically sorted.
  - The \textsc{DCGFlat} level is the subtype of \textsc{DCGBool} such that the clock hierarchy in the DCG is flat: every boolean clock signal is a direct child of the \textit{tick}. Moreover, each state variable (corresponding to delayed signals) is defined at \textit{tick}.

- Another aspect of the reorganization is the automatic reconstruction of the toolset from basic components. For that purpose, a new tool, called \textsc{pKmake}, has been developed, that allows the architect of the software to describe its structure and construction independently of external tools (such as \textsc{emacs} that was used previously). It is especially useful for portability reasons, considering the different systems on which the toolset is provided.

- A third aspect that has required special attention is the automatic generation of the documentation of the source, which is realized using \textsc{cmake}, with an automatic management of cross-references.

In the context of the ITEA2 OPEES project, the Polychrony toolset is being provided as base component of the open-source toolchain of the Polarsys platform and Industry Working Group of the Eclipse consortium. A qualification plan will be defined in this context.
5.2. New features of Polychrony

Participants: Loïc Besnard, François Fabre, Thierry Gautier, Paul Le Guernic.

Some new features have been implemented in the Signal toolbox of the Polychrony toolset:

- It is now possible to declare virtual objects (types, constants and process models), which are distinguished from external objects, though objects declared as external may also be redefined in the context of declaration. The actual value of an object declared as virtual is provided in the syntactic context of declaration or in a module. A module provides a context of definition for some of the objects described as virtual in the model or the module containing the module importation command. These virtual objects are overridden in this way if they are imported (as corresponding objects with the same name) from an imported module, or transitively, from a module imported in an imported module.

- Process models as (static) parameters have been implemented: the formal parameters of the interface of a process model can contain process model parameters, that appear as a formal name of process model typed with a process model type. The call of a process model sets up an expansion context in which an effective process model, designated by its name, is associated with each formal model.

- The connection to the SynDEx tool (http://www.syndex.org/) has been completed as follows. So far, only the functional part of a given application described in Signal was translated as a corresponding “algorithm” in SynDEx. The multicomponent architecture (typically, processors interconnected through communication medias) and the mapping of the algorithm onto the architecture had to be provided directly within SynDEx. As the polychronous model may be used as intermediate common formalism for applications described in languages where these aspects may be specified (this may be the case in AADL, for instance), they have to be taken into account in the translation. Thus, required elements of the architecture and distribution constraints are described using specific “pragmas” in Signal. These features are then translated into the SynDEx formalism. Using all these information, SynDEx can explore the possible implementations of the algorithm onto the multicomponent.

Moreover, we have redefined the meta-model of Signal in Ecplise, now called SSME (for Signal Syntax meta-model under Eclipse). The SME meta-model, that was used previously, suffered from several drawbacks. It was not fully complete in some parts of the language and, due to design choice, required a strict separation between clock and data flow relations. Thus specific program transformations had to be applied, which did not facilitate traceability. SSME is a full syntax oriented meta-model of Signal, very close to the abstract syntax that is used in the Signal toolbox. Compared to SME, this facilitates model transformations and traceability requirements, which are the primary objectives for its use. The transformation of AADL models into Signal, for instance, now uses the SSME meta-model.

5.3. Extensions of the language and the model

Participants: Loïc Besnard, Thierry Gautier, Paul Le Guernic, Jean-Pierre Talpin.

The different works on using the polychronous model as semantic median model (which has also a syntactic instance) for different effective models (AADL, Simulink via GeneAuto, UML via CCSL...) lead us to study various possible extensions of the semantic model as well as the syntactic one. Some of them have already been defined while for others, the study is still ongoing. In particular, we plan to add to the Signal language a new syntax for automata, partly inspired from AADL mode automata and hierarchic automata existing in other formalisms. An automaton is considered as an instance of a new process model and the “and” composition is the Signal composition.
A fundamental issue that we wish to address in a new way is that of globally asynchronous, locally synchronous (GALS), or globally asynchronous, locally polychronous systems. The idea we have is to extend Signal with a syntactic structure that encapsulates a polychronous (or synchronous) process $P$ in a system, $S$, that creates a continuous temporal domain providing a real-time clock presented in different time units (..., $fs$, ..., $ms$, ..., $sec$, $mn$, ...). Such a real-time clock can be used as a usual “synchronous” signal in the process $P$ encapsulated in $S$. Systems $S_1$, ..., $S_n$ may be composed (with the standard composition of Signal) in a same system $S$, but the $ms$ of a given system $S_i$ is a priori not synchronous with the $ms$ of another system $S_j$. Then it is possible to specify standard Signal constraints in the system $S$ on these different signals, to express for instance some variation limits of different clocks.

We have also started a new work on causality aspects in order to express and operate more elaborate dependencies than instantaneous dependencies currently computed on the graph of a program. This theoretical work allows one to express dependencies that cross several instants, in a formal framework of word automata and graph algebra.

5.4. Source to source traceability in Polychrony

Participants: Loïc Besnard, François Fabre, Thierry Gautier.

To fulfill a mandatory requirement for adoption and qualification of Polychrony environment on the open-source industrial platform of the Polarsys IWG, we have integrated source to source traceability features into the Polychrony toolset. The implementation of traceability is based on the definition of structures of data and algorithms allowing to follow the transformation of objects since the Eclipse modeler of the SME Platform until the generated code. These elements have a direct application with our industrial partners, as, for example, Geensoft with whom, within the framework of the ANR project Spacify, we implemented a simulator of embedded software for satellite applications. We have also integrated such a simulator mode in the Polychrony toolset. Moreover, the error messages from the Signal compiler (Signal Toolbox) are now directly visible on the SME Graphical User Interface and on the Synoptic model (Synoptic is a satellite domain-specific modeling language).

5.5. A simulation infrastructure for CCSL, the timing model of UML MARTE

Participants: Huafeng Yu, Loïc Besnard, Thierry Gautier, Jean-Pierre Talpin, Paul Le Guernic.

Clock Constraint Specification Language (CCSL) [32] is defined in an annex of the UML MARTE profile [48]. We are interested in the analysis, synthesis and code generation of multi-clocked/polychronous systems specified in CCSL. Timed systems subject to clock expressions or relations can be modeled, specified, analyzed, and simulated within the software environments, such as SCADE [41], TimeSquare [44] and Polychrony. However, code generation from a multi-clocked system is far from obvious. For instance, SCADE always uses a reference or master clock (the fastest); all clocks and all conditions are defined as a functional sampling of this master clock, from the highest specification down to the lowest generated code. In TimeSquare, clock constraints are solved using a heuristic algorithm, which is generally non-deterministic. On the contrary, in Polychrony, a formally defined refinement process yields to the generation of (sequential or concurrent) code by the addition of control variables to get a deterministic behavior satisfying the constraints and allowing the desired amount of concurrency.

The motivation of our work, to address the simulation and code generation of polychronous systems, is to take advantage of the formal framework of Polychrony in the context of a high-level specification formalism, MARTE CCSL [22]. Yet, our work considers a novel approach with regards to previous approaches: to generate executable specifications by considering discrete controller synthesis (DCS) [50], [45], [46]. Clock constraint resolution is addressed by DCS, which does not necessarily require a master clock to address polychronous clocks. In our approach, polychronous (CCSL) specifications are first partitioned: clock relations are considered as control objectives, other constraints are considered as the system to be controlled. The all the constraints are translated into, via SIGNAL, polynomial dynamical systems (PDSs). A PDS represents the transition system of a specification as well as the constraints (invariants) it must satisfy. The Sigali tool
is then used to generate the controller. Finally, the generated controller, together with the original system, is composed to complete the code generation for simulation. In our approach, the temporal semantics of CCSL is mapped onto a polychronous model of computation, on which effective synthesis is carried out to meet constraint requirements. This approach provides both a useful mapping in theory and a flow, which is practical in the generation of reactive controllers.

5.6. The CESAR demonstrator and reference technology platform

Participants: Huafeng Yu, Yue Ma, Loïc Besnard, Thierry Gautier, Jean-Pierre Talpin, Paul Le Guernic.

The design of embedded systems from multiple views and heterogeneous models is ubiquitous in avionics as, in particular, different high-level modeling standards are adopted for specifying the structure, hardware and software components of a system. The system-level simulation of such composite models is necessary but difficult task, allowing to validate global design choices as early as possible in the system design flow. Inspired by the Ptolemy [40], MoBIES [31], SML-Sys [47], etc., we propose an approach to the issue of composing, integrating and simulating heterogeneous models in a system co-design flow [21]. First, the functional behavior of an application is modeled with synchronous data-flow and Statechart diagrams using Simulink/Gene-Auto [54], [55]. The system architecture is modeled in the AADL standard [52]. These high-level, synchronous and asynchronous, models are then translated into a common model, based on a polychronous model of computation, allowing for a Globally Asynchronous Locally Synchronous (GALS) interpretation of the composed models. This translation is implemented as an automatic model transformation within Polychrony. Simulation, including profiling, value change dump demonstration [24], Syndex adequation [43], etc., is carried out based on the common model within Polychrony.

Polychrony has been integrated to the Reference Technology Platform (RTP) V2 and V3 of CESAR to serve as a framework for co-modeling and architecture exploration. ModelBus [49] is used for the integration of Polychrony into the RTP. ModelBus [25], an integration platform based on Service-Oriented Architecture (SOA), connects different services offered by tools connected to ModelBus. In the demonstration, we participated in the pilot application of Sub-Project 3 (SP3), whose aim is to use the RTP to define a complete software design flow for the doors management system (DMS) of an Airbus A350 in the framework of ModelBus. In the pilot application of the DMS, functional components are modeled in the synchronous model of computation of Simulink, whereas the architecture is modeled in the asynchronous model of computation of AADL [14], [18]. These high-level models are transformed into Signal programs via SME models. Additional models, which are used in the simulation of a closed system, are coded manually in Signal and synchronously composed with the Signal programs transformed from Simulink and AADL models. Finally, C or Java code is generated from Signal programs. Simulation can then be carried out for the purpose of performance evaluation and VCD (Value Change Dump) based demonstration in RTP V2. In RTP V3, Syndex adequation is also integrated to demonstrate real-time scheduling and distribution. Our whole model transformation and simulation chain has been implemented with Galileo Eclipse and attached to ModelBus as a provider of registered remote service. This demonstration also shows the integration of Polychrony with other tools, such as OSATE (AADL), Simulink, Gene-Auto, TimeSquare, ATL, Kermeta, etc.

5.7. Modeling AADL in a polychronous model of computation

Participants: Loïc Besnard, Thierry Gautier, Paul Le Guernic, Jean-Pierre Talpin, Huafeng Yu.

Architecture Analysis and Design Language (AADL) is an SAE standard aimed at high level design and evaluation of architecture of embedded systems. We are interested in the analysis, simulation and verification of timed systems specified in AADL. Polychrony is well suited for the GALS architecture, and it enables deterministic specifications and formal analysis for the design of safety-critical systems. In order to benefit from the advantages provided by Polychrony, a proposition of a methodology for system-level modeling and validation of embedded systems specified in AADL via the polychronous model of computation is proposed.
By studying the different timing semantics of AADL and Polychrony, we have proposed an approach that automatically translates AADL models to a polychronous model of computation (SSME model). In the Polychrony framework, the Signal program can be generated, and an executable model can be obtained. The systems can be analyzed by tools and technologies associated with Polychrony allowing early simulation, testing and verification.

We implemented a plug-in for Eclipse framework to perform model transformation from AADL to SSME (new meta model of Signal). This transformation is implemented in Java. The following new features have been developed this year:

- Temporal interpretation of AADL model. Due to the different timing semantics between AADL and Signal, we keep the ideal view of instantaneous computations of polychronous model, moving computing latencies and communication delays to specific memory process, that introduce delays and well suited synchronizations. Each component modeled in Polychrony is composed of a behavior process (which models the functional behaviors) and a property process (which models the temporal properties).
- Architecture restructures. The architecture of the transformation is optimized. Functional architecture and meta architecture are described to give a global view of the transformation. The translation is recursive. Each AADL component is separated into a java class. The hierarchy of classes are reserved.
- Library developments. We define a Signal library containing the Signal process models representing some basic AADL concepts.
- Documentation. A new technical documentation of the transformation from AADL to SSME has been developed to accompany its implementation. This document aims to provide a global view of our implementation, from a high-level structural view to low-level implementation technical details of components.
- Programming language updates. This version of model transformation uses Java as the programming language. It avoids the disadvantages of dependent on other model transformation languages, and it provides more conveniences and flexibility. The new version is integrated as a plug-in in the Eclipse platform.
- Papers published. Three papers [14], [18], [21] are published this year.

5.8. Composing Simulink and AADL

Participants: An Phung-Khac, Jean-Pierre Talpin, Benoit Combemale, Jean-Marc Jezequel.

The goal of this work is to improve an import function of the Polychrony environment proposed by the team. Particularly, Polychrony comprises a co-modeling tool supporting the import a high-level Simulink (functional) and AADL (architectural) specifications [21]. This import function is currently implemented by two different transformations, namely Simulink-to-Signal, and AADL-to-Signal. To integrate the Signal programs resulting from these transformations, some Signal interfaces are manually implemented. The composition of Simulink and AADL models thus depends on system designers who implement the interfaces, making difficult its maintenance and validation. To deal with this issue, the model composition approach proposed by the Triskell team, namely ModMap [37], could be used to build a new Simulink and AADL model composition framework.

In ModMap, model composition is considered as a pair of a mapping and an interpretation. A mapping aligns concepts of two meta-models, while the interpretation describes the composition goal. As a model mapping framework, ModMap provides an extensible modeling language supporting the definition of generic mappings and the definition of interpretations. Together with this language, the ModMap kernel is also implemented as an extensible set of mapping processing functions. Model composition frameworks are then built by extending the language and the kernel according to specific composition purposes.
As mentioned above, we intend to apply the ModMap approach to the development of the Simulink and AADL model composition framework. To this end, we need to extend the ModMap mapping language to obtain an other one that allows system designers to align elements between Simulink and AADL models regarding the purpose of co-simulation in Signal. Then, a transformation, namely ModMap-to-Signal, needs to be implemented by extending the ModMap kernel. This transformation uses mappings provided by system designers as inputs to generate Signal interfaces. The three transformations (i.e., Simulink-to-Signal, AADL-to-Signal, and ModMap-to-Signal) form the new model composition framework. Compared to the previous one, this framework will more automated. On the other hand, existing transformations will also be reused.

5.9. From affine-related dataflow models to Safety-critical Java

Participants: Adnan Bouakaz, Jean-Pierre Talpin, Jan Vitek.

The objective of this work is to investigate a dataflow concurrency model in order to help specifying, analyzing, and synthesizing functionally deterministic and schedulable SCJ applications. Indeed, the SCJ shared-memory concurrency model makes proving functional determinism and schedulability of applications quite hard if not impossible.

The new model is called the firing related dataflow (FRDF) model in which actors are connected to each other by means of bounded channels. The operational semantics of this model is based on the notion of firing relations. Each actor is associated with a firing clock (an infinite set of activation ticks). The proportionality of the rates of two clocks is expressed by a firing relation. A special and enough expressive case of firing relations is the class of affine relations. Some results about the canonical form of affine relations are already developed by the ESPRESSO team.

Our first study was about synthesizing affine relations between firing clocks in such a way that overflow and underflow exceptions cannot occur during execution. This synthesis is conducted by minimizing the overall of buffer sizes. It is proven that the operational semantics of the dataflow graph based on the computed affine relations is equivalent to the Kahn semantics. This implies that functional determinism is guaranteed.

The previous analysis step (called affine relations synthesis) aims to produce an abstract schedule of the dataflow graph. The computed schedule is abstract in the sense that it is independent from the implementation code of actors and from the target machine. Executing the graph on a mono-processor system using EDF scheduling algorithm is investigated in our study. We synthesize the timing characteristics of each actor (i.e. its period and phase) in such a way the set of tasks is schedulable. In this timing synthesis, we use the worst-case execution times computed from the Java implementation code of actors.

Our objective is to automatically generate a SCJ application from a dataflow specification. Currently, we work on increasing the expressivity of the underlying dataflow model together with providing the necessary analysis tool for generating deterministic and schedulable SCJ code.

5.10. Translation validation of Polychronous Equations with an iLTS Model-checker

Participants: Van-Chan Ngo, Jean-Pierre Talpin, Loïc Besnard.

Synchronous languages such as SIGNAL have been introduced and used successfully for the design and implementation of embedded and critical real-time systems. They rely on the fact that programs are modeled as data-flow equations or finite state machines that allow formal reasoning on designs. In consequence of that, a full toolset of synchronous languages provides formal transformation, automatic code generation, formal verification...
In general, the synchronous language’s compiler takes several translations from the source program before generating the target code (e.g. C/C++ or Java code), thus we present an approach to verify these translations of synchronous language compiler. Our approach adopts the translation validation notion \[49\]. The idea of translation validation is the following: rather than proving in advance that the compiler always produces correct translations, each individual translation (e.g. every run of the compiler) is followed by a validation phase which verifies that the final output of this run correctly implements the input source program. This method avoids the drawback of freezing the potential improvements and/or developments of the compiler of the traditional compiler verification. For every small change in the compiler, the verification must be redoing the proof, that is an extremely complex task.

The validation phase is made automated which consists of:

(i) Represent both the input source and output target SIGNAL programs as Polynomial Dynamical Systems - PDSs.

(ii) Propose a refinement relation for the PDS models of the source and target programs.

(iii) Use a syntactic simulation-based proof method which automatically verifies the refinement. This automated proof is done by extending the functionality of the model checker SIGALI in the Polychrony toolset.

5.11. PDSs for translation validation: from SIGNAL to C

Participants: Van-Chan Ngo, Jean-Pierre Talpin, Loïc Besnard.

Synchronous programming languages provide a formal and abstract model of concurrency to facilitate the implementation of concurrent embedded software by automating the most complex tasks of verification, validation and code generation. They also guarantee the reliability of the design/implementation of concurrent embedded software by providing either the proof of compiler’s correction or the validation of each run of the compiler. Adopting the translation validation approach \[49\], we provide an automatic process to formally verify the code C generation task of the SIGNAL’s compiler.

The verification framework will take the SIGNAL program and the generated C code program as the input and proves whether the generated C code correctly implements the SIGNAL program. It also allows to automatically generate the refinement and counterexamples of the generated C code.

Polynomial dynamical system - PDS is used as a common semantic framework to model the behavior of both the SIGNAL program and its generated C code. First, the generated C code is translated into the target SIGNAL program \[34\] thanks to the intermediate SSA forms. An appropriate relation called refinement for PDSs is proposed to represent the correct implementation relation between the SIGNAL program and its generated C code. The generated code C correctly implements the SIGNAL program if and only if there is a refinement for their PDSs and we say that the generated C code’s PDS refines the SIGNAL program’s PDS. A proof method which allows to generate the refinement or counterexamples, and then proposes a refining process for the generated C code.

5.12. Synchronous symbolic translation systems for translation validation

Participants: Van-Chan Ngo, Jean-Pierre Talpin.

We propose a framework for verification of the correct implementation of the SIGNAL compiler’s generation code task. In order to present the formal semantics of SIGNAL and generated code programs we introduce synchronous symbolic transition system (SSTS) which is the computational model of our formal verification approach. We denote \(\mathcal{D}_V = \prod_{i \in [1,n]} \mathcal{D}_{v_i}\) as the domain of a set of variables \(V = (v_1, \ldots, v_n)\). A set of states \(P \subset \mathcal{D}_V\) is defined as a predicate over the set of variables \(V\) such that the predicate is held in \(P\). An assignment \(A\) is a function \(A : \mathcal{D}_V \rightarrow \mathcal{D}_V\) that the values of the variable set \(V\). A SSTS is a tuple \(L = (V, \Theta, \Gamma, \mathcal{E})\) where:

- \(\mathcal{D}_V = (v_1, \ldots, v_n)\) is a set of variables,
- \(\Theta \subseteq \mathcal{D}_V\) is a predicate on \(V\) defining the initial condition on the variable set,
- \(\Gamma\) is a finite set of symbolic transitions \(\gamma = (P_\gamma, A_\gamma)\) where:
- $P_\gamma \subseteq \mathcal{D}_V$ is a predicate on $V$, which guards $\gamma$
- $A_\gamma : \mathcal{D}_V \rightarrow \mathcal{D}_V$ is the assignment function of $\gamma$

- $E \subseteq V$ is a set of externally observable variables.

The generated code correctly implements the SIGNAL program if and only if there is a refinement for their SSTSs and we say that the generated code’s SSTS refines the SIGNAL program’s SSTS. This framework also works with SIGNAL programs which is considered as infinite state systems. To obtain the verification results, we apply abstraction interpretation techniques [39] which provide over-approximations of the refinement relation between the input SIGNAL program’s model and the output generated code’s model.

5.13. An integrated environment for Esterel/Quartz and Polychrony/Signal

Participants: Jens Brandt, Ke Sun, Jean-Pierre Talpin.

The design of modern embedded software architectures relies on models and programs built and reused from engineering teams with specific skills and know-how. Each of these skills and backgrounds correspond to specific tools and processes that help implement the viewpoint under consideration with mathematically grounded foundations.

It is not uncommon, for instance, that the design of the only functional views of a system may require the use of tools as heterogeneous and exotic as Catia, Scade, Matlab or Rhapsody. The same holds for design objectives that may range from that of mapping the functional design on specific hardware architectures to that of virtual prototyping for simulation or performance or energy usage evaluation.

Co-modeling itself encompasses the variety of engineering activities that cross the border between the functional and physical views of system design. It is typically the system architects, who will put together functional components and explore different metrics for an effective and efficient mapping on target systems.

We wish to further and scale the framework and experiments developed within the CESAR and OPEES projects in that respect, by thinking a new, domain-specific language, built from synchronous modules designed with Quartz, an imperative synchronous programming language, and connected by data-flow networks described in Signal, the polychronous data-flow language at the core of Polychrony. The combination of viewpoints or paradigms offered by these two design environments provides powerful abstractions and easy to use concepts in order to address two design challenges of utmost importance:

- To provide a natural and dependable specification of elementary synchronous functionalities, most of them algorithmic and control-intensive, in the imperative framework offered by Quartz.
- To synthesize the scheduling of computations and communications among these functionalities starting from the multi-clocked synchronous abstractions offered by the Signal data-flow language.

The remaining long-term goal will then be homogenize this programming framework by further extending it with the capability to control polychromous networks, seen as modes of execution, with a Quartz module, which would control mode changes.

5.14. Quality assessment and qualification of Polychrony on the open-source Polarsys IWG platform

Participants: Loïc Besnard, Thierry Gautier, Paul Le Guernic, Jean-Pierre Talpin.
Since the open-source release of Polychrony and in the context of the ITEA2 OPEES project, we are collaborating with CS to the integration of Polychrony on the Polarsys platform. This integration proceeds according to guidelines and requirements under definition within the OPEES project and aims first, at putting them to the test. The qualification process of Polychrony in Polarsys consists of checking the maturity level of its implementation and documentation (a standard software engineering assessment) but is also concerned with its capabilities to be composed, inter-operated and mapped with other components on the platform to form a application-specific design toolchain, by using model-driven engineering technologies for model transformation and orchestration. The last phase of this assessment is with regards to its qualifiability, as a simulation tool, as a verification tool, as a code generation tools, which needs to adhere standards such as these defined the in DO178 documents. In parallel, the quality assessment of Polychrony is complemented with a case study, of the APOTA network protocol, whose aim is to document, as a tutorial, the use and added-value of the toolset for its future users on the Polarsys platform.
ESTIME Project-Team (section vide)
6. New Results

6.1. High level model for shapes

6.1.1. Constructive implicit modeling

**Participants:** Adrien Bernhardt, Marie-Paule Cani, Maxime Quiblier, Cédric Zanni.

Implicit surfaces are an appealing representation for free-form, volumetric shapes. In addition to being able to represent shapes of arbitrary topological genus, they have the ability to be constructed by successively blending different components, which eases interactive modeling.

Within Cédric Zanni’s PhD, we are collaborating with a researcher in formal computation, Evelyne Hubert, to improve and extend the analytical methods for computing closed form solutions for convolution surfaces. We introduced a warping method for enabling the modeling of complex helical shapes from a single implicit primitive (fig. 3), which greatly enhances efficiency [14]. We also proposed a method based on anisotropic, surface Gabor noise, for generating procedural details on skeleton-based implicit surfaces. The surfaces enhanced with details can still be smoothly blended, with a natural transition between the details they carry. A paper has been submitted for publication. We are currently developing normalized convolution surfaces, invariant through homothetic transformations, and which will provide an intuitive blending sharpness parameter, usable with simple additive blending.

![Figure 3. Top: Helical primitives. Bottom: Implicit modeling of a squid. Each tentacle is made of two helical primitives.](image_url)

Lastly, we contributed to a new blending operator, gradient blending, which enables us to blend implicit shapes not only in function of the field values but also of their gradients. This solves a number long standing problems in implicit modeling: we can generate bulge-free blending, ensure that the topological genius of the blended shape remains the one of the union of the input one, and avoid the blur of small details. A paper is currently submitted for publication.
6.1.2. **Ontology-based mesh segmentation**  
**Participant:** Olivier Palombi.

The smart use of data by automated systems is now a problem having implications as various as the optimization of the functioning of web search engine or medico-surgical simulation. The program MyCF is an attractive innovation in this field, gathering an organization of the biomedical knowledge in the form of ontologies, 3D acquisition of anatomical structures and also the possibility to export these 3D structures to biomechanics simulation programs, like SOFA. Our work consisted in creating, thanks to the program Protégé, an ontology of the functions of the human body (which didn’t existed then) and to couple it with the anatomical ontology FMA (ontology we significantly reworked). The objective was to build connections introducing a link between anatomical structures and functions they bear. Once this goal reached, it became possible for a computer to link the elimination of an anatomical structure and the loss of a function, this real-time. Thus we established the foundations of an ontology which currently gather 84484 entities (4330 of which are functional entities) and 4159 relations. So, our contributions are threefold: first of all, the creation of an ontology of functions of the human body which is an original one; then the redrafting of the FMA ontology which allowed us to complete some lacks and above all to make of it a tool more oriented towards the practical applications we waited about it, and finally, the contribution which seems to us the more significant is, without any doubt, the institution of a link between these two ontologies. This work is at is moment unfinished and should be pursued in order to approach always more the reality in the field of medico-surgical simulation.

6.1.3. **French translation of the Foundational Model of Anatomy (FMA) ontology**  
**Participant:** Olivier Palombi.

The goal of this study, performed in collaboration with the LITIS was to facilitate the translation of FMA vocabulary into French. We compare two types of approaches to translate the FMA terms into French. The first one is UMLS-based on the conceptual information of the UMLS metathesaurus. The second method is lexically-based on several Natural Language Processing (NLP) tools. The two approaches permitted us to semi-automatically translate 3,776 FMA terms from English into French, this was to added to the existing 10,844 French FMA terms in the HMTP (4,436 FMA French terms and 6,408 FMA terms manually translated).

6.1.4. **Homology computation**  
**Participants:** Dobrina Boltcheva, Jean-Claude Léon.

This work is a part of the BQR project IDEAL which is performed in collaboration with Leila de Floriani from the University of Genova in Italy. The main goal of this project is to study non-manifold geometrical models and to find out features allowing to classify these models and criteria for determining their shape. We are interested in non-manifold models such as idealized industrial CAD models, since they are still ill-understood even if they are frequently used in computer graphics and many engineering applications. This year, we have worked on the computation of topological invariants on non-manifold simplicial complexes, such as the homology groups, since they play a crucial role in the field of shape description and analysis. The goal was also to acquire a better understanding of the behaviour of the homological groups on non-manifold models. A first step towards this goal has been achieved this year and we have developed an efficient method for computing the homology of a large simplicial complex from the homologies of its sub-complexes. This work has been already published in a research report in 2010 and a journal paper in the context of the international conference on Solid and Physical Modeling.

6.1.5. **Creased paper modeling**  
**Participants:** Marie-Paule Cani, Stefanie Hahmann, Damien Rohmer.

Although very common in real life, 3D creased paper models are rarely seen in virtual scene due to the lack of available modeling tools.

---

1Laboratoire d’Informatique, de Traitement de l’Information et des Systèmes (LITIS) Institut National des Sciences Appliquées de Rouen – Université du Havre – Université de Rouen
We developed a new approach to efficiently generate a 3D model of creased paper from a boundary curve (see fig. 4). The generated surface lie on the given boundary curve while preserving the lengths with respect to the original pattern. Contrary to other approaches, this method can seamlessly handles sharp creases while automatically generating the optimal mesh to this shape. The generation is fast enough to be used interactively, and the physical properties such as developability are approximatively preserved. This generation of static surface generation has been published in EG short paper [22].

6.1.6. Spline surface models for arbitrary topologies

Participant: Stefanie Hahmann.

In geometric modeling quad meshes have always been popular, in the sense that NURBS surfaces which are composed of a tensor product network of quadrilateral patches, are the inevitable standard for describing free-form shapes. They are defined on a chess board like assembly of quadrilateral parameter domains. But when modeling shapes of arbitrary topological type with tensor product NURBS, it is necessary to overcome the restriction of the tensor product configuration where always 4 patches meet at a common corner by using singular parameterizations.

We are developing new smooth parametric surface models defined on irregular quad meshes are in fact a powerful alternative to singularly parameterized tensor product surfaces since they combine the advantages of both, the arbitrary topology of quad meshes and the smoothness of the tensor product patches. Herein, tensor product polynomial patches are assembled with tangent plane continuity, in one-to-one correspondence to the mesh faces. They are thus capable to represent manifold shapes of arbitrary topological type since no restriction on the number of patches assembled around a mesh vertex exists.

While subdivision surfaces can also produce a smooth shape with only a few subdivision steps from a coarse mesh, our parametric surfaces have the advantage to provide an explicit parameterization. Moreover, all classical modeling operations such as trimming, intersection, blending and boolean operations can be preformed with parametric patches. Tensor product patches can furthermore make profit from the powerful tools of existing modeling systems for purposes of evaluation, display, interrogation and all operations cited above.

In collaboration with G.-P. Bonneau (Artis team) several parametric triangular surface models for arbitrary topologies have been published in the past (CAGD, IEEE TVCG and ACM ToG). A new tensor product spline surface model has been developed this year. It solves the problem of defining a G^1-continuous surface interpolating the vertices of an irregular quad mesh with low degree polynomial tensor product patches. It further aims to produce shapes of very high visual quality while reducing the number of control points. A comparison with existing methods and a journal paper are on-going work.
6.1.7. Point sampled surfaces

Participant: Stefanie Hahmann.

Point sampled geometry from scanned data exhibits very characteristic shapes, due to the presence of sharp features in most manufactured and designed objects. Therefore, reconstruction of surfaces from unorganized point sets using MLS fitting requires additional attention. In fact, it is an inherent property of MLS fitting to produce smooth surfaces, thus all sharp features in the point cloud may also be smoothed out. Instead of searching for appropriate new fitting functions our approach was to introduce a new method for selecting an appropriate local point neighborhood for the projection operator so that a standard MLS fitting automatically reproduces sharp features.

This work was part of Christopher Weber’s Ph.D. thesis, which has been co-advised by S. Hahmann and H. Hagen from TU Kaiserslautern, Germany. First part of the work on Gauss map clustering for feature point detection has been published in the SMI 2010 proceedings. The second part has been submited to a Computer Graphics journal. The thesis has been defended in August 2011.

6.1.8. Volume preserving Free-Form Deformations

Participant: Stefanie Hahmann.

![Comparison between standard FFD deformation (top) and our method preserving the volume (bottom).](image)

Free Form Deformation (FFD) is a well established technique for deforming arbitrary object shapes in space. Although more recent deformation techniques have been introduced, amongst them skeleton-based deformation and cage based deformation, the simple and versatile nature of FFD is a strong advantage, and justifies its presence in nowadays leading commercial geometric modeling and animation software systems. Several authors have addressed the problem of volume preserving FFD. These previous approaches however make either use of expensive non-linear optimization techniques, or resort to first order approximation suitable only for small-scale deformations. Our approach was to take advantage from the multi-linear nature of the volume constraint in order to derive a simple, exact and explicit solution to the problem of volume preserving FFD. Two variants of the algorithm have been developed, without and with direct shape manipulation. Moreover, we showed that the linearity of our solution enables to implement it efficiently on GPU.

This work has been done in collaboration with G. Elber from TECHNION, H. Hagen from TU Kaiserslautern, G.-P. Bonneau and S. Barbier from Artis INRIA. It has been accepted for publication in the journal The Visual Computer [6].

6.2. High level models for animation

6.2.1. Geometrical methods for skinning character animations

Participants: Marie-Paule Cani, Stefanie Hahmann, Damien Rohmer.
Skeletal animation is an efficient and widely used technique in video games or movie industry due to its flexibility and simplicity. Still, the skinning method do not take into account informations about the physical properties of the underlying material. Therefore effects such as muscle bulging or fat tissue compression cannot be modeled without the addition of a tedious manual correction. Within Damien Rohmers PhD [1], an active geometry framework was proposed in order to enhance geometry information with a priori knowledge about how the underlying material can deform. For instance, bending the belly of an animal will be constraint to generate bulges that will preserve locally the volume (see fig. 6). The process can be either purely automatically generated, or it can be artistically controled.

6.2.2. Action representation, segmentation and recognition

Participant: Remi Ronfard.

Following Daniel Weinland’s PhD thesis, we published a survey of modern methods for representing, segmenting and recognizing full-body actions in video [12]. A taxonomy of methods is elaborated in that paper, where actions can be represented with local, structured or global features both in time and in space. The potential for future work in grammar-based action recognition is emphasized, with possible applications in corpus-based procedural modeling of actions.

6.2.3. Frame-based simulation of deformable solids

Participants: Guillaume Bousquet, François Faure.

We present a new type of deformable model which combines the realism of physically based continuum mechanics models and the usability of frame-based skinning methods [4]. The degrees of freedom are coordinate frames (see Figure 15). In contrast with traditional skinning, frame positions are not scripted but move in reaction to internal body forces. The displacement field is smoothly interpolated using blending techniques such as dual quaternions. The deformation gradient and its derivatives are computed at each sample point of a deformed object and used in the equations of Lagrangian mechanics to achieve physical realism. This allows easy and very intuitive definition of the degrees of freedom of the deformable object. The meshless discretization allows on-the-fly insertion of frames to create local deformations where needed. We formulate the dynamics of these models in detail and describe some pre-computations that can be used for speed. We show that our method is effective for behaviors ranging from simple unimodal deformations to complex realistic deformations comparable with Finite Element simulations.
Interaction and Visualization - New Results - Project-Team EVASION

Figure 7. Physical realism is obtained with very sparse sampling: two frames are sufficient to model a dynamically deformable bunny [3].

We extend the approach (see fig. 7) to the simulation of complex, intricately material distributions using material-aware shape functions [3]. Given a volumetric map of the material properties of an object and a number of control nodes, a distribution of the nodes is computed automatically, as well as the associated shape functions. Reference frames are attached to the nodes, and deformations are applied to the object using linear blend skinning. A continuum mechanics formulation is derived from the displacements and the material properties. We introduce novel material-aware shape functions in place of the traditional radial basis functions used in meshless frameworks. These allow coarse deformation functions to very efficiently resolve non-uniform stiffnesses. Complex models can thus be simulated at high frame rates using a small number of control nodes.

To encourage its use, the software is freely available in the simulation platform SOFA.

6.3. Towards interactive digital creation media

6.3.1. Sketch-based modeling and shape editing

Participants: Adrien Bernhardt, Rémi Brouet, Marie-Paule Cani, Jean-Claude Léon, Olivier Palombi.

Figure 8. User-sketched high-field modeling a terrain.
3D modeling from a sketch is a fast and intuitive way of creating digital content. We developed a method based on convolution surfaces for inferring free-form shapes in 3D from arbitrary progressive sketches, without any a priori knowledge on the objects being represented (see the section describing the Aestem Studio software). We recently investigated whether 2D deformation could be a better approach than sketching for defining the 2D sketch given as input [18]. Results are very promising; we are planning both to allow such intuitive deformations, combined with sketching, within the Aestem software, and to extend them to the editing of the 3D deformed shape. This will be done in the context of Rémi Brouet’s PhD thesis, co-advised by Renaud Blanch from the IHM/LIG team.

We also develop methods for interpreting complex sketches (contours with T-junctions) based on some a priori knowledge. Our first work on this topic used the conventions of anatomical drawing to infer the 3D geometry of vascular systems, with branching and occlusions, from a single sketch [10]. We are also investigating the design of realistic terrains from a single sketch, within the PhD thesis of Adrien Bernhardt (see fig. 8). Our first advances include a new representation and new methods for generating a high-field from user-sketched constraint curves [30], [17].

### 6.3.2. Free-form sculpture

**Participants:** Marie-Paule Cani, Lucian Stanculescu.

In the context of Lucian Stanculescu’s PhD thesis, co-advises by Raphaëlle Chaine from LIRIS (Lyon), we developed an interactive sculpting system enabling both arbitrary deformation and topological changes of a free-form shape [11]. Our method is based on a semi-regular mesh which adaptively refines and changes its topology according to the need. See Figure 9. We are currently extending the method for handing the sculpting of composite objects made of many different components.

![Figure 9. Sculpting with topological changes made within the framework from [11].](image)

### 6.3.3. Hand Navigator

**Participants:** Jean-Rémy Chardonnet, Jean-Claude Léon.

The different deformation models we developed in the past few years open the problem of providing intuitive interaction tools for specifying the desired deformations in real-time. Therefore, our recent work focused on developing new devices for interacting with the model to deform. For the past two years, we focused on developing a peripheral device similar to a mouse, called the HandNavigator, enabling to control simultaneously ten or more degrees of freedom of a virtual hand. This device consists in a 3D mouse for the position and orientation of the hand in 3D space, enhanced with many sensors for moving and monitoring the virtual fingers. Thanks to a pre-industrialization project funded by the incubator GRAVIT, the first prototype, patented by INRIA, has been extended with the incorporation of new sensors and new shapes to improve the device efficiency. An ongoing extension of the patent and a partnership with HAPTION company are new...
step toward the industrialization of this device. Dissemination to general public has been performed at the “Fête de la Science” and another exhibition. Publications will take place after setting up the patent extension. The ongoing BQR INTUACTIVE funded by Grenoble-INP will lead to further scientific topics regarding interactions during grasping as well as with deformable bodies and a partnership has been set up with GIPSA-Lab to study the muscular activity during interactions.

6.3.4. Procedural modeling

Participants: Marie-Paule Cani, Arnaud Emilien.

We developed a method for procedurally generating villages with the appropriate roads and streets on arbitrary terrains, in collaboration with Eric Galin from LIRIS, Lyon. This work will be continued within Arnaud Emilien’s PhD thesis towards more general models for populating terrains with houses, vegetation, and animals. We will focus on the development of intuitive ways to edit procedural models, to overcome the main drawback of these approaches.

6.3.5. Computational model of film editing

Participant: Remi Ronfard.

Building on Remi Ronfard’s experience leading the virtual cinematography research team at Xtranormal Technology, Montreal, we designed a novel computational model for automatic editing of animated movies (see fig. 10). A prototype has been implemented in a collaboration with the Bunraku/mimetic team, and demonstrated in poster sessions at the Symposium on Computer Animation (SCA) [31] and International Conference on Interactive Digital Storytelling (ICIDS) [21]. This early work opens new directions that will be further explored by the IMAGINE team, including corpus-based learning of cinematography and editing styles.
6. New Results

In the continuation of our previous work, in 2011 we developed our work on evaluation of ontology matching and especially in running new experiments and generating new tests (§ 6.1.1). We also continued our work on trust in semantic peer-to-peer systems (§ 6.2.2), the use of the $\mu$-calculus for evaluating RDF path queries (§ 6.2.1) and ontology matching for linking data (§ 6.1.2).

6.1. Ontology matching and alignment

We pursue our work on ontology matching and alignment support with contributions to evaluation, data interlinking and multilingual matching.

6.1.1. Evaluation

Participants: Cássia Trojahn dos Santos [Contact], Jérôme Euzenat, Jérôme David.

Evaluation of ontology matching algorithms requires to confront them with test ontologies and to compare the results. Since 2004, we run the Ontology Alignment Evaluation Initiative (OAEI) which organises evaluation campaigns for assessing the degree of achievement of actual ontology matching algorithms [4]. This year, the evaluation campaign had 16 different teams entered the evaluation which consisted of 5 different sets of tests. The participating systems and evaluation results were presented in the 6th Ontology Matching workshop, that was held in Bonn, DE [17][9].

The main activities carried out in 2011 were related to the automation and execution of the OAEI 2011 campaign, in the framework of the SEALS project (see § 8.2.1). This involved the following main tasks:

- describe evaluation processes within the early version of the SEALS platform [11];
- develop a client allowing participants to validate their wrapped tools and evaluate (offline and locally) their tools;
- develop a test generator for automatic generation of systematic benchmarks [12];
- providing participants with a better way to bundle their tools so that they can be evaluated within the SEALS platform; and
- analysis and report of the evaluation campaign results [9].

This work has been used in the OAEI 2011 evaluation campaign. More information on OAEI can be found at http://oaei.ontologymatching.org/.

6.1.2. Ontology matching for linked data

Participants: Zhengjie Fan, Jérôme Euzenat [Contact], Jérôme David.

The web of data consists of using semantic web technologies to publish data on the web in such a way that they can be interpreted and connected together. It is thus critical to be able to establish links between these data, both for the web of data and for the semantic web that it contributes to feed.

In the context of the Datalift project (see § 8.1.1), we are developing a data interlinking module. Based on our analysis of the relationships between ontology matching and data interlinking [13], our goal is to generate data interlinking scripts on from ontology alignments. For that purpose, we have integrated existing technologies within the Datalift platform: the Alignment API, for taking advantage of the EDOAL language and Silk, developed by Frei Universität Berlin, for processing linking scripts. So far we have demonstrated the ability to process simple scripts.

This work is part of the PhD of Zhengjie Fan, co-supervised with François Scharffe (LIRMM), within the Datalift project.
6.1.3. Multilingual ontology matching

**Participants:** Cássia Trojahn dos Santos [Contact], Jérôme David, Jérôme Euzenat, Giuseppe Pirrò.

We have participated in the creation of a benchmark for multilingual ontology matching, the MultiFarm dataset. This dataset is composed of a set of ontologies translated in different languages and the corresponding alignments between these ontologies. It is based on the OntoFarm dataset, which has been used successfully for several years in the Ontology Alignment Evaluation Initiative. By translating the ontologies of the OntoFarm set into eight different languages – Chinese, Czech, Dutch, French, German, Portuguese, Russian, and Spanish – we created a comprehensive set of realistic test cases. We plan to include this new dataset in the OAEI 2012 campaign.

Finally, in the context of the Cameleon project (see § 8.3.1) we have been working on the creation of a multilingual comparable corpora using as seed a set of multilingual aligned ontologies. These resources will be exploited in the process of populating and enriching ontologies as well as in the process of cross-lingual ontology alignment.

6.2. Ontology networks

Dealing with the semantic web, we are interested in ontology networks, i.e., sets of distributed ontologies that have to work together. One way for these systems to interact consists of exchanging queries and answers. For that reason, we pay particular attention to query systems.

6.2.1. Path queries and $\mu$-calculus

**Participants:** Melisachew Wudage Chekol [Contact], Jérôme Euzenat, Pierre Genevès, Nabil Layaïda.

Querying the semantic web is mainly done through SPARQL [ 15 ]. One of its extensions, PSPARQL (Path SPARQL) provides queries with paths of arbitrary length. We study the static analysis of queries written in this language with techniques based on $\mu$-calculus interpretation that have been used for XPATH. We have more specifically considered PSPARQL query containment: determining whether, for any graph, the answers to a query are contained in those of another query [ 18 ][ 14 ]. To that extent, we proposed an encoding of RDF graphs as transition systems and PSPARQL queries as $\mu$-calculus formulas. We then reduce the containment problem to testing satisfiability in the logic.

This work is part of the PhD of Melisachew Wudage Chekol, co-supervised with Nabil Layaida (WAM).

6.2.2. Trust in peer-to-peer semantic systems

**Participants:** Manuel Atencia [Contact], Jérôme Euzenat, Marie-Christine Rousset.

In a semantic peer-to-peer network, peers use separate ontologies and rely on alignments between their ontologies for translating queries. Nonetheless, alignments may be incorrect – unsound or incomplete – and generate flawed translations, thus leading to unsatisfactory answers. We have put forward a trust mechanism that can assist peers to select those peers in the network that are better suited to answer their queries [ 8 ]. The trust that a peer has towards another peer depends on a specific query and represents the probability that the latter peer will provide a satisfactory answer. In order to compute trust, we exploit both alignments and peers’ direct experience, and perform Bayesian inference. We have implemented our technique and conducted an evaluation. Experimental results showed that trust values converge as more queries are sent and answers received. Furthermore, the use of trust is shown to improve both precision and recall of query answers.

This work has been developed in collaboration with Marie-Christine Rousset (LIG) in the context of the DataRing project (see § 8.1.2 ).
6. New Results

6.1. Autonomous Development of Representations

6.1.1. Open-ended bootstrapping of new sensorimotor representations

Participants: Alexander Gepperth.

We have explored a novel approach to the open-ended development of internal representations in autonomous agents, addressing in particular the transfer of knowledge between different modalities or abstraction levels. We propose a self-organized neural learning paradigm termed PROPRE (projection-prediction) that is driven by predictability: competitive advantages are given to those feature-sensitive elements that are inferable from activity in a reference representation, which may be innate or previously formed by learning. For generating and adapting the new induced representations, PROPRE implements a bi-directional interaction of clustering (“projection”) and inference (“prediction”), the key ingredient being an easy-to-compute online measure of predictability, by which the projection step is encouraged to favor sensitivity to predictable clusters. We demonstrated the potential of this paradigm by several simulation experiments with synthetic inputs. We showed that induced representations are indeed significantly more sensitive to predictable stimuli, that they are continuously being adapted to changing input statistics and that the behavior under severe resource constraints is favorable.

6.1.2. The contribution of context information to object detection in intelligent vehicles

Participants: Alexander Gepperth, Michael Garcia Ortiz.

In this work package, we explored the potential contribution of multimodal context information to object detection in an "intelligent car". The used car platform incorporates several sophisticated processing subsystems, both for the detection of objects from local visual patterns as well as for the estimation of global scene properties, e.g., the shape of the road area, or the 3D position of the ground plane (sometimes denoted "scene context" or just "context"). Annotated data recorded on this platform is publicly available as the "HRI RoadTraffic" vehicle video dataset, which formed the basis for this investigation.

In order to quantify the contribution of context information, we investigated whether it can be used to infer object identity with little or no reference to local patterns of visual appearance. Using a challenging vehicle detection task based on the "HRI RoadTraffic" dataset, we trained selected algorithms to estimate object identity from context information alone. In the course of our performance evaluations, we also analyzed the effect of typical real-world conditions (added noise, high dimensions, environmental variation) on context model performance.

As a principal result, we showed that the learning of context models is feasible with all tested algorithms, and that object identity can be estimated from context information with similar accuracy as by relying on local pattern recognition methods. We also found that the use of basis function representations (also known as "population codes") allows the simplest (and therefore most efficient) learning methods to perform best in the benchmark, suggesting that the use of context is feasible even in systems operating under strong performance constraints.

6.1.3. Discovering object concept through developmental learning

Participants: Natalia Lyubova, David Filliat.

The goal of this work is to design a visual system for a humanoid robot. Taking inspiration from children’s perception and following the principles of developmental robotics, the robot should detect and learn objects from interactions with people and from experiments it performs with objects, avoiding the use of image databases or of a separate training phase. In our model, all knowledge is therefore iteratively acquired from low-level features and builds up hierarchical object models, which are robust to changes in the environment, background and camera motion.
In our scenario, people in front of the robot are supposed to interact with objects to encourage the robot to focus on them. We therefore assume that the robot is attracted by motion and we segment possible objects based on clustering of the optical flow. Additionally, the depth information from a Kinect is used to filter visual input, considering the constraints of the robot’s working area and to refine the object contours obtained from motion segmentation.

The appearance of objects is encoded following the Bag of Visual Words approach with incremental dictionaries. We combine several complementary features to maximize the completeness of the encoded information (SURF descriptor and superpixels with associated colors) and construct pairs and triples of these features to integrate local geometry information. These features make it possible to decide if the current view has been already seen or not. A multi-view object model is then constructed by associating recognized views and views tracked during object motion.

This system is implemented on the iCub humanoid robot, which detects objects in the visual space and characterizes their appearance, their relative position and their occurrence statistics. Ten objects were presented in the current experiment; each of them was manipulated by a person during 1-2 minutes. Once the vocabulary reached a sufficient amount of knowledge, the robot was able to reliably recognize human hands and most of objects.

6.1.4. Scaling-up Knowledge for a Cognizant Robot

Participants: Thomas Degris, Joseph Modayil.

A cognizant robot is a robot with a deep and immediately accessible understanding of its interaction with the environment—an understanding that the robot can use to flexibly adapt to novel situations. Such a robot will need a vast amount of situated, revisable, and expressive knowledge to display flexible intelligent behaviors. Instead of relying on human-provided knowledge, we consider the case where an arbitrary robot can autonomously acquire pertinent knowledge directly from everyday interaction with the environment. We study how existing ideas in reinforcement learning theory can be used to formalize knowledge and use reinforcement learning techniques to enable a robot to maintain and improve its own knowledge. We consider robot performing a continual learning process that scales-up knowledge acquisition to cover a large number of facts, skills and predictions. This knowledge has semantics that are grounded in sensorimotor experience and can then be used for more abstract process such as planning. We see the approach of developing more cognizant robots as a necessary key step towards broadly competent robots.

Paper being published: Scaling-up Knowledge for a Cognizant Robot accepted at Designing Intelligent Robots: Reintegrating AI, AAAI Spring Symposium 2012.

6.1.5. Learning parallel combinations of motor primitives from demonstration and linguistic guidance with non-negative matrix factorization

Participants: Olivier Mangin, Pierre-Yves Oudeyer.

We have elaborated and experimented a novel approach to joint language and motor learning from demonstration. It enables discovery of a dictionary of motor and linguistic primitives, that can be combined in parallel to represent training data as well as novel skills in the form of combinations of known skills. These methods and the results of our experiments participate in addressing two main issues of developmental robotics: 1) symbol grounding for language learning; 2) achieving compositionality in motor-learning from demonstration, which enables re-using knowledge and thus scaling to complex tasks. In particular, we are interested in learning motor primitives active in parallel, a less explored way of combining such primitives. To address these challenges we have explored and studied the use of nonnegative matrix factorization to discover motor primitives from histogram representations of data acquired from real demonstrations of dancing movements. Initial results were presented in [30] and further results are presented in an article under review.

6.2.1. The SAGG-RIAC algorithm: competence based active learning of motor skills

Participants: Adrien Baranès, Pierre-Yves Oudeyer.
We have continued to develop and experiment the Self-Adaptive Goal Generation - Robust Intelligent Adaptive Curiosity (SAGG-RIAC) algorithm as an intrinsically motivated goal exploration mechanism which allows high-dimensional redundant robots with various body schemas to efficiently and actively learn motor skills in their task space. The main idea is to push the robot to perform active babbling in the low-dimensional goal/task space, as opposed to motor babbling in the high-dimensional actuator space (possibly defined with motor primitives), by self-generating goals actively and adaptively in regions of the task space which provide a maximal competence improvement for reaching those goal states. Then, a lower level active motor learning algorithm is used to drive the robot to locally explore how to reach a given self-generated goal. We have conducted systematic experiments with high-dimensional continuous sensorimotor spaces related to different robotic setups such as a highly-redundant robotic arm, a quadruped, and an arm controlling a fishing rod with a flexible wire and show that 1) exploration in the task space can be a lot faster than exploration in the actuator space for learning inverse models in redundant robots; 2) selecting goals based on the maximal improvement heuristics creates developmental trajectories driving the robot to progressively focus on areas of increasing complexity and is statistically significantly more efficient than selecting goals randomly, as well as more efficient than different standard active motor babbling methods. These results were published in [13], [15], [17] and a journal publication is in preparation.

6.2.2. SGIM-D: Bootstrapping Intrinsically Motivated Learning with Human Demonstration

Participants: Mai Nguyen, Pierre-Yves Oudeyer.

We have studied the coupling of internally guided learning and social interaction, and more specifically the improvement owing to demonstrations, of the learning by intrinsic motivation. We have designed Socially Guided Intrinsic Motivation by Demonstration (SGIM-D), an algorithm for learning the mapping between high dimensions in continuous, non-preset, highly redundant environments. We have shown through a robot learning experiment involving a high-dimensional sensorimotor space related to fishing skills that SGIM-D efficiently combines the advantages of social learning and intrinsic motivation to gain a wide repertoire while being specialised in specific subspaces. An article presenting aspects of this work was awarded the second best student paper award in IEEE ICDL/Epirob 2011 [27].

6.2.3. Maturationally-Constrained Competence-Based Intrinsically Motivated Learning

Participants: Adrien Baranès, Pierre-Yves Oudeyer.

We have continued to develop computational models of the coupling of intrinsic motivations and physiological maturational constraints, showing that both mechanisms may have complex bidirectional interactions allowing the active control of the growth of complexity in motor development which directs an efficient learning and exploration process. The coupling relies on the Self-Adaptive Goal Generation - Robust Intelligent Adaptive Curiosity algorithm (SAGG-RIAC) that instantiates an intrinsically motivated goal exploration mechanism for motor learning of inverse models. Then, we have introduced a functional model of maturational constraints inspired by the myelination process in humans, and showed how it can be coupled with the SAGG-RIAC algorithm, forming a new system called McSAGG-RIAC. We have then conducted systematic experiments to evaluate qualitative and, more importantly, quantitative properties of these systems when applied to the learning of the forward and inverse kinematic of an unknown robotic arm of up to 60 dimensions, the learning of walking in a 12DOF quadruped controlled with 24 dimensions motor synergies, and learning the control of a fishing rod involving a flexible/rope component. These results were published in [13], [15], [17] and a journal publication is in preparation.

6.2.4. Actor-Critic for Parallel Learning

Participants: Thomas Degris, Matha White, Richard Sutton.

Parallel learning is necessary for a robot to learn multiple tasks in parallel while executing a behavior in the environment not necessarily directly related to the tasks to learn. In previous existing work, an interesting class of learning algorithms for control are actor–critic. First, these algorithms can be used with high-dimensional action space. Second, they also sometimes provide computational models for biological decision-making systems. At FLOWERS, we work on new actor–critic algorithms suitable for parallel learning, with
theoretical guaranties, applicable and practical to use with robots, and formulated in the general framework of
reinforcement learning.

6.2.5. Curiosity for Parallel Learning of Predictions and Tasks from the Continuous Interaction of a Robot with its Environment

Participants: Thomas Degris, Adam White, Pierre-Yves Oudeyer.

On one hand, a robot needs a wide variety of knowledge to fully interact with its environment. On the other hand, a robot, like humans or animals, can only perform one behavior at a time in the real world to learn this vast amount of knowledge. A solution to scale up learning while keeping the interaction time with the real world realistic is to learn multiple elements of knowledge simultaneously in parallel. The Horde architecture proposes a set of demons each learning about new policies (i.e. skills) and predictions about these skills (i.e. partial models) off-policy simultaneously. The number of demons learning in parallel is limited only by memory and processing power, and not by the fact that there is only one sensorimotor interaction with the environment to learn from. At FLOWERS, we investigate the question of what the behavior policy of the robot should be to speed-up learning of the demons. Our goal is to test if the Horde scales-up to complex humanoid robots and if, driven by intrinsic motivations, it can autonomously learn building blocks of knowledge for future, more complex, behaviors.

6.2.6. Optimal Teaching on Sequential Decision Tasks

Participants: Manuel Lopes, Maya Cakmak.

A helpful teacher can significantly improve the learning rate of an autonomous learning agent. Teaching algorithms have been formally studied within the field of Algorithmic Teaching. These give important insights into how a teacher can select the most informative examples while teaching a new concept. However the field has so far focused purely on classification tasks. In this paper we introduce a novel method for optimally teaching sequential decision tasks. We present an algorithm that automatically selects the set of most informative demonstrations and evaluate it on several navigation tasks. Next, we present a set of human subject studies that investigate the optimality of human teaching in these tasks. We evaluate examples naturally chosen by human teachers and found that humans are generally sub-optimal. Then based on our proposed optimal teaching algorithm we try to elicit better teaching from humans. We do this by explaining the intuition of the teaching algorithm in an informal language prior to the teaching task. We found that this improves the examples elicited from human teachers on all considered tasks. This shows that a simple modification the instructions given to human teachers, has the potential of greatly improving the performance of the agent trained by the human [41].

6.2.7. Inverse Coordinated Reinforcement Learning

Participants: Manuel Lopes, Jonathan Sprauel.

Inverse Coordinated Reinforcement Learning

We extended of inverse reinforcement learning to the multi-agent case. Under this formalism a team of agents can learn a task goal, encoded as a reward function, by observing another team executing that task. Our agents behave using local information and limited communication following the coordinated reinforcement learning framework. We show that a team behavior can be learned using this formalism and how well this mechanism can deal with changing initial conditions and number of agents [68].

6.3. Motor Learning and Morphological Computation

6.3.1. Morphological Computation in Acroban the Humanoid: Balance Control and Dynamic Walking

Participants: Olivier Ly, Pierre-Yves Oudeyer, Matthieu Lapeyre, Jérome Béchu, Paul Fudal, Haylee Fogg.
We have continued to elaborate and experiment the humanoid platform Acroban and its use to study various scientific topics. Our goal was to study three main issues: 1) Compliance and semi-passive dynamics in the framework of dynamic walking in humanoid robots and more generally its impact in terms of semi-passive interactive motor primitives and their robustness to unknown external perturbations; 2) the advantage of a bio-inspired multi-articulated vertebral column in the dynamics of these motor primitives; The platform uses mechatronic components that allow us to adjust dynamically the compliance of actuators, which combines with the intrinsic mechanical compliance of the structure due to the use of elastics and springs. We have explored how these capabilities can allow us to enforce morphological computation in the design of robust dynamic locomotion. Compliance also allows us to design semi-passive motor primitives using the torso as a system of accumulation/release of potential/kinetic energy. This is made possible by the combination of adequate morphology and materials, full-body compliance, semi-passive and self-organized stable dynamics, as well as the possibility to experiment new motor primitives by trial-and-error thanks to light-weightedness. These results were presented in [25]. A dedicated web page with videos is available at: http://flowers.inria.fr/acroban.php.

6.3.2. Maturational constraints for motor learning in high-dimensions: the case of biped walking
Participants: Matthieu Lapeyre, Pierre-Yves Oudeyer, Olivier Ly.
We have elaborated and began to experiment a new developmental approach to motor learning in very high-dimensions, applied to learning biped locomotion in humanoid robots. This approach relies on the formal modeling and coupling of several advanced mechanisms inspired from human development for actively controlling the growth of complexity and harnessing the curse of dimensionality: 1) Maturational constraints for the progressive release of new degrees of freedoms and progressive increase their explorable ranges; 2) Motor synergies; 3) Morphological computation; 4) Social Guidance. An experimental setup involving a simulated version of the Acroban Humanoid robot, based on the V-REP simulator, has been elaborated, and initial encouraging results were obtained. These results are presented in [23].

6.3.3. Acroban v2: improving morphological computation with dampers
Participant: Olivier Ly.
Theoretical studies and experiments concerning in particular dynamics of passive walkers drove us to design, construct and continue to experiment a new version of Acroban. This new version has two goals both fitting in the study of the impact of morphology in the behaviour of the robot:

- experiment deep structural modifications of the morphology, in order to avoid as much as possible inelastic chocks. Indeed, during the gait, the unstability is mainly due to chock at the landing of the foot.
- improve the global ratio weight/power of the robot in order to get more dynamic movements.

Indeed, this new version uses RX-28 motors which are lighter than the RX-64 motors which are used in the first version of Acroban. The robot is smaller and lighter. First experiments show that the obtained ratio weight/power is better than the first version. Movements of the robot, and in particular amplitude of locomotion movements, are not limited by torque now. Second, we have experimented plastic materials to design the structure in order to makes is naturally flexible comparing to the metal used in the first version. This way, we improve the natural compliance of the robot. Finally, and this is probably the most important change, we used non actuated linear joints in the hip and in the spline. To control these linear joints, instead of servo-motors, we use dampers. This kind of design is new in humanoid robotic. While bringing new control problems (because of the non-controlled joints which makes the robot semi-passive), this design softens chocs in a significant maner. Experiment shows that stability of the whole structure is greatly improved especially during locomotion.

6.4. HRI and Robot Language Teaching
6.4.1. Intuitive and Robust Physical Human-Robot Interaction with Acroban
Participants: Olivier Ly, Pierre-Yves Oudeyer, Pierre Rouanet, Matthieu Lapeyre, Jérome Béchu, Paul Fudal, Haylee Fogg.
We have experimented and shown how the humanoid robot Acroban allows whole-body robust, natural and intuitive physical interaction with both adults and children. These physical human-robot interaction are made possible through the combination of several properties of Acroban: 1) it is whole-body compliant thanks to variable impedance control and also thanks to the use of elastics and springs; 2) it has a bio-inspired vertebral column allowing more flexibility in postural and equilibrium control; 3) it is light-weight; 4) it has simple low-level controllers that leverage the first three properties. Moreover, the capabilities for physical human-robot interaction that we show are not using a model of the human, and in this sense are “model free”: 1) the capability of the robot to keep its equilibrium while being manipulated or pushed by humans is a result of the intrinsic capability of the whole body to absorb unpredicted external perturbations; 2) the capability of leading Acroban by the hand is an emergent human-robot interface made possible by the self-organizing properties of the body and its low-level controllers and was observed a posteriori only after the robot was conceived and without any initial plan to make this possible. Finally, an originality of Acroban is that is is made with relatively low-cost components which lack of precision is counterbalanced with the robustness due to global geometry and compliance. These results were presented in [28]. A dedicated web page with videos is available at: http://flowers.inria.fr/acroban.php.

6.4.2. A Real World User Study of Different Interfaces for Teaching New Visually Grounded Words to a Robot

Participants: Pierre Rouanet, Pierre-Yves Oudeyer, Fabien Danieau, David Filliat.

We have continued to elaborate and experiment an integrated system based on a combination of advanced Human-Robot Interaction, visual perception and machine learning methods that allows non-expert users to intuitively and robustly teach new visually grounded words to robots. This system is based on the state-of-the-art bags of words technique but focuses on different mediator based interfaces that we can propose to the users. Indeed, we argue that by focusing on interaction we could help users to collect good learning examples and thus improve the performance of the overall learning system. We compared four different interfaces and their impact on the overall system through a real world study where we asked participants to show and teach a robot names for five different objects. Three interfaces were based on mediator objects such as an iPhone, a Wiimote and a laser pointer and provided the users with different kinds of feedback of what the robot is perceiving. The fourth interface was gesture based with a Wizard-of-Oz recognition system included in order to compare our mediator interfaces with a more natural interaction. We showed that the interface may indeed strongly impact the quality of the learning examples collected by users, especially for small objects. More precisely, we showed that interfaces such as the iPhone interface do not only give feedback about what the robot is perceiving but also drive users to pay attention to the learning examples they are collecting. Thus, this interface allows non-expert users to intuitively and easily collect almost as good learning examples as expert users trained for this task and aware of the different visual perception and machine learning issues. Finally, we showed that the mediator based interfaces were judged as easier to use than the a priori more natural gestures based interface. This work was presented in [29].

6.4.3. Language Acquisition as a Particular Case of Context-Dependant Motor Skills Acquisition

Participants: Thomas Cederborg, Pierre-Yves Oudeyer.

Imitation learning, or robot programing by demonstration, have made important advances in recent years. We have proposed to extend the usual contexts investigated to also include linguistic expressions. We have proposed a modification to existing algorithms within the imitation learning framework so that they can handle learning from the demonstration of several unlabelled tasks (or motor primitives) without having to inform the imitator of what task is being demonstrated or what the number of tasks is, which then allows directly for relatively complex language learning. A mechanism for detecting wether or not linguistic/speech input is relevant to the task has also been proposed. With these additions it becomes possible to build an imitator that bridges the gap between imitation learning and language learning by being able to learn linguistic expressions using methods from the imitation learning community. In this sense the imitator learns a word by knowing that a certain speech pattern present in the context means that a specific task is to be executed. The imitator is
however not assumed to know that speech is relevant and has to figure this out on its own by looking at the
demonstrations. To demonstrate this ability to find the relevance of speech non linguistic tasks are learnt along
with linguistic tasks and the imitator has to figure out when speech is relevant (in some tasks speech should
be completely ignored and in other tasks the entire policy is determined by speech). A simulated experiment
demonstrates that an imitator can indeed find the number of tasks it has been demonstrated, discover what
demonstrations are of what task, for which of the tasks speech is relevant and successfully reproduce those
tasks. This work is presented in a publication under review.

6.4.4. Robot Learning by Imitation of Internal Cognitive Operations in the Context of
Language Acquisition

Participants: Thomas Cederborg, Pierre-Yves Oudeyer.

We have examined the problem of learning socio-linguistic skills through imitation when those skills involve
both observable motor patterns and internal unobservable cognitive operations. This approach is framed in
a research program trying to investigate novel links between context-dependent motor learning by imitation
and language acquisition. More precisely, the paper presents an algorithm for learning how to respond to
communicative/linguistic actions of one human, called an interactant, by observing how another human, called
a demonstrator, responds. The response of the demonstrator, which depends on the context, including the
signs of the interactant, is assumed to be appropriate and the robotic imitator uses these observations to build
a general policy of how to respond to interactant actions. In this paper the communicative actions of the
interactant is hand signs, and the learnt behavior consists of how to respond to the hand signs of a small and
simple sign language, both in terms of adequately focusing attention on the right part of the scene, and in terms
of responding physically. As a response to two continuous signs of the interactant, the demonstrator focuses
on one out of three objects, and then performs a movement in relation to the object focused on. An algorithm
is proposed based on a similarity metric between demonstrations, and a simulated experiment is presented
where the unseen “focus on object” operation and the hand movements are successfully imitated, including in
situations where there are no demonstrations. This work has been published in [ 21 ]

6.4.5. Learning Simultaneously New Tasks and Feedback Models in Socially Guided Robot
Learning

Participants: Manuel Lopes, Thomas Cederborg, Pierre-Yves Oudeyer.

We have developped a system that allows a robot to learn simultaneously new tasks and feedback models from
ambiguous feedback in the context of robot learning by imitation. We have considered an inverse reinforcement
learner that receives feedback from a user with an unknown and noisy protocol. The system needs to estimate
simultaneously what the task is, and how the user is providing the feedback. We have further explored the
problem of ambiguous protocols by considering that the words used by the teacher have an unknown relation
with the action and meaning expected by the robot. This allows the system to start with a set of known symbols
and learn the meaning of new ones. We have presented computational results that show that it is possible to
learn the task under a noisy and ambiguous feedback. Using an active learning approach, the system is able to
reduce the length of the training period. [ 24 ], [ 26 ].

6.5. Hardware

6.5.1. Ergo-Robots/FLOWERS Fields: Towards Large-Scale Robot Learning Experiments in
the Real World

Participants: Jérome Béchu, Fabien Bénureau, Haylee Fogg, Paul Fudal, Hugo Gimbert, Matthieu Lapeyre,
Olivier Ly, Olivier Mangin, Pierre Rouanet, Pierre-Yves Oudeyer.
In the context of its participation to the exhibition “Mathematics: A Beautiful Elsewhere” at Fondation Cartier pour l’Art Contemporain in Paris, starting from 19th October 2011 and to be held until 18th March 2012, the team has elaborated and experimented a robotic experimental set-up called “Ergo-Robots/FLOWERS Fields”. This set-up is not only a way to share our scientific investigations with the general public, but attacks a very important technological challenge impacting the science of developmental robotics: How to design a robot learning experiment that can run continuously and autonomously for several months? Indeed, developmental robotics takes life-long learning and development as one of its central objective and object of study, and thus shall require experimental setups that allow robots to run, learn and develop for extended periods of time. Yet, in practice, this has not been possible so far due to the unavailability of platforms adapted at the same time to learning, exploration, easy and versatile reconfiguration, and extended time of experimentation. Most experiments so far in the field have a duration ranging from a few minutes to a few hours. This is an important obstacle for the progress of developmental robotics, which would need experimental set-ups capable of running for several months. This is exactly the challenge explored by the Ergo-Robots installation, which we have approached by using new generations of affordable yet sophisticated and powerful off-the-shelf servomotors (RX Series from Robotis) combined with an adequately designed software and hardware architecture, as well as processes for streamlined maintenance. The experiment is now running for five months, six days a week, in a public exhibition which has strong constraints over periods of functioning and no continual presence of dedicated technicians/engineers on site. The experiment involves five robots, each with 6 degrees of freedoms, which are endowed with curiosity-driven learning mechanisms allowing them to explore and learn how to manipulate physical objects around them as well as to discover and explore vocal interactions with humans/the visitors. The robots are also playing language games allowing them to invent their own linguistic conventions. A battery of measures has been set up in order to study the evolution of the platform, with the aim of using the results (to be described in an article) as a reference for building future robot learning experiments on extended periods of time, both within the team and in the developmental robotics community. More information available at: http://flowers.inria.fr/ergo-robots.php and http://fondation.cartier.com/.

Figure 15. Installation of Ergo Robots at Foundation Cartier.
6. New Results

6.1. Fluid motion estimation

6.1.1. Multiscale PIV method based on turbulent kinetic energy decay

Participants: Patrick Héas, Dominique Heitz, Etienne Mémin.

We have proposed a new multiscale PIV method based on turbulent kinetic energy decay. The technique is based on scaling power laws describing the statistical structure of turbulence. A spatial regularization constrains the solution to behave through scales as a self similar process via second-order structure function and a given power law. The real parameters of the power-law, corresponding to the distribution of the turbulent kinetic energy decay, have been estimated from a simple hot-wire measurement. The method has been assessed in a turbulent wake flow and grid turbulence through comparisons with HWA measurements and other PIV approaches. Results have indicated that the present method is superior because it accounts for the whole dynamic range involved in the flows.

6.1.2. Stochastic uncertainty models for motion estimation

Participants: Thomas Corpetti, Etienne Mémin.

In this work we have proposed a stochastic formulation of the brightness consistency used principally in motion estimation problems. In this formalization the image luminance is modeled as a continuous function transported by a flow known only up to some uncertainties. Stochastic calculus enables to built then conservation principles which take into account the motion uncertainties. These uncertainties defined either from isotropic or anisotropic models can be estimated jointly to the motion estimates. Such a formulation besides providing estimates of the velocity field and of its associated uncertainties allows us to define a natural linear scale space multiresolution framework. The corresponding estimator implemented within a local least squares approach has shown to improve significantly the results of the corresponding deterministic estimator (Lucas and Kanade estimator). This fast local motion estimator has been shown to provide results that are in the same order of accuracy than state-of-the-art dense fluid flow motion estimator for particle images. This work has been published in a conference proceeding and has been accepted for publication in the journal Ieee trans. on image processing [23], [16]. We intend to pursue this formalization to define dense motion estimators that allows handling in the same way luminance conservation under motion uncertainty principles.

6.1.3. 3D flows reconstruction from image data

Participants: Ioana Barbu, Dominique Heitz, Cédric Herzet, Etienne Mémin.

Our work focusses on the design of new tools for the problem of 3D reconstruction of a turbulent flow motion. This task includes both the study of physically-sound models on the observations and the fluid motion, and the design of low-complexity and accurate estimation algorithms. On the one hand, state-of-the-art methodologies such as “sparse representations” will be investigated for the characterization of the observation and fluid motion models. Sparse representations are well-suited to the representation of signals with very few coefficients and offer therefore advantages in terms of computational and storage complexity. On the other hand, the estimation problem will be placed into a probabilistic Bayesian framework. This will allow the use of state-of-the-art inference tools to effectively exploit the strong time-dependence of the fluid motion. In particular, we will investigate the use of “ensemble Kalman” filter to devise low-complexity sequential estimation algorithms.
This year, we have more particularly focused on the problem of reconstructing the particle positions from several two-dimensional images. Our approach is based on the exploitation of a particular family of sparse representation algorithms, namely the so-called “pursuit algorithms”. Indeed, the pursuit procedures generally allow a good trade-off between performance and complexity. Hence, we have performed a thorough study comparing the reconstruction performance and the complexity of different state-of-the-art algorithms to that achieved with pursuit algorithms. This work has led to the publication of two conference papers in experimental fluid mechanics [ 21 ], [ 34 ].

6.1.4. Motion estimation techniques for turbulent fluid flows

Participants: Patrick Héas, Dominique Heitz, Cédric Herzet, Etienne Mémin.

Based on physical laws describing the multi-scale structure of turbulent flows, this article proposes a regularizer for fluid motion estimation from an image sequence. Regularization is achieved by imposing some scale invariance property between histograms of motion increments computed at different scales. By reformulating this problem from a Bayesian perspective, an algorithm is proposed to jointly estimate motion, regularization hyper-parameters, and to select the most likely physical prior among a set of models. Hyper-parameter and model inference is conducted by likelihood maximization, obtained by marginalizing out non-Gaussian motion variables. The Bayesian estimator is assessed on several image sequences depicting synthetic and real turbulent fluid flows. Results obtained with the proposed approach in the context of fully developed turbulence improve significantly the results of state of the art fluid flow dedicated motion estimators. This work has been published in several conferences and in the journal Tellus, Serie A [ 18 ].

6.1.5. Wavelet basis for multi-scale motion estimation

Participants: Pierre Dérian, Patrick Héas, Cédric Herzet, Souleymane Kadri Harouna, Etienne Mémin.

This work aims at exploring wavelet representations for fluid motion estimation from consecutive images. This scale-space representation, associated to a simple gradient-based optimization algorithm, sets up a natural multi-resolution framework for the optical flow estimation well suited to medium range velocity magnitude. Moreover, a very simple closure mechanism, approaching locally the solution by high-order polynomials, is provided by truncating the wavelet basis at fine scales. Well-known turbulence regularities and multifractal behaviors on the reconstructed motion field can also be imposed on the wavelet coefficients. Accuracy and efficiency of the proposed method has been evaluated on scalar and particles image sequences of turbulent fluid flows. Particularly good results have been observed for particle image velocimetry. This offers a very interesting alternative to traditional PIV techniques. This work has been published in computer vision or turbulence conferences [ 26 ], [ 25 ].

6.1.6. Divergence-free wavelet basis and high-order regularization

Participants: Pierre Dérian, Patrick Héas, Souleymane Kadri Harouna, Etienne Mémin.

Expanding on a wavelet basis the solution of an inverse problem provides several advantages. Wavelet bases yield a natural multisolution analysis that may alleviate the use of Gauss Newton strategy for medium range motion amplitude. The continuous representation of the solution with wavelets enables analytical calculation of regularization integrals over the spatial domain. By choosing differentiable wavelets, high-order derivative regularizers can be designed, either taking advantage of the wavelet differentiation properties or via the basis’s mass and stiffness matrices. Moreover, differential constraints on vector solutions, such as the divergence-free volume preserving constraint, can be handled with biorthogonal wavelet bases. Numerical results on synthetic and real images of incompressible turbulence show that divergence-free wavelets and high-order regularizers are particularly relevant in the context of incompressible fluid flows. This work has been partly published in a conference proceeding [ 25 ].

6.1.7. Divergence-free wavelet basis and high-order regularization

Participants: Pierre Dérian, Patrick Héas, Souleymane Kadri Harouna.
This work presents a method for regularization of inverse problems. The vectorial bi-dimensional unknown is assumed to be the realization of an isotropic divergence-free fractional Brownian Motion (fBm). The method is based on fractional Laplacian and divergence-free wavelet bases. The main advantage of these bases is to enable an easy formalization in a Bayesian framework of fBm priors, by simply sampling wavelet coefficients according to Gaussian white noise. Fractional Laplacians and the divergence-free projector can naturally be implemented in the Fourier domain. An interesting alternative is to remain in the spatial domain. This is achieved by the analytical computation of the connection coefficients of divergence-free fractional Laplacian wavelets, which enables to easily rotate this simple prior in any sufficiently “regular” wavelet basis.

Taking advantage of the tensorial structure of a separable fractional wavelet basis approximation, isotropic regularization is then computed in the spatial domain by low-dimensional matrix products. The method is successfully applied to fractal image restoration and turbulent optic-flow estimation.

6.1.8. Bayesian inference of hyper-parameters and models in motion estimation

**Participants:** Patrick Héas, Cédric Herzet, Etienne Mémin.

Bayes rule provides a nice framework for motion estimation from image sequences. We rely on a hierarchical modeling linking the image intensity function variable, the motion field variable, hyper-parameters composed of the likelihood and prior model inverse variances and of robust parameters, and finally the observation and prior model. The variable dependence can thus be expressed as a 4-level hierarchy. Applying the Bayes rule on this hierarchy, we obtain three levels of inference, which enable us to obtain, by marginalizing out intermediate variables, a direct dependence of the variable of interest to the image intensity function. Thus, the estimates of regularization parameters, of robust parameters associated to semi-quadratic norms of a family of M-estimators, and of observation and prior models are inferred in a maximum likelihood sense while maximizing jointly the motion field a posteriori probability. The quality of the method is demonstrated on synthetic and real two-dimensional turbulent flows and on several computer vision scenes of the "Middlebury" data-base. This work has been accepted for publication in IEEE transaction on Image Processing (IP) [17].

6.1.9. Method to quantify the uncertainty of motion measurement

**Participants:** Patrick Héas, Dominique Heitz, Cédric Herzet.

Measurement uncertainty is a general concept associated with any measurement that can be used to quantify the confidence of the estimation. The ‘Guide to the expression of uncertainty in measurement’ (GUM) provides a framework to account for all uncertainties and then to propagate them. However, in particle image velocimetry (PIV), measurement uncertainty estimation is a tricky task since it has to be done through the propagation of distributions via Monte Carlo simulations for each velocity components and all pixel location in the image. Considering a standard Bayesian formulation of the optical flow problem together with a Gaussian assumption the uncertainty associated to the estimated velocity field has been provided and described. First PIV measurement uncertainty estimations and discussions have been recently published in a conference issue [36].

6.1.10. Sparse-representation algorithms

**Participant:** Cédric Herzet.

We have pursued the study of efficient sparse decomposition algorithms. In particular, we have addressed the problem of finding good sparse representations into a probabilistic framework [24]. First, we have showed that one of the standard formulations - the Lagrangian formulation - of this problem can be interpreted as a limit case of a maximum a posteriori (MAP) problem involving Bernoulli-Gaussian variables. Then, we have proposed different tractable implementations of this MAP problem and explained some well-known pursuit algorithms (MP, OMP, StOMP, CoSaMP and SP) as particular cases of the proposed algorithms. Experimentations led on synthetic data show a good general behavior of the proposed methods.

Exploiting further this probabilistic framework, we have then considered the design of soft pursuit algorithms. In particular, instead of making hard decisions on the support of the sparse representation and the amplitude of the non-zero coefficients, our soft procedures iteratively update probability on the latter values. The proposed algorithms are designed within the framework of the mean-field approximations and resort to the so-called variational Bayes EM algorithm to implement an efficient minimization of a Kullback-Leibler criterion.
6.2. Tracking and data assimilation

6.2.1. Stochastic filtering for fluid motion tracking

**Participants:** Sébastien Béyou, Anne Cuzol, Sai Gorthi, Etienne Mémin.

We investigated the study of a recursive Bayesian filter for tracking velocity fields of fluid flows. The filter combines an Ito diffusion process associated to 2D vorticity-velocity formulation of Navier-Stokes equation and discrete image error reconstruction measurements. In contrast to usual filters designed for visual tracking problems, our filter combines a continuous law for the description of the vorticity evolution with discrete image measurements. We resort to a Monte-Carlo approximation based on particle filtering. The designed tracker provides a robust and consistent estimation of instantaneous motion fields along the whole image sequence.

When the likelihood of the measurement can be modeled as Gaussian law, we have also investigated the use of the so-called ensemble Kalman filtering for fluid tracking problems. This kind of filters introduced for the analysis of geophysical fluids is based on the Kalman filter update equation. Nevertheless, unlike traditional Kalman filtering setting, the covariances of the estimation errors, required to compute the so-called Kalman gain, relies on an ensemble of forecasts. Such a process gives rise to a Monte Carlo approximation for a family of non-linear stochastic filters enabling to handle state spaces of large dimension. We have recently proposed an extension of this technique that combines sequential importance sampling and the propagation law of an ensemble Kalman filter. This technique leads to an ensemble Kalman filter with an improved efficiency. This year we have investigated the introduction of a nonlinear direct image measurements operator within this ensemble Kalman scheme. This modification of the filter provides very good results on 2D numerical and experimental flows even in the presence of strong noises. We are currently assessing its application to oceanic satellite images for the recovering of ocean streams. We are studying also the impact on the stochastic dynamics of turbulent noise defined as auto-similar Gaussian random fields and the introduction within an incremental ensemble analysis scheme of multiscale motion measurements. This work has been published in conference issues [28], [27], [35].

6.2.2. Reduced-order models for flows representation from image data

**Participants:** Patrick Héas, Cédric Herzet, Etienne Mémin, Véronique Souchaud.

One of the possibilities to neglect the influence of some degrees of freedom over the main characteristics of a flow consists in representing it as a sum of $K$-orthonormal spatial basis functions weighted with temporal coefficients. To determine the basis function of this expansion one of the usual approaches relies on the Karhunen-Loeve decomposition (referred as proper orthogonal decomposition – POD – in the fluid mechanics domain). In practice, the spatial basis functions, also called modes, are the eigen vectors of an empirical auto-correlation matrix which is built from “snapshots” of the considered physical process.

In this axis of work we focus on the case where one does not have a direct access to snapshots of the considered physical process. Instead, the POD has to be built from the partial and noisy observation of the physical process. Instances of such scenarios include situations where real instantaneous vector-field snapshots are estimated from a sequence of images. We have been working on several approaches dealing with such a new paradigm. A first approach consists in extending standard penalized motion-estimation algorithms to the case where the sought velocity field is constrained to span a low-dimensional subspace [38]. Giving a probabilistic interpretation to this problem, we have designed novel optimization procedures in the framework of maximum a posteriori estimation problem. This work has led to the publication of a paper in the Gretsi conference. We are currently working on an EM-algorithm implementation of this approach.

In a second approach, we are considering the design of the POD as the solution of a minimum least squares estimation problem based on the distribution of the (unknown) velocity field given a sequence of images. This alternative formulation allowed us to take explicitly the uncertainty on the velocity field into account into our optimization process. We are currently working on several practical implementations of this problem, relying on Monte-Carlo integration and Krylov subspaces.
In a third axis we have studied two variational data assimilation techniques for the estimation of low order dynamical models for fluid flows. Both methods are built from optimal control recipes and rely on POD representation associated to Galerkin projection of the Navier Stokes equations. The proposed techniques differ in the control variables they involve. The first one introduces a weak dynamical model defined only up to an additional uncertainty time dependent function whereas the second one, handles a strong dynamical constraint in which the coefficients of the dynamical system constitute the control variables. Both choices correspond to different approximations of the relation between the reduced basis on which is expressed the motion field and the basis components that have been neglected in the reduced order model construction. The techniques have been assessed on numerical data and for real experimental conditions with noisy Image Velocimetry data. This work has been presented in several conferences. A journal paper has been recently accepted with minor changes to the journal of computational Physics.

6.2.3. Optimal control techniques for the coupling of large eddy dynamical systems and image data

**Participants:** Dominique Heitz, Etienne Mémin, Cordelia Robinson, Yin Yang.

This work aims at investigating the use of optimal control techniques for the coupling of Large Eddies Simulation (LES) techniques and 2D image data. The objective is to reconstruct a 3D flow from a set of simultaneous time resolved 2D image sequences visualizing the flow on a set of 2D plans enlightened with laser sheets. This approach will be experimented on shear layer flows and on wake flows generated on the wind tunnel of Irstea Rennes. Within this study we wish also to explore techniques to enrich large-scale dynamical models by the introduction of uncertainty terms or through the definition of subgrid models from the image data. This research theme is related to the issue of turbulence characterization from image sequences. Instead of predefined turbulence models, we aim here at tuning from the data the value of coefficients involved in traditional LES subgrid models or in longer-term goal to learn empirical subgrid models directly from image data. An accurate modeling of this term is essential for Large Eddies Simulation as it models all the non resolved motion scales and their interactions with the large scales.

First tests have been conducted with two-dimensional Direct Numerical Simulations (DNS) of mixing layer coupled with noisy observations. By modifying the initial condition of the system, the proposed method recovers the state of an unknown function with good accuracy. This work has been published in the International Symposium on Turbulence and Shear Flow Phenomena (TSFP) 2011 [29].

6.2.4. Free surface flows reconstruction and tracking

**Participants:** Benoît Combes, Dominique Heitz, Etienne Mémin.

Characterising a free-surface flow (space and time-dependent velocity and geometry) given observations/measures at successive times is an ubiquitous problem in fluid mechanic and in hydrology. Observations can consist of e.g. measurements of velocity, or like in this work of measurements of the geometry of the free-surface. Indeed, recently developed depth/range sensors allow to capture directly a rough 3D geometry of surfaces with high space and time resolution. The main purpose of this study is to evaluate the ability of the Kinect sensor to estimate time-dependent 3D free-surface geometries. Then, based on these observations and on a stochastic data assimilation method, we want to estimate both time dependent geometry and displacement field associated to a free-surface flow from a simple temporal sequence of Kinect data. This year we have demonstrated on real data the possibility to measure free surface flow geometry with Kinect sensor and on synthetic data to estimate both time dependent geometry and displacement field associated to a free-surface flow from a simple temporal sequence of Kinect-like data. This work has been published in the new conference Flow Volume Reconstruction [22]. We intend to extend such a study to hydrological applications.

6.2.5. Stochastic filtering technique for the tracking of closed curves

**Participants:** Christophe Avenel, Etienne Mémin.
We have proposed a filtering methodology for the visual tracking of closed curves. Opposite to works of the literature related to this issue, we consider here a curve dynamical model based on a continuous time evolution law with different noise models. This led us to define three different stochastic differential equations that capture the uncertainty relative to curve motions. This new approach provides a natural understanding of classical level-set dynamics in terms of such uncertainties. These evolution laws have been combined with various color and motion measurements to define probabilistic state space models whose associated Bayesian filters can be handled with particle filters. This on going work will be continued within extensive curve tracking experiments and extended to the tracking of other very high dimensional entities such as vector fields and surfaces. This work has been published in conference proceedings and a journal article is conditionally accepted to minor changes for publication in a meteorological journal.

6.2.6. Sequential smoothing for fluid motion

Participants: Anne Cuzol, Etienne Mémin.

In parallel to the construction of stochastic filtering techniques for fluid motions, we have proposed a new sequential smoothing method within a Monte-Carlo framework. This smoothing aims at reducing the temporal discontinuities induced by the sequential assimilation of discrete time data into continuous time dynamical models. The time step between observations can indeed be long in environmental applications for instance, and much longer than the time step used to discretize the model equations. While the filtering aims at estimating the state of the system at observations times in an optimal way, the objective of the smoothing is to improve the estimation of the hidden state between observation times. The method is based on a Monte-Carlo approximation of the filtering and smoothing distributions, and relies on a simulation technique of conditioned diffusions. The proposed smoother can be applied to general non linear and multidimensional models. It has been applied to a turbulent flow in a high-dimensional context, in order to smooth the filtering results obtained from a particle filter with a proposal density built from an Ensemble Kalman procedure.

6.2.7. Stochastic fluid flows dynamics under Gaussian uncertainty

Participant: Etienne Mémin.

In this research axis we aim at devising stochastic Eulerian expression for the description of fluid flow evolution laws incorporating uncertainty on the particles location. Such an uncertainty modeled through the introduction of a random term allows taking into account approximations or truncation effects performed within the dynamics analytical constitution steps. This includes for instance the modeling of unresolved scales interaction in large eddies simulation (LES) or in Reynolds average numerical simulation (RANS), but also uncertainties attached to non uniform grid discretization. This model is mainly based on a stochastic version of the Reynolds transport theorem. Within this framework various simple expressions of the mean drift component can be exhibited for different models of the random field carrying the uncertainties we have on the flow. We aim at using such a formalization within image based data assimilation framework and to derive appropriate stochastic versions of geophysical flow dynamical modeling.

6.2.8. Variational assimilation of images for large scale fluid flow dynamics with uncertainty

Participants: Souleymane Kadri Harouna, Etienne Mémin.

In this work we explore the assimilation of a large scale representation of the flow dynamics with image data provided at a finer resolution. The velocity fields at large scales is described as a regular smooth components whereas the complement component is a highly oscillating random velocity field defined on the image grid but living at all the scales. Following this route we have started to assess the performances of a variational assimilation technique with direct image data observation. Preliminary results obtained for a wavelet based 2D Navier Stokes implementation and images of a passive scalar transported by the flow are very encouraging.

6.3. Analysis and modeling of turbulent flows

6.3.1. Mixing layers between a uniform flow and a shear flow

Participant: Dominique Heitz.
We have addressed the analysis and modelling of noncanonical turbulent mixing layers between a uniform flow and a shear flow. From a parametric study by bidimensional direct numerical simulations two mixing layer configurations between a uniform flow and a shear flow have been selected. These two configurations share the same shear flow but have a different uniform flow.

The shear flow was obtained with curved gauze. However, the theoretical shear parameter predicted by the literature is different from the value obtained by experiments. In order to study these discrepancies, the flow through a gauze was studied by particle image velocimetry. This allowed the general modeling of the uniform flow through curved wire gauze, leading to linear mean velocity profiles. From a hot-wire anemometry study of the two flow configurations it was observed that one flow behaves like a mixing layer whereas the other flow yields a wake behaviour. The mixing layer indicates an increasing turbulent kinetic energy along its longitudinal development, while the wake exhibits an asymmetry.

6.3.2. Hot-wire anemometry at low velocities

Participant: Dominique Heitz.

A new dynamical calibration technique has been developed for hot-wire probes. The technique permits, in a short time range, the combined calibration of velocity, temperature and direction calibration of single and multiple hot-wire probes. The calibration and measurements uncertainties were modeled, simulated and controlled, in order to reduce their estimated values. This year a patent application has been submitted.

6.3.3. Experimental studies for the assessment of turbulence statistical models

Participants: Patrick Héas, Dominique Heitz, Etienne Mémin.

[In collaboration with G. Artana and P. Minini (Univ. Buenos Aires)]

Selecting directly from images the most likely scaling motion priors enables the recovery of physical quantities related to the energy flux and the flow regularity. Such measurements are of major interest for turbulence studies. In particular, determining the energy flux across scales and characterizing intermittency is very important to assess the relevance of the statistical models proposed for atmospheric turbulence. Although, the measurement of flux and atmospheric flow regularity has already been obtained previously using in situ data, it required an important measurement campaign lasting several years based on sensors placed on airplanes. Therefore, the proposed motion estimation technique described above represents an attractive tool since it enables the direct estimation of these quantities from a couple of images. A paper concerning an atmospheric turbulence study using Meteosat Second Generation (MSG) images has been accepted in the journal Tellus A. Experimental studies of three-dimensional turbulence behind a grid or in the wake of a cylinder have been performed and will be submitted in the journal Experiments in fluids. New experiments for the assessment of turbulence statistical models are currently going on in collaboration with the laboratory of fluid mechanics and turbulence scientists in Argentina. They focus on two-dimensional turbulence of soap films visualized with a Schlieren imagery system. The goal of this work is to validate experimentally the theoretical model predicting non-intermittent inverse energy cascades in pure two-dimensional flows.

6.4. Visual servoing approach for fluid flow control

6.4.1. Fully exploitation of the controlled degrees of freedom of the 2D plane Poiseuille flow

Participants: Christophe Collewet, Xuan Quy Dao.

This work concerns the Phd of Xuan-Quy Dao and can be seen as an extension of the works carried out by Roméo Tatsambon. Since visual measurements are used, we propose here to use advanced visual servoing techniques to fully exploit the controlled degrees of freedom of the 2D plane Poiseuille flow. To achieve this goal we propose to design a control law based on partitioned visual servo control (this approach has been first proposed in the robotics community by [46] but in a very different context). Therefore, we have shown that, following this way and contrary to the literature concerning drag reduction, it becomes easy to simultaneously reduce the drag and the kinetic energy density of the flow. That is of great importance since the controlled flow is in an unstable state and may become turbulent when the kinetic energy density is growing. This key
problem is not well taken into account in the literature. Indeed, either the drag or the kinetic energy density is reduced, but never both of them. Moreover, we have shown that in practice, the way the drag is reduced does not influence the way the kinetic energy density is reduced. In addition, since dense visual measurements are used, our approach is very robust against measurement noise.

6.4.2. Visual servoing for the 3D plane Poiseuille flow  
Participant: Christophe Collewet.

We focus here on the 3D plane Poiseuille flow which is much more realistic than the 2D case. In that case, it can be shown that the reduced linearized flow is in a stable configuration. However, it is possible to find some bad initial conditions which causes the flow to present high transient energy growths. Indeed, a small perturbation velocity value in the reduced linearized system leads to a transient effect which is characterized by a growth in a short-time behaviour of the kinetic energy density, before a decay occurs. Practically, this transient effect, if not controlled, can cause transition to turbulence. Usually, the streamwise shear stress component at a point belonging to the wall is used as the output of the system in order to control it in a closed-loop fashion. We have proposed a vision-based approach to control this flow (see section 3.4). Our approach has revealed to be the most efficient approach in comparison to existing ones. Indeed, the transient energy is highly reduced. In addition, as in the 2D plane Poiseuille flow, the initialization problem is not of concerned in the vision-base approach. In addition, our approach is robust to measurement noise when a large number of flow measurements is available, which is possible in real practical situations. This work has been published in several conferences [33], [20], [32] and has been recently accepted for publication in the International Journal of Flow Control [19].

6.5. National Initiatives

6.5.1. ANR-COSINUS PREVASSEMBLE: Ensemble methods for assimilation of observations and for prevision in Meteorology and Oceanography  
Participants: Sébastien Béyou, Anne Cuzol, Etienne Mémin.

duration 36 months.

The purpose of this project is to further study ensemble methods -, and to develop their use for both assimilation of observations and prediction. Among the specific questions to be studied are the theory of Particle Filters and Ensemble Kalman Filters, the possibility of taking temporal correlation into account in ensemble assimilation, the precise assessment of what can and cannot be achieved in ensemble prediction, and the objective validation of ensemble methods.

The partners of this project are Laboratoire de Météorologie Dynamique/ENS (leader), Météo-France and three INRIA groups (ALEA, ASPI, FLUMINANCE).

6.5.2. ANR SYSCOMM MSDAG: MultiScale Data Assimilation in Geophysics  
Participants: Pierre Dérian, Patrick Héas, Dominique Heitz, Cédric Herzet, Etienne Mémin.

duration 36 months.

Changing scale is a well-known topic in physics (geophysics, fluid mechanics and turbulence, theoretical and statistical physics, mechanics, porous media, etc.) It has lead to the creation of powerful sophisticated mathematical tools: renormalization, homogenization, etc. These ideas are also used in numerical analysis (the so-called multigrid approach) for solving efficiently partial differential equations. Data assimilation in geophysics is a set of methods that allows to combine optimally numerical models in large spaces with large dataset of observations. At the confluence of these two topics, the goal of this project is to study how to embed the change of scales (a multiscale point of view) issue into the framework of geophysical data assimilation, which is a largely unexplored subject.

The partners of this 3 years project are the CEREA/CLIME INRIA group (leader), the LSCE/CEA, the INRIA groups MOISE and FLUMINANCE.
6.5.3. **ANR SYSCOMM GeoFluids:**

**Participants:** Patrick Héas, Dominique Heitz, Etienne Mémin, Véronique Souchaud.

*duration 48 months.*

The project Geo-FLUIDS focuses on the specification of tools to analyse geophysical fluid flows from image sequences. Geo-FLUIDS aims at providing image-based methods using physically consistent models to extract meaningful features describing the observed flow and to unveil the dynamical properties of this flow. The main targeted application domains concern Oceanography and Meteorology. The project consortium gathers the INRIA research groups: FLUMINANCE (leader), CLIME, IPSO, and MOISE. The group of the “Laboratoire de Météorologie Dynamique” located at the ENS Paris, the IFREMER-CERSAT group located at Brest and the METEOFRANCE GMAP group in Toulouse.

6.5.4. **Britanny concil ARED IMAGEO:**

**Participants:** Cédric Herzet, Etienne Mémin, Véronique Souchaud.

*duration 36 months.* This project of the Britanny concil, which finances the PhD thesis of Véronique Souchaud, aims at studying methods for the estimation of reduced order modeling of fluid flows evolution laws from image sequences. The goal consists here at defining the estimation of a reduced basis describing the flow evolution as a motion estimation problem.

6.6. **International Initiatives**

6.6.1. **INRIA Associate Teams**

6.6.1.1. **HURACAN**

**Title:** Analysis and control of fluid flows from image sequences  
**INRIA principal investigator:** Etienne Memin  
**International Partner:**  
Institution: Universidad de Buenos Aires (Argentina)  
Laboratory: Fluid Dynamics Laboratory  
**International Partner:**  
Institution: IRSTEA (France)  
**Duration:** 2010 - 2012  
**See also:** [http://huracan.inria.fr](http://huracan.inria.fr)

The HURACAN associated team is centered on the analysis and the control of fluid flows from image sequences. The research objectives of this team are organized into two distinct work axes. The first one aims at defining and studying visual servoing techniques for fluid flows control. In addition to the definition of efficient visual servoing schemes this axis of work gathers research issues related to fluid flows velocity measurement from images and to flows excitation through plasma actuators. The second research axis focuses on the coupling between large scales representations of geo-physical flows and image data. More precisely, it aims at studying means to define directly from the image sequences the small scales terms of the dynamics. This research axis includes the study of coupling models and data defined at different scales, problems of multiscale velocities estimation respecting turbulence phenomenological laws and issues of experimental validation.
6. New Results

6.1. Contracts and sessions

Participants: Ugo Dal Lago, Ornella Dardha, Maurizio Gabbrielli, Elena Giachino, Claudio Guidi, Jacopo Mauro, Fabrizio Montesi.

Contracts are descriptions of the functionalities offered by a component or a service, and of the way these functionalities may be accessed by clients. A contract may include a description of the component capabilities, place constraints on their usage, as well as declare preferences, entitlements and credentials. When a client wants to use one of the functionalities offered, it engages a dialogue (e.g., a sequence of interactions) with the servers; this is usually called a session.

The expected dialogue in a session can be specified by means of types, the session types. We have studied \[11\] the integration of union and session types in a class-based language for building network applications, which amalgamates sessions and methods in order to flexibly exchange data according to communication protocols. We have established type safety properties guaranteeing that, after a session has started, computation cannot get stuck on a communication deadlock, and studied type inference. On a similar topic is the paper \[23\].

We have used types \[32\] to guarantee bounds on sessions. These are polynomial bounds, on both time and space needed by the interacting processes to carry out the interactions in their sessions. This is the first example of a refinement of session types guaranteeing quantitative properties beyond the usual safety property, and builds on earlier work on soft linear logic.

In service-oriented architectures, the mechanism that allows to manage sessions and, in particular, to assign incoming messages to the correct sessions, is critical for efficiency and performance. A well-known solution to this problem, first introduced by BPEL, makes use of correlation sets. Intuitively these distinguish different sessions by means of the values for some specific variables which are present also in messages, thus allowing for their routing to sessions on the basis of these values. We have studied \[36\] a typed language for programming services based on correlation sets, that takes into account key aspects of service-oriented systems, such as distribution, loose coupling, open-endedness and integration. We have provided an implementation of the language as an extension of the Jolie language and applied it to a nontrivial real-world example of a fully-functional distributed user authentication system.

In current SOC languages based on correlation sets, a message can be assigned to a unique session. In another line of work on correlation sets \[35\], we have studied the possibility – useful in many practical examples – of broadcasting messages to more than one session. We have investigated a data structure, based on radix trees, and an algorithm for managing a correlation mechanism, that support the broadcast primitive without degrading performances.

6.2. Fault Handling, compensations and transactions

Participants: Mila Dalla Preda, Maurizio Gabbrielli, Ivan Lanese, Jacopo Mauro, Gianluigi Zavattaro.

One of the predominant properties of CBUS is the loose coupling among the components. In fact, components can dynamically connect/disconnect and can be modified/updated at run time. It is thus important to support unexpected events, called faults.

In \[30\] we have studied the problem of fault handling in the kind of object-oriented languages developed in the EU Hats project; notably these languages have asynchronous method calls whose results are returned inside futures. We present an extension for those languages where futures are used to return fault notifications and to coordinate error recovery between the caller and callee. This can be exploited to ensure that invariants involving many objects are restored after faults.
Traditional fault handling mechanisms, including those based on try-catch operators, do not seem sufficient to deal with the non-local errors and failures of distributed systems. At the application level, more advanced transactional models and primitives are needed to guarantee integrity and continuity of the whole system. We study approaches based on long running transactions and compensations. A long running transaction is a computation that either successfully terminates, or it aborts. In case of abort, a compensation is executed to take the system to a consistent state. In [53], extending work started last year, we make a thorough comparison among different approaches to the specification of compensations, in particular static forms of recovery where the compensation is statically defined together with the transaction, and dynamic forms where the compensation is progressively built along with a computation.

We have also continued our study on faults and compensations in Service Oriented Computing. The approach to the interplay between bi-directional request-response interaction and faults, proposed in our past works on the Jolie language, supported the idea that the bi-directional pattern should not be interrupted in case of faults. However, this may cause long delays or even deadlocks if the communicating partner disappears. On the contrary, the approach of WS-BPEL causes no delay, but it does not allow to compensate the remote activity. We have investigated [38] an intermediate approach in which it is not necessary for the fault handler to wait for the response, but it is still possible on response arrival to gracefully close the conversation with the remote service.

A related work, but mainly developed in 2010, is [21].

6.3. Service orchestration and choreography

**Participants:** Mila Dalla Preda, Maurizio Gabbielli, Claudio Guidi, Ivan Lanese, Jacopo Mauro, Fabrizio Montesi, Marco Pistore, Gianluigi Zavattaro.

Orchestration has to do with the definition of services that should obey given behaviours. The services may be realised by composing services already available. Orchestration is often discussed in relationship with “choreography”, which refers to global descriptions of the intended behaviour of a system of components, stating the role of each participant and the set of coordination requirements.

In [55] we have studied the basic linguistic constructs and a reference implementation for aggregation, a mechanism for composing services that abstracts from the order of their communications. Aggregation is widely used in practice. However, since it is not natively supported by service-oriented languages, it is mostly implemented by means of ad-hoc solutions which typically exploit middleware technology.

A critical aspect for pervasive computing is the possibility to discover and use process knowledge at run time depending on the specific context. This can be achieved by using an underlying service-based application and exploiting its features in terms of dynamic service discovery, selection, and composition. Pervasive process fragments represent a service-based tool that allows to model incomplete and contextual knowledge. In [40] we provide a solution to automatically compose such fragments into complete processes, according to a specific context and specific goals. We compute the solution by encoding process knowledge, domain knowledge and goals into an AI planning problem.

Concerning choreography languages, two main approaches have been followed in their design: the interaction-oriented approach at the basis of WS-CDL and the process-oriented approach of BPEL4Chor. In [52] we investigate the relationships between the two approaches. In particular, we point out several possible interpretations for interaction-oriented choreographies: one synchronous and various asynchronous. Under each of these possible interpretations we characterize the class of interaction-oriented choreographies which have a direct process-oriented counterpart, and we formalize the corresponding notion of equivalence between the initial interaction-oriented choreography and the corresponding process-oriented counterpart.

In [50] we study the issue of checking a multiparty choreography against formal protocol specifications, and then projecting it onto a description of the individual service orchestrators. Contributions are also the definition of a multiparty choreography model, and the correctness proof for the projection.
6.4. Primitives for adaptable and evolvable components

Participants: Mario Bravetti, Ivan Lanese, Michael Lienhardt, Jacopo Mauro, Marco Pistore, Davide Sangiorgi, Gianluigi Zavattaro.

In Focus we study linguistic primitives for components, and models for them following the process calculus approach. A special emphasis is given to the adaptability and evolvability of the components — important issue in complex software systems. Components indeed are often used in contexts that had not been predicted at the time when the components were built. Moreover, the needs and the requirements on a system may change over time: one may find that the original specification was incomplete or ambiguous, or new needs may arise that had not been predicted at design time. As designing and deploying a system is costly, it is important that the system be capable of evolving and adapting itself to changes in the surrounding environment.

Models and linguistic constructs for adaptability and evolvability of components are studied in [34] and [19]. The key features of the component model in [34] are: a hierarchical structure of components; the capacity to move, update, wrap components; method interfaces for components; and capacities to isolate and distribute components. In the model in [19], adaptable processes have a location and can be subject to dynamic update actions at runtime (related to this paper is also [20]).

In [22] we provide an adaptation approach that can automatically adapt business processes to run-time context changes that impede achievement of a business goal. We define a formal framework that adopts planning techniques to automatically derive necessary adaptation activities on demand. The adaptation consists in identifying recovery activities that guarantee that the execution of a business process can be successfully resumed and, as a consequence, the business goals are achieved. The solution proposed is evaluated on a real-world scenario from the logistics domain.

Adaptability and evolvability are major concerns in Software Product Lines. The EU Hats project has developed the idea of delta-oriented programming (DOP) as a technique for implementing Software Product Lines based on modifications (add, remove, modify) to a core object-oriented program. Such modifications can introduce errors into a program, when type signatures of classes are modified. To overcome this problem we have introduced [54] a type system for delta-oriented programs. The system is based on row polymorphism, a well-known method in type systems for records.

6.5. Resource Control

Participants: Ugo Dal Lago, Marco Gaboardi, Daniel Hirschkoff, Simone Martini, Paolo Parisen Toldin, Giulio Pellitta, Davide Sangiorgi.

In Focus, we study both foundations and methodologies for controlling the amount of resources programs and processes make use of. The employed techniques mainly come from the world of type theory and proof theory, and as such have been used extensively in the context of sequential computation. Interesting results have been obtained recently indicating that those techniques can be quite useful in the concurrent context too, thus being potentially interesting for CBUS.

We have continued our work on techniques for ensuring termination of programs. On the one hand we have refined [25] previous techniques, enhancing them by taking into account input/output capabilities of channels and subtyping. On the other hand we have studied [28] how to transport techniques initially devised for processes onto sequential higher-order languages with imperative features (e.g., \( \lambda \)-calculi with references). The method employed makes it possible to combine term rewriting measure-based techniques for termination of imperative languages with traditional approaches to termination in purely functional languages, such as logical relations.

In [31], a type system of linear and dependent types, called dlPCF, has been proved to be a sound, but also relatively complete, way to prove intensional (but also extensional) properties of PCF programs. In other words, not only all properties of programs proved by typing are operationally valid, but all true properties of programs can be proved so by way of dlPCF. This holds not only for terms of base type, but also for (first-order) functions: this makes the type system more expressive than intersection type disciplines.
A characterization of probabilistic polynomial time classes by way of linear typing systems for a variant of Godel’s T called RSLR, has been proposed [51]. Classes like BPP and PP are characterized by RSLR once appropriate constraints on the probability of error are imposed.

A unifying methodology for the study of resource consumption of processes has been presented in [13]; it is a refinement of realizability, in which not only termination but also concrete resource bounds can be obtained by showing a function to be realized by a program.

On the same topic is the paper [26], that polishes previous work.

6.6. Verification of extensional properties

Participants: Elena Giachino, Cosimo Laneve, Tudor Alexandru Lascu, Davide Sangiorgi, Gianluigi Zavattaro.

Extensional refers to properties that have to do with behavioral descriptions of a system (i.e., how a system looks like from the outside). Examples of such properties include classical functional correctness and deadlock freedom. We mainly employ techniques based on behavioral equivalences (and preorders), and on types and logics. Type systems offer a good trade-off between expressiveness and efficiency of the techniques. A substantial amount of the work carried out this year has to do with the transfer of techniques between the areas of concurrency theory and object-oriented languages.

We have developed [29] a technique for the deadlock analysis of systems of concurrent object groups. The technique makes use of types in the form of contracts, that is, abstract descriptions of method’s behaviours. Object groups are collections of objects that perform collective work. Within a group, there can be only one running thread at a time; the scheduling of threads is cooperative.

We have studied [37] the concept of ownership types, originally introduced for (sequential) object-oriented languages, in the setting of pure message-passing concurrency. Ownership types have the effect of statically preventing certain communications, and can block the accidental or malicious leakage of secrets. Intuitively, a channel defines a boundary and forbids access to its inside from outer channels, thus preserving the secrecy of the inner names from malicious outsiders.

In a different line of work, we have analyzed ad hoc networks, intended as networks of devices connected by wireless links and communicating via broadcast. We have considered [27], [18] models in which the communication topology of a network is represented as a graph. Nodes represent states of individual processes, and adjacent nodes represent single-hop neighbors. Processes are finite state automata that communicate via selective broadcast messages. Reception of a broadcast is restricted to single-hop neighbors. In these systems we have studied various forms of reachability (example: the existence of an initial topology in which the execution of the protocol can lead to a configuration with at least one node in a certain state).

Induction is a pervasive tool in Computer Science and Mathematics for defining structures and reasoning on them. Coinduction is the dual of induction, and as such it brings in tools that are quite different from those provided by induction. The best known instance of coinduction is bisimulation, mainly employed to define and prove equalities among potentially infinite objects: processes, streams, non-well-founded sets, and so on. Sangiorgi has completed [47], [49] two comprehensive textbooks on bisimulation and coinduction (in [49], Sangiorgi is an editor, and author of two chapter contributions [48], [46]). The books explain the fundamental concepts and techniques, and the duality with induction. A special emphasis is put on bisimulation as a behavioural equivalence for processes. Thus the books also serve as an introduction to models for expressing processes, and to the associated techniques of operational and algebraic analysis.

6.7. Tutorial papers on Service-Oriented Computing

Participants: Mario Bravetti, Ivan Lanese, Davide Sangiorgi, Gianluigi Zavattaro.

We have contributed to a few tutorial papers that summarise the work on languages and tools for Service-Oriented Computing that has been carried out within the EU project Sensoria in Focus and elsewhere. The papers appear as chapters of a book dedicated to the topic.
The chapters [45] and [43] present and contrast the primitives and the behavioural theories of the main process calculi designed for modeling services.

Languages and models for service-oriented applications usually include primitives and constructs for exception and compensation handling. Exception handling is used to react to unexpected events while compensation handling is used to undo previously completed activities. In [44] we investigate the impact of exception and compensation handling in service-oriented process calculi.

The chapter [42] deals with contracts: descriptions intended to provide support for the automatic on-demand discovery of functionalities offered by a service. The approach followed is to describe such contracts as process calculi expressions. We show how, in certain cases, service contracts can be automatically extracted out of service behaviour, and how they can be used to formally check compliance among the communication protocols followed by the interacting services.

Finally, in [41] we present different tools that have been developed for verifying properties of service implementations with respect to their formal specifications in an automated, or semi-automated, way.

### 6.8. Expressiveness of computational models

**Participants:** Mila Dalla Preda, Ugo Dal Lago, Ivan Lanese, Cosimo Laneve, Davide Sangiorgi.

Expressiveness refers to the study of the expressive power of computational models. In 2011 we have addressed four main aspects.

First, we have continued our investigation of reversible computations. Reversibility is a main ingredient in the study of programming abstractions for reliable systems, e.g. for exception handling. In fact, reversibility can be used for going back to some consistent state after an exception has occurred. In previous years we had defined $\rho\pi$, a higher-order calculus where processes can both go forward and backward in the computation. This year we have studied [33] fine-grained rollback primitives to control reversibility. The definition of a proper semantics for such a primitive is a surprisingly delicate matter because of the potential interferences between concurrent rollbacks. We have also considered lower-level distributed semantics, which are closer to an actual implementation of the rollback primitives, and their relationship with the high-level semantics.

A thread of research close to that of $\rho\pi$ is the study of the properties and the expressive power of a simple calculus with reversible transitions, called reversible structures. In [24], we have demonstrated a standardization theorem for these structures. When terms in reversible structures have unique id, the standardization theorem may be strengthened in a form that bears a quadratic algorithm for reachability, a problem that is EXPSPACE-complete for generic structures (as in Petri Nets). The expressive power of reversible structures has been studied in [17], [12] and a compilation of asynchronous Reversible CCS has been provided.

A second aspect has been motivated by the analogy between malicious software and biological infections [39]. In the paper, we have used a formalism originally developed for the analysis of biological systems — the kappa calculus by Danos and Laneve — for the formalization and analysis of malicious software. In particular we have modeled the different actors involved in a malicious code attack in the kappa-calculus. Then, by simulating the behavior, we have shown how to extract relevant information that can drive the choice of the defense technique to apply.

A third aspect has been the refinement [14] of some previous work on the expressiveness and decidability of higher-order concurrent languages. — formalisms for concurrency in which processes can be passed around in communications.

A fourth aspect has been the study of properties of a simple calculus for quantum computation. In [16], we have demonstrated a confluence property both for finite and infinite computations using a novel technique.
6. New Results

6.1. Simulation

6.1.1. Simulation of vector architecture

Participants: Vania Joloboff, Yang Yu.

Many architectures including PowerPC and ARM now have vectorized instructions, that is, instructions that can execute on several data items in parallel (e.g. 8 simultaneous additions) on specific vector data.

We have implemented the ALTIVEC extension of the PowerPC to support the vector instructions.

6.1.2. Native translation using LLVM

Participants: Vania Joloboff, Xinlei Zhou, Zuyu Zhang.

We have started to implement a new technique of dynamic translation. This new method consists in decompiling the binary object code into an abstract representation and recompiling it to native host code.

The decompilation of the program amounts to reconstructing the simulated program Control Flow Graph using an intermediate representation. We have chosen LLVM (Low Level Virtual Machine), defined by University of Illinois, and now widely adopted in many projects, as our representation format. Using LLVM allows us to directly use the LLVM Intel code generator.

The SimSoC binary decoder has been modified to identify basic blocks (blocks of sequential instructions ending with a branch instruction). After instructions have been grouped into basic blocks, they are translated into an LLVM representation and finally the LLVM compiler is called to generate native code.

A first version of this technique has been implemented for both the ARM and Power Architecture. We have reach a considerable speed improvement in the generated code, with the execution speed multiplied by factor of 2 to 8. However the translation time from binary to LLVM and from LLVM to native code is significant (translation speed is roughly 1000 instructions per second). Consequently the overall speed is improved by only a factor of 20 to 50 percent when the simulation are relatively short test programs [20].

In order to reach still higher simulation speed we need to use a more sophisticated analysis of the control flow graph. The idea is to do an edge profiling analysis of the basic blocks in order to identify larger blocks. This work is under development.

Another idea is to use multi-processor hosts machine to parallelize translation from LLVM to native code. This is also under investigation.

6.1.3. Trace Analysis

Participants: Guillaume Merle, Vania Joloboff.

Simulation sessions produce huge trace files, sometimes now in hundreds of gigabytes, that are hard to analyze with a quick response time. This comes down to two sub-problems:

- The trace file size. Trace files are huge because they include lots of information. But when looking for a specific problem, one does not need all of this information. To search one given defect, one may ignore a large amount of the data in the trace file. One would like the trace file to contain only relevant information to the concerned problem.

- The expressive power of the language to analyze the trace, and its usability. If the language is limited to expression search, it is easy to use but hard to construct sophisticated formulas. If the language used is Linear Temporal Logic (LTL), there is a lot of expressive power but many engineers are unable to write a LTL formula and to maintain it over time.
We would like to build a trace analysis tool that includes a language which allows expression of time-related formulas but is simple to formulate expressions. When this language is compiled, ideally the compiler is smart enough to identify independent formulae, the search of which can be parallelized, and it is also smart enough to generate "filter scripts".

When compiling one trace language input file, it would generate, from one input file, N filter scripts and N analyzers. Then during the simulation, the huge raw trace file is actually split into N smaller trace files, each relevant to one problem only, filtering out all unnecessary data. Hence trace files sizes would be considerably reduced.

We have started to design a trace language and a compiler, and extended the SimSoC simulator to support generation of trace files with a filter.

A first version of the trace language compiler has been coded in OCAML.

In the current version under development, the filters are not generated but coded manually, and filters are not parallelized.

6.1.4. Generation of simulators from vendor specification

**Participants:** Frédéric Blanqui, Vania Joloboff, Jean-François Monin, Xiaomu Shi, Frédéric Tuong.

Starting last year, we undertook the task of generating automatically an instruction set simulator (ISS) from the vendor specification in a PDF file. In order to generate the C code of the simulator, it is assumed such vendor specification contains at least some formal definitions of the instruction set that can be analyzed. It is the case to a wide extent for the ARM, the PowerPC and the SH architectures.

The process of generating the simulator consists of 4 major steps, first eliminating from the PDF file irrelevant information, next construct from the relevant data an abstract syntax representation of the instruction set, then to generate the C code of the simulator, using some additional data provided manually to complete the vendor specification.

This work was completed last year for the ARM architecture with the documentation form ARM corporation [35]. This year, we did similar work for the SH architecture from specification from RENESAS corporation. We have indeed generated a simulator for the SH4 architecture [31], which has not been fully tested yet.

However, this works has proved that the abstract syntax we have defined is powerful enough to describe two different architectures with significant differences in the way they are described by the vendor.

6.1.5. First steps towards the certification of an ARM simulator

**Participants:** Frédéric Blanqui, Jean-François Monin, Xiaomu Shi, Frédéric Tuong.

The simulation of Systems-on-Chip (SoC) is nowadays a hot topic because, beyond providing many debugging facilities, it allows the development of dedicated software before the hardware is available. Low-consumption CPUs such as ARM play a central role in SoC. However, the effectiveness of simulation depends on the faithfulness of the simulator. To this effect, in [24], we propose here to prove significant parts of such a simulator, SimSoC. Basically, on one hand, we develop a Coq formal model of the ARM architecture while on the other hand, we consider a version of the simulator including components written in Compcert-C [61]. Then we prove that the simulation of ARM operations, according to Compcert-C formal semantics, conforms to the expected formal model of ARM. Size issues are partly dealt with using automatic generation of significant parts of the Coq model and of SimSoC from the official textual definition of ARM. However, this is still a long-term project. We report here the current stage of our efforts and discuss in particular the use of Compcert-C in this framework.

6.2. Type and rewriting theory

6.2.1. A type theory for Coq

**Participants:** Jean-Pierre Jouannaud, Qian Wang.
In this joint work with Bruno Barras and Pierre-Yves Strub [17], we describe an abstract model of CoqMT [73] called CoqMTU, which puts together the Calculus of Inductive Constructions, decidable first-order theories, and an infinite hierarchy of universes which are all predicative but the first impredicative universe of propositions. We have shown its consistency, strong normalization and decidability of type checking in presence of weak elimination (and absence of strong elimination). An important feature of this work is that the first-order theory is abstract, characterized by the three natural axioms that (i) it is non-degenerated (its models have at least two elements), (ii) constructors are free, and (iii) defined symbols are completely defined. On the theoretical side, this allows us to give an abstract elimination principle for such non-canonical theories. On the practical side, this justifies the implementation of CoqMT in which decidable theories can be dynamically downloaded. It should be noticed that these proofs are done in Coq, except for the strong normalization part. Qian Wang is now continuing this work at Ecole Polytechnique with Bruno Barras and Pierre-Yves Strub, the target being strong normalization.

6.2.2. Confluence by decreasing diagrams

Participants: Jean-Pierre Jouannaud, Huiying Luo, Jiaxiang Liu.

Invented by Vincent Van Oostrom, decreasing diagrams capture both kinds of diagrams arising from Newman’s Lemma and Hindley’s Lemma: they indeed allow to reduce all known confluence methods to critical pairs computations, and a search of decreasing diagrams for them all, where decreasingness is measured by a well-founded order on proof steps.

In [55], we give a new simple proof of Van Oostrom’s main theorem, and extend the method of decreasing diagrams to rewrite relations on a term algebra. We prove that the union of a terminating left-linear systems, and a non-terminating linear system is confluent provided the various critical pairs existing in in their combination have decreasing diagrams (with respect to some order built from the respective orders of both systems).

During this year, we have further simplified and generalized these results in order to get rid of the left-linearity assumption for the first system, and of the right-linearity assumption for the second. This yields a true generalization of the well-known Knuth-Bendix-Huet confluence result for terminating systems, and at the same time of various critical-pair based results found in the literature for non-terminating systems.

6.2.3. Confluence of normal rewriting

Participants: Jean-Pierre Jouannaud, Jianqi Li.

Confluence results for first-order and higher-order rewriting differ in many ways: by the rewriting relation used, and by the strong normalization assumption made. We believe that these differences hide the strong similarities of these (and other) kinds of rewriting.

In this work, we introduce a new notion of rewriting, normal rewriting, which aims at capturing all known results reducing confluence to critical (and extension) pair computations in presence of some termination assumption.

We achieve this goal in the following way. First, we consider theories made of a set $R$ of rules, a set $S$ of simplifiers, and a set $E$ of equations. Rewriting operates on terms in $S$ modulo $E$ normal forms, and uses $S \cup E$-pattern matching for firing the rules in $R$, before to normalize the result with respect to $S$ modulo $E$. Termination is assumed for the union of $S$ modulo $E$ and $R$ modulo $S \cup E$. Second, we introduce relations on an abstract set of terms, and an abstract, well-founded set of positions, and reduce the Church-Rosser property of abstract normal rewriting to abstract notions of critical pairs and extensions. We can then apply this result to first-order rewriting, as well as to various forms of higher-order rewriting. These results capture plain rewriting ($S \cup E = \emptyset$), Stickel’s rewriting modulo ($S = \emptyset$), Nipkow’s higher-order rewriting ($S$ is made of beta-reduction and eta-expansion, and $E$ is alpha-conversion), and allow to describe new forms of first and higher-order rewriting relations.

6.2.4. Argument filterings and usable rules in higher-order rewrite systems

Participant: Frédéric Blanqui.
The static dependency pair method is a method for proving the termination of higher-order rewrite systems à la Nipkow [62]. It combines the dependency pair method introduced for first-order rewrite systems with the notion of strong computability introduced for typed lambda-calculi [52]. Argument filterings and usable rules are two important methods of the dependency pair framework used by current state-of-the-art first-order automated termination provers [51], [53]. In [12], we extend the class of higher-order systems on which the static dependency pair method can be applied. Then, we extend argument filterings and usable rules to higher-order rewriting, hence providing the basis for a powerful automated termination prover for higher-order rewrite systems.

6.3. Decision procedures

6.3.1. A certificate framework for DPLL(T)

Participants: Min Zhou, Fei He, Bow-Yaw Wang, Wenrui Meng.

Satisfiability Modulo Theories (SMT) techniques are widely used nowadays. SMT solvers are used to decide the satisfiability of first-order formulas. When an SMT solver is invoked, it is important to ensure correctness of the result. For this purpose, we proposed a certificate framework based on DPLL(T), including generation of certificates and verification of certificates. Some properties are discussed and proved theoretically. The certificate is easy to generate because it only needs minor modification to the existing SMT solvers. Experiment results show that the overhead for certificates generation is only 10%. Moreover, verifying the certificate requires few memory and time, which outperforms other approaches.

6.3.2. Automated verification of termination certificates

Participants: Frédéric Blanqui, Kim-Quyen Ly, Sidi Ould Biha.

The research community on rewriting developed a grammar for termination certificates called CPF [29] (given by a XML Schema file). Our goal is to develop a safe, modular and efficient termination certificate verifier based on the formal library of mathematical results on termination called CoLoR that has been developed for the proof assistant Coq [11].

Because the CPF format is regularly modified and extended with new features, it is useful to have a tool that can automatically generate data structures, parsers and pretty-printers for that format. Hence, we developed a first version of such a tool in OCaml.

Once we got a representation of termination certificates in Coq, we could start defining a boolean function checking the correctness of a certificate, and formally prove its correctness. For the moment, we only considered the case of polynomial interpretations on integers. The proof is almost finished. To do so, we had to modify some of the CoLoR files to be able to use its results (transformation of modules into records that are first-class objects). The use of dependent types in CoLoR makes also definitions and proofs much more difficult.

6.3.3. Proving computational geometry algorithms in TLA+2

Participants: Hui Kong, Hehua Zhang, Ming Gu.

Geometric algorithms are widely used in many scientific fields like computer vision, computer graphics. To guarantee the correctness of these algorithms, it is important to apply formal method to them. In this work, we propose an approach to proving the correctness of geometric algorithms [22]. The main contribution is that a set of proof decomposition rules is proposed which can help improve the automation of the proof of geometric algorithms. We choose TLA+2, a structural specification and proof language, as our experiment environment. The case study on a classical convex hull algorithm shows the usability of the method.

6.4. Compositional verification

6.4.1. BDD-based assume-guarantee reasoning through implicit learning

Participants: Fei He, Bow-Yaw Wang, Lei Zhu.
We present a purely BDD-based assume-guarantee reasoning technique to improve the scalability of symbolic model checking. The new technique adopts a BDD learning algorithm to generate BDD’s as contextual assumptions. A new witness analysis algorithm is proposed to exploit the multitude of traces returned by symbolic model checkers. Using the classification tree-based BDD learning algorithm to generate contextual assumptions, we compare assume-guarantee reasoning with monolithic symbolic model checking. The new technique always infers smaller contextual assumptions than contexts in our experiments.

6.4.2. Predicate generation for learning-based loop invariant inference

**Participant:** Bow-Yaw Wang.

We address the predicate generation problem in the context of loop invariant inference. Motivated by the interpolation-based abstraction refinement technique, we apply the interpolation theorem to synthesize predicates implicitly implied by program texts. Our technique is able to improve the effectiveness and efficiency of the learning-based loop invariant inference algorithm in [21]. Experiments excerpted from Linux, SPEC2000, and Tar source codes are reported.

This is a joint work with Yungbum Jung, Wonchan Lee, and Kwangkuen Yi of Seoul National University, South Korea.

6.4.3. Thread-modular model checking with iterative refinement

**Participants:** Wenrui Meng, Fei He, Bow-Yaw Wang.

Thread-modular analysis is an incomplete compositional technique for verifying concurrent systems. The heuristic works rather well when there is limited interaction among system components. In this project, we develop a refinement algorithm that makes thread-modular model checking complete. Our algorithm refines abstract reachable states by exposing local information through auxiliary variables. The experiments show that our complete thread-modular model checking can outperform other complete compositional reasoning techniques.

6.5. Specification and verification of TLA+ and PLC systems

6.5.1. Formal semantics of PLC programming languages

**Participants:** Sidi Ould Biha, Litian Xiao, Ming Gu.

We formalized a semantics of the Instruction List (IL) language, one of the five programming languages defined in the IEC 61131-3 standard for PLC programming [23]. This semantics support a significant subset of the IL language that includes on-delay timers. This semantics was used in a join work to with Jan Olaf Blech from Fortiss (Germany) to prove some safety properties for a real industrial example of PLC program [18].

A second widely used language for programming PLC is the graphical language Ladder Diagrams (LD). We defined a formal semantics of LD in the proof assistant Coq. Based on this semantics and the IL one, we developed a translation function from LD to IL. We also proved a semantic preservation property for this translation function. We have now a certified compilation function from the graphical language LD to IL. This work opens the way for the development of a certified compilation chain for PLC. A journal paper about this work and others aspects of PLC certification is under reviewing.

In [16], [15], we study the definition of denotational semantics on PLC program language, which is convenient to PLC programs modeling and model checking. The purpose of the work is the correctness verification on PLC programs by formal methods. Based on the extended λ-calculus definition, this work has defined the configuration of PLC program architecture, denotational semantics of PLC programs and functions of denotational semantics. It is the basis of model checking and theorem proving.

6.5.2. Formalization and verification of PLCs

**Participants:** Hai Wan, Litian Xiao, Ming Gu.
PLCs are widely used in embedded systems. Timers play a pivotal role in PLC real-time applications. The formalization of timers is of great importance. In [13], we present a formalization of PLC timers in the theorem proving system Coq, in which the behaviors of timers are characterized by a set of axioms at an abstract level. The authors discuss how to model timers at a proper and sound abstract level. PLC programs with timers are modeled. As a case study, a quiz machine problem with a timer is investigated. This work demonstrates the complexity of formal timer modeling.

In [25], we modeled kernel data type and basic statements and the denotational semantics of PLC program in Coq. It has given the correctness proof of PLC program based on theorem proving, i.e. based on semantics function the relationship of configuration between the before codes execution and the after is proved. The main purpose is to prove whether a PLC program satisfies certain nature within a scan period.

6.5.3. Synthesis of PLC programs

Participants: Rui Wang, Ming Gu.

PLCs are complex cyber-physical systems which are widely used in industry. In [14], we present a robust approach to design and implement PLC-based embedded systems. Timed automata are used to model the controller and its environment. We validate the design model with resort to model checking techniques. We propose an algorithm to generate PLC code from timed automata and implement this algorithm with a prototype tool. This method can condense the developing process and guarantee the correctness of PLC programs. A case study demonstrates the effectiveness of the method.

6.5.4. Domain-driven probabilistic analysis of PLCs

Participants: Hehua Zhang, Yu Jiang, Ming Gu.

Programmable Logic Controllers are widely used in industry. Reliable PLCs are vital to many critical applications. We present a novel symbolic approach for analysis of PLC systems [27]. The main components of the approach consists of: (1) calculating the uncertainty characterization of the PLC systems, (2) abstracting the PLC system as a Hidden Markov Model, (3) solving the Hidden Markov Model using domain knowledge, (4) integrating the solved Hidden Markov Model and the uncertainty characterization to form an integrated (regular) Markov Model, and (5) harnessing probabilistic model checking to analyze properties on the resultant Markov Model. The framework provides expected performance measures of the PLC systems by automated analytical means without expensive simulations. Case studies on an industrial automated system are performed to demonstrate the effectiveness of our approach.

6.5.5. Edola: a domain modeling and verification language for PLCs

Participants: Hehua Zhang, Ming Gu.

Formal modeling and verification of PLC systems become paramount in engineering applications. The work presents a novel PLC domain-specific modeling language Edola [26]. Important characteristics of PLC embedded systems, such as reactivity, scan cycling, real-time and property patterns, are embodied in the language design. Formal verification methods, such as model checking and automatic theorem proving, are supported in Edola modeling. The TLA+ specification language constitutes an intermediate language layer between Edola and the verification tools, enhancing a large degree of reusability. A prototype IDE for Edola and its seamless integration of a model checker TLC and an automatic theorem prover Spass are implemented. A case study illustrates and validates the applicability of the language.

6.6. Distributed algorithms

6.6.1. Formal model and proofs for Netlog protocols

Participants: Meixian Chen, Jean-François Monin.

Joint work with Yuxin Deng (Jiaotong University, Shanghai) and Stéphane Grumbach (LIAMA/Netquest).
Netlog is a language designed and implemented in the Netquest project for describing protocols. Netlog has a precise semantics, provides a high level of abstraction thanks to its Datalog flavor and benefits from an efficient implementation. This makes it a very interesting target language for proofs of protocols. Netlog comes with two possible semantics: a synchronous semantics, better suited to tightly coupled parallel systems and an asynchronous semantics, better suited to distributed systems.

We designed a formal model of Netlog in Coq, where the two possible semantics are derived from common basic blocks. In a fully certified framework, a formal proof of the Netlog engine (running on each node) would be required. We don’t attack this part at the moment: we assume that the implementation respects the general properties stated in our model and focus on the issues raised by the distributed model of computation provided by Netlog.

As a proof of concept, we applied in 2010 this framework to an algorithm constructing a Breadth-First Search Spanning Tree (BFS) in a distributed system [46]. This work has been slightly improved this year and published in [19].

Moreover, we generalized the model in order to take the removal of datalog facts into account, and started to use this feature for more complicated protocols. In main one under study is Prim’s algorithm (publication under submission), and we target next GHS, which still resists to palatable proof techniques.
GALAAD Project-Team

6. New Results

6.1. Algebraic Algorithms for Geometric Computing

6.1.1. An Algebraic Approach to Continuous Collision Detection for Ellipsoids

Participant: Bernard Mourrain.

In [28], we present algebraic conditions for characterizing three configurations of two ellipsoids in $\mathbb{R}^3$ that are the most relevant to collision detection: separation, external touching and overlapping. These conditions are given in terms of explicit formulae expressed by the subresultant sequence of the characteristic polynomial of the two ellipsoids and its derivative. For any two ellipsoids, the signs of these formulae can easily be evaluated to classify their configuration. Furthermore, based on these algebraic conditions, an efficient method is developed for continuous collision detection for two moving ellipsoids under arbitrary motion.

This is a joint work with Xiaohong Jia, Yi-King Choi and Wenping Wang from the university of Hong Kong.

6.1.2. On Continued Fraction Expansion of Real Roots of Polynomial Systems, Complexity and Condition Numbers

Participants: Angelos Mantzaflaris, Bernard Mourrain.

In [29], we elaborate on a correspondence between the coefficients of a multivariate polynomial represented in the Bernstein basis and in a tensor-monomial basis, which leads to homography representations of polynomial functions, that use only integer arithmetic (in contrast to Bernstein basis) and are feasible over unbounded regions. Then, we study an algorithm to split this representation and we obtain a subdivision scheme for the domain of multivariate polynomial functions. This implies a new algorithm for real root isolation, MCF, that generalizes the Continued Fraction (CF) algorithm of univariate polynomials. A partial extension of Vincent’s Theorem for multivariate polynomials is presented, which allows us to prove the termination of the algorithm. Bounding functions, projection and preconditioning are employed to speed up the scheme. The resulting isolation boxes have optimized rational coordinates, corresponding to the first terms of the continued fraction expansion of the real roots. Finally, we present new complexity bounds for a simplified version of the algorithm in the bit complexity model, and also bounds in the real RAM model for a family of subdivision algorithms in terms of the real condition number of the system. Examples computed with our C++ implementation illustrate the practical aspects of our method.

This is a joint work with E. Tsigaridas, from the Department of Computer Science, University of Aarhus.

6.1.3. Matrix-based representations of rational hypersurfaces

Participants: Laurent Busé, Nicolas Botbol.

This ongoing work is related to matrix-based representations of rational hypersurfaces whose theoretical foundations has been recently developed by our team and several other authors in the context of the implicitization problem. Being given a parameterized curve or hypersurface, this method consists in building a matrix whose entries are typically linear forms in the variables of the ambient space and such that the ideal generated by the maximal minors of this matrix provide a good approximation of the original curve or surface.

We aim to study and determine the geometric informations that are contained in a representation matrix. In particular, we are currently adressing the two following questions:

1) understand the extraneous components that are added by taking the initial Fitting ideal of a representation matrix, with respect to the original curve or surface. Indeed, these extraneous components appear because of the good behavior of Fitting ideals under change of bases. Therefore, one can expect that these extraneous components yields some geometric properties of a curve or surface as a member of a certain family. 2) examine the extraction of singularities from a representation matrix, similarly to the recent results on what is called "singular factors" for the case of rational curves.
6.1.4. The surface/surface intersection problem by means of matrix based representations  
**Participants:** Laurent Busé, Thang Luu Ba.

Evaluating the intersection of two rational parameterized algebraic surfaces is an important problem in solid modeling. In this work, we made use of some generalized matrix based representations of parameterized surfaces in order to represent the intersection curve of two such surfaces as the zero set of a matrix determinant. As a consequence, we extended to a dramatically larger class of rational parameterized surfaces the applicability of a general approach to the surface/surface intersection problem due to J. Canny and D. Manocha. In this way, we obtained compact and efficient representations of intersection curves allowing to reduce some geometric operations on such curves to matrix operations using results from linear algebra.

See the preprint version at [http://hal.inria.fr/inria-00620947/en/](http://hal.inria.fr/inria-00620947/en/)

6.2. Symbolic-Numeric Analysis

6.2.1. A Subdivision Method for Computing Nearest Gcd with Certification  
**Participants:** André Galligo, Bernard Mourrain.

A new subdivision method for computing the nearest univariate gcd is described and analyzed in [24]. It is based on an exclusion test and an inclusion test. The exclusion test in a cell exploits Taylor expansion of the polynomial at the center of the cell. The inclusion test uses Smale’s alpha-theorems to certify the existence and unicity of a solution in a cell. Under the condition of simple roots for the distance minimization problem, we analyze the complexity of the algorithm in terms of a condition number, which is the inverse of the distance to the set of degenerate systems. We report on some experimentation on representative examples to illustrate the behavior of the algorithm.

This is a joint work with Guillaume Chèze and Jean-Claude Yakoubsohn (University Paul-Sabatier, Toulouse).

6.2.2. An Adapted Version of the Bentley-Ottmann Algorithm for Invariants of Plane Curves Singularities  
**Participant:** Bernard Mourrain.

In [34], we report on an adapted version of the Bentley-Ottmann algorithm for computing all the intersection points among the edges of the projection of a three-dimensional graph. This graph is given as a set of vertices together with their space Euclidean coordinates, and a set of edges connecting them. More precisely, the three-dimensional graph represents the approximation of a closed and smooth implicitly defined space algebraic curve, that allows us a simplified treatment of the events encountered in the Bentley-Ottmann algorithm. As applications, we use the adapted algorithm to compute invariants for each singularity of a plane complex algebraic curve, i.e. the Alexander polynomial, the Milnor number, the delta-invariant, etc.

This is a joint work with Madalina Hodorog and Joseph Schicho, from RICAM, Linz, Austria.

6.2.3. Virtual Roots of a Real Polynomial and Fractional Derivatives  
**Participant:** André Galligo.

After the works of Gonzales-Vega, Lombardi, Mahé, and Coste, Lajous, Lombardi, Roy, we consider the virtual roots of a univariate polynomial $f$ with real coefficients. Using fractional derivatives, we associate to $f$ a bivariate polynomial $f'_a(x, t)$ depending on the choice of an origin $a$, then two type of plan curves we call the FDcurve and stem of $f$. We show, in the generic case, how to locate the virtual roots of $f$ on the Budan table and on each of these curves. The paper [32] is illustrated with examples and pictures computed with the computer algebra system Maple. It is a joint work with Daniel Bembe.

6.2.4. Computing monodromy via continuation methods on random Riemann surfaces  
**Participant:** André Galligo.
In [25], we consider a Riemann surface $X$ defined by a polynomial $f(x, y)$ of degree $d$, whose coefficients are chosen randomly. Hence, we can suppose that $X$ is smooth, that the discriminant $\delta(x)$ of $f$ has $d(d-1)$ simple roots $\Delta$ and that $\delta(0) \neq 0$, i.e. the corresponding fiber has $d$ distinct points $\{y_1, \ldots, y_d\}$. When we lift a loop $0 \in \gamma \subset \mathbb{C} - \Delta$ by a continuation method, we get $d$ paths in $X$ connecting $\{y_1, \ldots, y_d\}$, hence defining a permutation of that set. This is called monodromy.

Here we present experimentations in Maple to get statistics on the distribution of transpositions corresponding to loops around each point of $\Delta$. Multiplying families of “neighbor” transpositions, we construct permutations and the subgroups of the symmetric group they generate. This allows us to establish and study experimentally two conjectures on the distribution of these transpositions and on transitivity of the generated subgroups.

Assuming that these two conjectures are true, we develop tools allowing fast probabilistic algorithms for absolute multivariate polynomial factorization, under the hypothesis that the factors behave like random polynomials whose coefficients follow uniform distributions. It is a joint work with Adrien Poteaux (University of Lille).

6.3. Algebraic representations for geometric modeling

6.3.1. Multihomogeneous Polynomial Decomposition using Moment Matrices

Participants: Alessandra Bernardi, Jérôme Brachat, Bernard Mourrain.

In [33], we address the important problem of tensor decomposition which can be seen as a generalisation of Singular Value Decomposition for matrices. We consider general multilinear and multihomogeneous tensors. We show how to reduce the problem to a truncated moment matrix problem and we give a new criterion for flat extension of Quasi-Hankel matrices. We connect this criterion to the commutation characterization of border bases. A new algorithm is described: it applies for general multihomogeneous tensors, extending the approach of J.J. Sylvester on binary forms. An example illustrates the algebraic operations involved in this approach and how the decomposition can be recovered from eigenvector computation.

This is a joint work with Pierre Comon (I3S, CNRS).

6.3.2. On the variety parametrizing completely decomposable polynomials.

Participant: Alessandra Bernardi.

The purpose of the paper [15] is to relate the variety parameterizing completely decomposable homogeneous polynomials of degree $d$ in $n + 1$ variables on an algebraically closed field, called Split$_d(\mathbb{P}^n)$, with the Grassmannian of $n - 1$ dimensional projective subspaces of $\mathbb{P}^{n+d-1}$. We compute the dimension of some secant varieties to Split$_d(\mathbb{P}^n)$ and find a counterexample to a conjecture that wanted its dimension related to the one of the secant variety to $\mathcal{G}(n-1, n + d - 1)$. Moreover by using an invariant embedding of the Veronese variety into the Plücker space, then we are able to compute the intersection of $\mathcal{G}(n-1, n + d - 1)$ with Split$_d(\mathbb{P}^n)$, some of its secant variety, the tangential variety and the second osculating space to the Veronese variety.

This is a joint work with Enrique Arrondo (Universidad Complutense de Madrid, Spain).

6.3.3. Computing symmetric rank for symmetric tensors.

Participant: Alessandra Bernardi.

In [21] we consider the problem of determining the symmetric tensor rank for symmetric tensors with an algebraic geometry approach. We give algorithms for computing the symmetric rank for $2 \times \ldots \times 2$ tensors and for tensors of small border rank. From a geometric point of view, we describe the symmetric rank strata for some secant varieties of Veronese varieties.

This is a joint work with Alessandro Gimigliano and Monica Idà (Università di Bologna, Italy).

6.3.4. Higher secant varieties of $\mathbb{P}^n \times \mathbb{P}^m$ embedded in bi-degree $(1, d)$.

Participant: Alessandra Bernardi.
6.3.5. On the X-rank with respect to linear projections of projective varieties.

Participant: Alessandra Bernardi.

In [17] we improve the known bound for the X-rank $R_X(P)$ of an element $P \in \mathbb{P}^N$ in the case in which $X \subset \mathbb{P}^n$ is a projective variety obtained as a linear projection from a general $\nu$-dimensional subspace $V \subset \mathbb{P}^{n+\nu}$. Then, if $X \subset \mathbb{P}^n$ is a curve obtained from a projection of a rational normal curve $C \subset \mathbb{P}^{n+1}$ from a point $O \in \mathbb{P}^{n+1}$, we are able to describe the precise value of the X-rank for those points $P \in \mathbb{P}^n$ such that $R_X(P) \leq R_C(O) - 1$ and to improve the general result. Moreover we give a stratification, via the X-rank, of the osculating spaces to projective cuspidal projective curves $X$. Finally we give a description and a new bound of the X-rank of subspaces both in the general case and with respect to integral non-degenerate projective curves.

This is a joint work with Edoardo Ballico (Università di Trento, Italy).

6.3.6. Decomposition of homogeneous polynomials with low rank.

Participant: Alessandra Bernardi.

Let $F$ be a homogeneous polynomial of degree $d$ in $m+1$ variables defined over an algebraically closed field of characteristic zero and suppose that $F$ belongs to the $s$-th secant varieties of the standard Veronese variety $X_{m,d} \subset \mathbb{P}^{\binom{m+d}{d}-1}$ but that its minimal decomposition as a sum of $d$-th powers of linear forms $M_1, \ldots, M_r$ is $F = M_1^s + \cdots + M_r^s$ with $r > s$. In [16] we show that if $s + r \leq 2d + 1$ then such a decomposition of $F$ can be split in two parts: one of them is made by linear forms that can be written using only two variables, the other part is uniquely determined once one has fixed the first part. We also obtain a uniqueness theorem for the minimal decomposition of $F$ if the rank is at most $d$ and a mild condition is satisfied.

This is a joint work with Edoardo Ballico (Università di Trento, Italy).

6.3.7. On the X-rank with respect to linearly normal curves.

Participant: Alessandra Bernardi.

In [18] we study the X-rank of points with respect to smooth linearly normal curves $X \subset \mathbb{P}^n$ of genus $g$ and degree $n + g$.

We prove that, for such a curve $X$, under certain circumstances, the X-rank of a general point of $X$-border rank equal to $s$ is less or equal than $n + 1 - s$.

In the particular case of $g = 2$ we give a complete description of the X-rank if $n = 3, 4$; while if $n \geq 5$ we study the X-rank of points belonging to the tangential variety of $X$.

This is a joint work with Edoardo Ballico (Università di Trento, Italy).

6.3.8. Symmetric tensor rank with a tangent vector: a generic uniqueness theorem

Participant: Alessandra Bernardi.

Let $X_{m,d} \subset \mathbb{P}^N$, $N := \binom{m+d}{m}-1$, be the order $d$ Veronese embedding of $\mathbb{P}^n$. Let $\tau(X_{m,d}) \subset \mathbb{P}^N$, be the tangent developable of $X_{m,d}$. For each integer $t \geq 2$ let $\tau(X_{m,d}, t) \subset \mathbb{P}^N$, be the join of $\tau(X_{m,d})$ and $t - 2$ copies of $X_{m,d}$. In [19] we prove that if $m \geq 2, d \geq 7$ and $t \leq 1 + \lceil \binom{m+d-2}{m-1} \rceil$, then for a general $P \in \tau(X_{m,d}, t)$ there are uniquely determined $P_1, \ldots, P_{t-2} \in X_{m,d}$ and a unique tangent vector $\nu$ of $X_{m,d}$ such that $P$ is in the linear span of $\nu \cup \{ P_1, \ldots, P_{t-2} \}$, i.e. a degree $d$ linear form $f$ (a symmetric tensor $T$ of order $d$) associated to $P$ may be written as
\[ f = L_{t-1}^d L_t + \sum_{i=1}^{t-2} L_i^d, \quad (T = v_i^{(d-1)} v_{i+1} + \sum_{i=1}^{t-2} v_i^{(d)}) \]

with \( L_i \) linear forms on \( \mathbb{P}^m \) (\( v_i \) vectors over a vector field of dimension \( m + 1 \) respectively), \( 1 \leq i \leq t \), that are uniquely determined (up to a constant).

This is a joint work with Edoardo Ballico (Università di Trento, Italy).

6.3.9. Parametrization of computational domain in isogeometric analysis: methods and comparison

**Participants:** André Galligo, Bernard Mourrain.

Parameterization of computational domain plays an important role in isogeometric analysis as mesh generation in finite element analysis. In this paper, we investigate this problem in the 2D case, i.e., how to parametrize the computational domains by planar B-spline surface from the given CAD objects (four boundary planar B-spline curves). Firstly, two kinds of sufficient conditions for injective B-spline parameterization are derived with respect to the control points. Then we show how to find good parameterization of computational domain by solving a constraint optimization problem, in which the constraint condition is the injectivity sufficient conditions of planar B-spline parametrization, and the optimization term is the minimization of quadratic energy functions related to the first and second derivatives of planar B-spline parameterization. By using this method, the resulted parameterization has no self-intersections, and the isoparametric net has good uniformity and orthogonality. After introducing a posteriori error estimation for isogeometric analysis, we propose \( r \)-refinement method to optimize the parameterization by repositioning the inner control points such that the estimated error is minimized. Several examples are tested on isogeometric heat conduction problem to show the effectiveness of the proposed methods and the impact of the parameterization on the quality of the approximation solution. Comparison examples with known exact solutions are also presented. This joint work with Régis Duvigneau (EPI OPALE) and Gang Xu (Hangzhou Dianzi University, China) is published in [31].

6.3.10. Variational Harmonic Method for Parameterization of Computational Domain in 2D Isogeometric Analysis

**Participants:** André Galligo, Bernard Mourrain.

In isogeometric analysis, parameterization of computational domain has great effects as mesh generation in finite element analysis. In this paper, based on the concept of harmonic map from the computational domain to parametric domain, a variational approach is proposed to construct the parameterization of computational domain for 2D isogeometric analysis. Different from the previous elliptic mesh generation method in finite element analysis, the proposed method focuses on isogeometric version, and converts the elliptic PDE into a nonlinear optimization problem. A regular term is integrated into the optimization formulation to achieve more uniform grid near convex (concave) parts of the boundary. Several examples are presented to show the efficiency of the proposed method.

This joint work with Régis Duvigneau (EPI OPALE) and Gang Xu (Hangzhou Dianzi University, China) is published in [36].

6.3.11. Warp-based Helical Implicit Primitives

**Participant:** Evelyne Hubert.

Implicit modeling with skeleton-based primitives has been limited up to now to planar skeletons elements, since no closed-form solution was found for convolution along more complex curves. We show that warping techniques can be adapted to efficiently generate convolution-like implicit primitives of varying radius along helices, a useful 3D skeleton found in a number of natural shapes. Depending on a single parameter of the helix, we warp it onto an arc of circle or onto a line segment. For those latter skeletons closed form convolutions are known for entire families of kernels. The new warps introduced preserve the circular shape of the normal cross section to the primitive.
This is joint work with Cédric Zanni and Marie-Paule Cani from the project-team EVASION (INRIA Grenoble Rhône-Alpes / LJK Laboratoire Jean Kuntzmann) which is published in [37].

6.4. National Initiatives

6.4.1. PlantScan3D

PlantScan3D is an ARC between coordinated by the EPI Virtual Plants (UMR DAP, INRIA-CIRAD, Montpellier), with the EPI Galaad (INRIA, Méditerranée) and Evasion (INRIA Rhône-Alpes, Grenoble).

A close collaboration between specialists in plant structures modelling, algebraic geometry, and 3D computer graphic is required to address plant structure reconstruction from laser scanned point clouds. Indeed it is required to take into account efficiently knowledge from topology and geometry to allow mapping and reconstruction of data despite noise, occlusions, and thinness of structure. The objective of the project is to provide as output a compact geometrical model that model smoothly branching point of tubular structure and organs (like leaves). At the end, this model should make it possible an interactive visualisation and automatize different measurement operators needed by biological partners.

6.4.2. GEOLMI

GEOLMI - Geometry and Algebra of Linear Matrix Inequalities with Systems Control Applications - is an ANR project working on topics related to the Geometry of determinantal varieties, positive polynomials, computational algebraic geometry, semidefinite programming and systems control applications.

The partners are LAAS-CNRS, Univ. de Toulouse (coordinator), LJK-CNRS, Univ. Joseph Fourier de Grenoble; INRIA Sophia Antipolis Méditerranée; LIP6-CNRS Univ. Pierre et Marie Curie; Univ. de Pau et des Pays de l’Adour; IRMAR-CNRS, Univ. de Rennes.

6.4.3. ANEMOS

ANEMOS - Advanced Numeric for ELMs : Modeling and Optimized Schemes - is an ANR project devoted to the numerical modelling study of such ELM control methods as Resonant Magnetic Perturbations (RMPs) and pellet ELM pacing both foreseen in ITER. The goals of the project are to improve understanding of the related physics and propose possible new strategies to improve effectiveness of ELM control techniques. The study of spline spaces for isogemetric finite element methods is proposed in this context.

The partners are IRFM, CEA, Cadarache; JAD, University of Nice - Sophia Antipolis; INRIA, Bacchus; Maison de la Simulation CEA-CNRS-INRIA-University of Orsay- University of Versailles St Quentin.

6.5. European Initiatives

6.5.1. FP7 Projects

6.5.1.1. TERRIFIC

Title: Towards Enhanced Integration of Design and Production in the Factory of the Future through Isogeometric Technologies

Type: COOPERATION (ICT)

Defi: PPP FoF: Digital factories: Manufacturing design and product lifecycle manage

Instrument: Specific Targeted Research Project (STREP)

Duration: September 2011 - August 2014

Coordinator: SINTEF, Oslo (Norway)
Others partners:
Alenia Aeronautica (Italy) INRIA Méditerranée (France); Jozef Kepler universitet, Linz (Austria) JOTNE, Oslo (Norway); MAGNA, Steyr (Austria); Missler Software (France); Siemens AG (Germany); Technische Universität Kaiserslautern (Germany); University of Pavia (Italy).
See also: http://terrific-project.eu

Abstract: The project aims at significant improvement of the interoperability of computational tools for the design, analysis and optimization of functional products. An isogeometric approach is applied for selected manufacturing application areas (cars, trains, aircraft) and for computer-aided machining. Computer Aided Design and numerical simulation algorithms are vital technologies in modern product development, yet they are today far from being seamlessly integrated. Their interoperability is severely disturbed by inconsistencies in the mathematical approaches used. Efficient feedback from analysis to CAD and iterative refinement of the analysis model is a feature of isogeometric analysis, and would be an essential improvement for computer-based design optimization and virtual product development. Our vision is to provide and disseminate tangible evidence of the performance of the isogeometric approach in comparison to traditional ones in four important application areas as well as addressing interoperability and other issues that necessarily arise in a large-scale industrial introduction of isogeometry.

6.5.1.2. EXCITING

Title: Exact geometry simulation for optimized design of vehicles and vessels
Type: FP7-CP-SST-2007-RTD-1-218536, COOPERATION (TRANSPORTS)
Instrument: Specific Targeted Research Project (STREP)
Duration: October 2008 - September 2011
Coordinator: Jozef Kepler universitet, Linz (Austria)
Others partners:
SINTEF, Oslo (Norway); Siemens AG (Germany); National Technical University of Athens (Greece); Hellenic Register of Shipping (Greece); University of Technology, Munich (Germany); INRIA Méditerranée (France); VA Tech Hydro (Austria); Det Norske Veritas AS (Norway).
See also: http://exciting-project.eu/

Abstract: This project focuses on computational tools for the optimized design of functional free-form surfaces. Specific applications are ship hulls and propellers in naval engineering and car components, frames, and turbochargers in the automotive and railway transportation industries. The objective is to base the corresponding computational tools on the same exact representation of the geometry. This should lead to huge benefits for the entire chain of design, simulation, optimization, and life cycle management, including a new class of computational tools for fluid dynamics and solid mechanics, simulations for vehicles and vessels based. This seamless integration of CAD and FEM will have direct applications in product design, simulation and optimization of core components of vehicles and vessels.

6.5.1.3. SAGA

Title: ShApe, Geometry and Algebra, 2008-2012
Type: FP7-PEOPLE-2007-1-1-ITN.
Instrument: Initial Training Network (ITN)
Duration: November 2008 - October 2012
Coordinator: SINTEF (Norway)
Others partners: University of Oslo (Norway); Johannes Kepler Universitaet Linz (Austria); Universidad de Cantabria, Santander (Spain); Vilniaus Universitetas (Lithuany); National and Kapodistrian University of Athens (Greece); INRIA Méditerranée (France); GraphiTech (Italy); Kongsberg SIM GmbH (Austria); Missler Software (France);

See also: http://saga-network.eu/.

Abstract: The project aims at promoting the interaction between Geometric Modeling and Real Algebraic Geometry and, in general, at strengthening interdisciplinary and inter-sectorial research and development concerning CAD/CAM. Its objective is also to train a new generation of researchers familiar with both academic and industry viewpoints, while supporting the cooperation among the partners and with other interested collaborators in Europe.

6.5.1.4. DECONSTRUCT

Title: Decomposition of Structured Tensors, Algorithms and Characterization.
Type: PEOPLE (FP7-PEOPLE-2009-IEF)
Instrument: Marie Curie Intra-European Fellowships for Career Development (IEF)
Duration: November 2010 - November 2012
Coordinator: INRIA (France)

See also: http://www-sop.inria.fr/teams/galaad/joomla/index.php/international-collaborations-147/172-deconstruct.html

Abstract: Tensors play a wide role in numerous application areas as Signal Processing for Telecommunications, Arithmetic Complexity or Data Analysis. In some applications tensors may be completely symmetric, or symmetric only in some modes, or may not be symmetric. In most of these applications, the decomposition of a tensor into a sum of rank-1 terms is relevant, since tensors of interest have a reduced rank. Most of them are structured i.e. they are either symmetric or enjoy some index-invariance. Lastly, they are often real, which raises open problems concerning the existence and calculation of the decompositions. These issues build the basic bricks of the research program we propose. The classes of tensors described above have a geometric translation in terms of classical algebraic varieties: Segre, Veronese, Segre-Veronese varieties and Grassmannians and their secant varieties. A complete description of equations for those secant varieties and their dimensions is still not known (only dimensions of secant varieties to Veronesean are classified), although they have been studied by algebraic and differential geometers and algebraists for a long period up to now. The aim of this research project is:

- to attack both the description of the ideal of those secant varieties and their dimensions, starting from low dimensions and low degrees,
- to propose algorithms able to compute the rank of structured tensors.

6.6. International Initiatives

6.6.1. Visits of International Scientists

Annie Cuyt and Wen-Shin Lee (University of Antwerpen, Belgium) visited from January 24th to February 2nd to initiate a collaboration on the topic of shape from moments.

George Labahn (University of Waterloo, Canada) visited February 14th-18th and October 3rd-8th to collaborate with Evelyne Hubert on scaling invariants and their application to symmetry reduction of dynamical system (with parameters).

Mark Hickman (University of Canterbury, New Zealand) visited from March to June, as part of his sabbatical year, to collaborate with Evelyne Hubert on the topic of integral and moment invariants and their applications in computer vision.
Nelly Villamizar (University of Oslo) visited us from March 15 to May 15, to collaborate with B. Mourrain on splines spaces, for her secondment in the context of the ITN Marie-Curie SAGA.

Nguyen Tuan Thien (JKU, LINZ) visited us from March to May, to collaborate with B. Mourrain and A. Galligo on parameterization problems in isogeometric analysis, for his secondment in the context of the ITN Marie-Curie SAGA.

6.6.2. Participation In International Programs

6.6.2.1. PAI STAR South Corea collaboration

Participants: Laurent Busé, André Galligo, Evelyne Hubert, Angelos Mantzaflaris, Bernard Mourrain.

The objective of this collaboration is to conduct research in algebraic techniques for solving geometric modeling problems. More specially, we are interested in developing efficient and robust methods to solve non-linear constraints which appear in geometric computation. These methods will be used in applications such as shape design and reconstruction for solving interpolation or approximation problems. A typical area in which we will apply our methods is ship design. Experimentation and validation will lead to open source software implementation.

Collaborators from Seoul National University: Tae-Wan Kim, Sharma Rajiv, Hur Seok, Yeong-hwa Seo.

Tae-Wan Kimm visited INRIA-GALAAD from April 17 to April 23.
6. New Results

6.1. Reconstruction

**Participants:** Panagiotis Koutsourakis, Helene Langet, Loic Simon, Olivier Teboul, Gilles Fleury, Elisabeth Lahalle, Yves Trousset, Cyril Riddell, Nikos Paragios.

- **Image-based Procedural Modeling of Urban environments:** In [20] we develop a multiple hypotheses testing algorithm for image-based/grammar-driven building modeling. Shape grammars are used to express the variation of the observed architecture. Such a model is coupled with the observations through a maximum likelihood principle where the aim is to maximize the posterior segmentation probability in the image plane given the partition being determined from the grammar derivation. The unknown parameters of the process involve the grammar derivation tree and the associated parameters. Such a mixed continuous/discrete problem is solved through a hill climbing approach that involves joint perturbations in the derivation and parameter space. Promising results demonstrated the potentials of such a formulation for complex Parisian architectures. This idea was further extended in [40] where reinforcement learning was used as optimization principle. Performance in particular computational gain over [20] demonstrated the extreme potentials of such a formulation. In order to cope with multi-view geometry, the grammar was further derived to include 3D components and the optimization process was amended to deal with multiple views. An evolutionary computation process (based on consistent mutation and recombination of partial grammar trees) was proposed to fuse image and depth-based information. The use of the Pareto frontier between the two concurrent components of the objective function provides a principle way to determine the optimal solution of the designed objective function.

- **Compressed Sensing Digital Subtraction Rotational Angiography:** in [39] we develop an extension of iterative filtered backprojection method for reconstruction of three-dimensional vascular structures from two spins. Our contribution refers to an approach that improves the reconstruction quality of non-sparse volumes when there exists a sparse combination of these volumes. This is achieved through a joint reconstruction of the mask and contrast volumes via \(l_1\)-minimization of sparse priors. These ideas were further explored to address three-dimensional reconstruction in interventional radiology in [30] through a regularized extension of the iterative filtered backprojection algorithm. To this end the conventional TV-norm was replaced from a new sparsity constraint that relies on the \(l_1\)-minimization-norm and the positivity constraint. The use of such a constraint allows for removing most of the subsampling artifacts while preserving background structures.

6.2. Matching/Segmentation

**Participants:** Haithem Boussaid, Iasonas Kokkinos, Chaohui Wang, Bo Xiang, Ahmet Besbes, Ben Glocker, Nikos Komodakis, Nikos Paragios.

- **Rapid Deformable Part Model Detection:** in [27] we introduce a Branch-and-Bound technique which efficiently finds the most promising configuration of a pictorial structure model given an image. The fastest previously known techniques are linear in the image size; our technique has a best-case complexity that is logarithmic in the image size. When evaluated on standard datasets (Pascal benchmark) our technique gives a 5- to 15-fold speedup. Moreover, when evaluated in the multi-object detection problem our technique’s complexity scales sublinearly also in the number of objects, resulting in 20- to 100- fold speedups when evaluated with 20 object categories.
• **Segmentation with Deformable Graph-based Priors:** In [22] we have introduced a novel formulation to address deformable segmentation using graph-based priors while being able to handle partial-correspondences. Segmentation was formulated as a matching task, where candidate correspondences were determined using boosting, and the assignment problem was solved using MAP inference constrained by a graph-based deformable prior. The notion of missing/erroneous correspondences was introduced in the process leading to state-of-the-art results once compared with prior art in the field. The same prior was used in the context of the segmentation of tagging MR heart images [37]. The main contribution of this paper was the exact estimation of the region-based probability likelihood within a pair-wise MRF through the use of Stokes theorem and integral images.

• **Deformable Model-based 3D reconstruction:** In [23] we introduce a model-based optimization approach to the 3D reconstruction of Femur images using a small set of low-dose X-Ray images. We use a parametric deformable model of the Femur surface and fit it to the acquired data by optimizing its parameters. We incorporate in our optimization criterion multiple aspects of the problem, namely the 3D surface- to 2D plane projection, region-based statistics, and edge-based terms. Our evaluation includes both in vitro and in vivo experiments, where our method is shown to yield promising results, while alleviating the need for time demanding, manual annotations.

• **Pose-invariant Higher Order Graph-based Priors:** In [36] we have introduced a novel method for 3D model inference from 2D images in the absence of camera pose parameters. The method exploits higher (fourth) order priors, which alleviate the need of the estimation of the camera parameters. Furthermore, the proposed formulation couples 3D model inference with 2D correspondences and results on a single shot solution for both problems in the absence of knowledge of the observer internal and external parameters.

6.3. **Fusion/Registration**

**Participants:** Stavros Alchatzidis, Nicolas Honnorat, Fabrice Michel, Aristeidis Sotiras, Chaohui Wang, Alex Bronstein, Michael Bronstein, Christos Davatzikos, Ben Glocker, Nikos Komodakis, Yangming Ou, Dimitris Samaras, Regis Vaillant, Yun Zeng, Nikos Paragios.

• **Intrinsic Dense 3D Surface Matching:** In [38] a probabilistic tracking framework for registering two 3D shape that relies on accurate correspondences between all points across the two frames was proposed. The definition of the matching cost is done using the “uniformization” theory that is combined with regularization terms that enforce spatial and temporal motion consistencies, into a maximum a posteriori (MAP) problem which we approximate using a Markov Random Field (MRF).

• **Optimal Linear Registration:** In [26] we proposed a novel formulation to address linear registration of volumetric images (translation, rotation and scale) that guarantees the optimality of the obtained solution. This was achieved through the approximation of the volumetric data using a sparse representation and the expression of the registration criterion in the form of a difference of convex functions. Cutting plain algorithms in the high-dimensional space were used to provide the optimal solution of the registration problem.

• **Quasi-real Time Registration:** In [21] we proposed a novel message-passing based optimization method to for pair-wise Markov Random Fields models and their applications in medical imaging and computer vision. Such a method was integrated to the deformable registration paradigm introduced in [12]. Such an optimization framework was combined with efficient use of modern architectures (Graphics Processing Units) leading to a speed up of at least one order of magnitude with respect to [12] making quasi real-time deformable registration feasible.

• **Metric Learning:** In [31] we extend prior work on similarity sensitive hashing to address multimodal 3D registration. The method consists of combining invariant to translation/rotation/scale features defined at the Gabor space with a machine learning/boosting method that aims to projection corresponding visual patterns to binary vectors with minimal Hamming distance while maximizing the distance between no corresponding samples.
- **Symmetric Deformable Fusion**: in [9] a novel graph-based formulation combining image and geometric terms was proposed for deformable registration. The method aimed at constraining iconic registration using a set of landmark correspondences that are sparse, do not inherit redundancy and are symmetric. The central idea was to simultaneously deform the target and the source image using two symmetric flows such that the similarity criterion is reaching its lowest potential. This was achieved through the use of composite symmetric deformation fields. This formulation was expressed as a graph-based optimization problem leading to promising experimental results.

- **Deformable registration of gene expression data**: in [28] the combined iconic/geometric registration framework introduced in [9] was extended to deal with gene expression data. Similarity Sensitive Hashing was used to establish costs for landmark correspondences, and a graph-based formulations with unknowns the deformation vectors was adopted for the objective function. Such an idea was extended to deal with combined segmentation/registration approach through an atlas in [29] where subdivision surfaces were considered to represent the deformation grid.

### 6.4. Physiological Modeling & Spatio-Temporal Analysis

**Participants:** Nicolas Honnorat, Sarah Parisot, Stephane Chemouny, Hugues Dufaut, Regis Vaillant, Nikos Paragios.

- **Low Gliomas Brain Map**: in [33] we introduce a graph-based modeling approach towards spatial position interpretation of low gliomas brain tumors. This was achieved through unsupervised clustering from exemplars, where spatial and geometric proximity of tumors were used to determine the strength connectivity of a graph. Towards automatic estimation of the lowest rank graph that is able to express the observed variation of tumors, an LP problem was solved that determines automatically the number of clusters and their centers while associating the training exemplars with them. Promising results that are well aligned with observations from neuro-sciences demonstrate the potentials of the proposed formulation.

- **Coupled Iconic/Geometric Spatio-temporal Segmentation**: in [25] we have introduced a combined elongated structures segmentation/tracking approach that was based on a two-layer graphical model. The image layer was exploiting the visual space and was seeking to minimize a data-driven cost while the geometric layers was seeking to establish temporal correspondences of the deforming structure. These two layers were coupled through a common set of variables acting on the deformation of the control points representing the elongated structure. Guide-wire segmentation [24] and tracking in low signal-to-noise ratio interventional images demonstrated the extreme potentials of our approach.
6. New Results

6.1. Formal verification of compilers and static analyses

6.1.1. The CompCert verified compiler for the C language

**Participants:** Xavier Leroy, Sandrine Blazy [project-team Celtique], Alexandre Pilkiewicz.

In the context of our work on compiler verification (see section 3.3.1), since 2005 we have been developing and formally verifying a moderately-optimizing compiler for a large subset of the C programming language, generating assembly code for the PowerPC, ARM, and x86 architectures [5]. This compiler comprises a back-end part, translating the Cminor intermediate language to assembly and reusable for source languages other than C [4], and a front-end translating the CompCert C subset of C to Cminor. The compiler is mostly written within the specification language of the Coq proof assistant, from which Coq’s extraction facility generates executable Caml code. The compiler comes with a 50000-line, machine-checked Coq proof of semantic preservation establishing that the generated assembly code executes exactly as prescribed by the semantics of the source C program.

This year, we improved the CompCert C compiler in several ways:

- The formal semantics for the CompCert C source language was made executable and turned into a reference interpreter. This interpreter is proved sound and complete with respect to the formal semantics. It makes it possible to animate the semantics on test programs, identifying undefined behaviors and enumerating all possible execution orders. Another application is to provide an experimental validation of the semantics itself.

- The top-level statements of compiler correctness were strengthened. In particular, semantic preservation is shown to hold even in the presence of a non-deterministic execution context. Also, we showed that if the source program goes wrong after performing some input/output actions, the compiled code performs at least these actions before continuing with an arbitrary behavior.

- A new optimization pass, redundant reload optimization, was added, improving performance by up to 10% on the x86 architecture.

- A general annotation mechanism was added to observe the values of local program variables at user-specified program points, such observations being guaranteed to produce the same results in the source code and in the compiled code. These annotations can be used to improve the precision of worst-case execution time (WCET) analysis over the compiled code. They can also provide stronger evidence of traceability for code qualification purposes.

Three versions of the CompCert development were publically released, integrating these improvements: versions 1.8.1 in March, 1.8.2 in April, and 1.9 in August.

In parallel, we continued our collaboration with Jean Souyris, Ricardo Bedin França and Denis Favre-Felix at Airbus. They are conducting an experimental evaluation of CompCert’s usability for avionics software, and studying the regulatory issues (DO-178 certification) surrounding the potential use of CompCert in this context. Preliminary results were reported at the Predictability and Performance in Embedded Systems workshop [20]. More detailed results will be presented at the 2012 Embedded Real-Time Software and Systems conference (ERTS’12) [19].

6.1.2. Formal specification and verified compilation of C++

**Participants:** Tahina Ramananandro, Gabriel Dos Reis [Texas A&M University], Xavier Leroy.
This year, under Xavier Leroy’s supervision and with precious C++ advice from Gabriel Dos Reis, Tahina Ramananandro tackled the issue of formally specifying object construction and destruction in multiple-inheritance languages, especially the C++ flavour featuring non-virtual and virtual inheritance (allowing repeated and shared base class subobjects), and also structure array fields. This formalization consists in specifying, in Coq, a small-step operational semantics for a subset of C++ featuring multiple inheritance, static and dynamic casts, field accesses, and object construction and destruction, and mechanically proving properties about resource management, thus obtaining a formal account of the RAII (Resource Acquisition is Initialization) principle. Moreover, this formalization also studies the impact of object construction and destruction on the behaviour of dynamic operations such as virtual function dispatch, introducing the notion of generalized dynamic type. These results were accepted for publication at the POPL 2012 symposium [29].

Finally, this formalization includes a verified realistic compiler for this subset of C++ to a CFG-style 3-address intermediate language featuring low-level memory accesses in the style of the CompCert RTL language. Following usual compilation schemes and techniques inspired from the Common Vendor ABI for Itanium (which has since been reused and adapted by GNU GCC), the target language additionally features virtual tables to model object-oriented features, and virtual table tables to model the generalized dynamic type changes during object construction and destruction. This verified compiler reuses and extends the results of a previous work on verified C++ object layout by Tahina Ramananandro, Gabriel Dos Reis and Xavier Leroy published this year at the POPL 2011 symposium [28].

6.1.3. Validation of polyhedral optimizations

Participants: Alexandre Pilkiewicz, François Pottier.

The polyhedral representation of loop nests with affine bounds is a unified way to compute and represent a large set of optimizations, including loop fusion, skewing, splitting, peeling, tilling etc. Polyhedral optimizers usually rely on heavily optimized C tools and libraries to manipulate polyhedrons. Those C libraries are, like any other programs, bug prone, which can easily lead to erroneous optimizations.

Those two facts—powerful yet error prone—make the formal proof of such optimizations appealing. Proving a full optimizer however would probably be unrealistic: the proof would be terribly challenging, but even writing in Coq an optimizer efficient enough to handle non trivial loop nest might be impossible.

Another option is to write and prove in Coq a validator: after each run of the unproved optimizer—considered as a black box—the validator is used to compare the program before and after optimization to make sure that its semantics—the meaning of the program—has not been change. If the validator does not report an error, we have formal certitude that no bug has been introduced by the optimization.

Alexandre Pilkiewicz, under François Pottier’s supervision, has implemented and proved in Coq such a validator.

6.1.4. A formally-verified parser for CompCert

During a 6-month Master’s internship (M2), Jacques-Henri Jourdan built a formally-verified parser for the C99 language. This parser was obtained through a general method for checking that an LR(1) parser produced by the parser generator Menhir is correct and complete, that is, it conforms exactly to the specification represented by the context-free grammar. This check is carried out by a validator that is implemented in Coq and proved correct, so that, in the end, there is no need to trust Menhir. A paper describing this work was accepted for presentation at the ESOP 2012 conference [24].

6.1.5. Formal verification of an alias analysis

Participants: Valentin Robert, Xavier Leroy.
As part of his 5-month Master’s internship, Valentin Robert developed and proved correct a static analysis for pointers and non-aliasing. This alias analysis is intraprocedural and flow-sensitive, and follows the “points-to” approach of Andersen [40]. An originality of this alias analysis is that it is conducted over the RTL intermediate language of the CompCert compiler: since RTL is essentially untyped, the traditional approaches to field sensitivity do not apply, and are replaced by a simple but effective tracking of the numerical offsets of pointers with respect to their base memory blocks. Using the Coq proof assistant and techniques inspired from abstract interpretation, Valentin Robert proved the soundness of his alias analysis against the operational semantics of RTL.

6.2. Type systems

6.2.1. A type-and-capability calculus with hidden state

Participants: François Pottier, Jan Schwinghammer [Saarland University, Saarbrücken], Lars Birkedal [IT University of Copenhagen], Bernhard Reus [University of Sussex, Brighton], Kristian Støvring [University of Copenhagen], Hongseok Yang [University of Oxford].

During the year 2010, François Pottier developed a machine-checked proof of an expressive type-and-capability system. Such a system can be used to type-check and prove properties of imperative ML programs. The proof, which follows a “syntactic” method, is carried out in Coq and takes up roughly 20,000 lines of code. It confirms that earlier publications by Charguéraud and Pottier [1], [7] were indeed correct, offers insights into the design of the type-and-capability system, and provides a firm foundation for further research. In the first half of 2011, François Pottier wrote a paper that describes the system and its proof in detail. This paper has been submitted for publication [37].

Together with Jan Schwinghammer and other co-authors, François Pottier also worked on a (pencil-and-paper) proof of this type-and-capability system. This proof is based on a “semantic” method and is quite different from the proof mentioned in the previous paragraph. It offers somewhat different insights, and proves (for the first time) that the ideas presented in an unpublished note by Pottier (“Generalizing the higher-order frame and anti-frame rules”, 2009) were correct. A paper that describes this proof has been submitted for publication [39].

6.2.2. Fine-grained static control of side effects in HaMLet

Participants: Jonathan Protzenko, François Pottier.

In the past ten years, the type systems community and the separation logic community, among others, have developed highly expressive formalisms for describing ownership policies and controlling side effects in imperative programming languages. In spite of this extensive knowledge, it remains very difficult to come up with a programming language design that is simple, effective (it actually controls side effects!) and expressive (it does not force programmers to alter the design of their data structures and algorithms). Jonathan Protzenko and François Pottier have recently made significant progress on this topic. They are designing a programming language, tentatively called HaMLet, in the tradition of ML and Caml-Light. The language offers immutable and mutable algebraic data structures and first-class functions. It allows very fine-grained control of ownership and side effects. The project is still at a preliminary stage and no publications have appeared yet.

6.2.3. Partial type inference with first-class polymorphism

Participants: Didier Rémy, Boris Yakobowski [CEA, LIST laboratory], Gabriel Scherer.

The language MLF uses optional type annotations of function parameters and instance bounded polymorphism—quantification over all types that are instances of a given type—to smoothly combine the simple type inference mechanism of ML with the expressive types of System F. In MLF, programs need only type annotations on parameters of functions that are used polymorphically in their body.

While the surface language requires just these very few type annotations, MLF also comes with an internal language, called xMLF, where all type manipulations become explicit so that they it can traced during program transformations and symbolic evaluation. The internal language is described in a journal paper [13].
Gabriel Scherer has maintained and improved a prototype implementation of MLF including the elaboration of MLF into xMLF and an extension to higher-order types.

6.2.4. First-class module systems

Participants: Benoît Montagu [University of Pennsylvania], Didier Rémy, Gabriel Scherer.

Singleton kinds are used to handle type definitions in modules. They accurately model the propagation of type definitions through higher-order functor applications. However, type equivalence in the presence of singleton types is hard to formalize and to implement. In his PhD dissertation [48], Benoît Montagu has proposed a new way of checking equivalence in the presence of singleton types, based on expansors. Expansors are eta-expansion constants that are inserted in the source program in such a way that equivalence of two programs becomes equality of their normal forms after insertion of expansors. This approach was described in an article to be submitted to a conference.

Since October, Gabriel Scherer has been working on mixin modules. Mixin modules are an attractive generalization of modules with horizontal composition, a mechanism that allows more flexible construction of modules.

Gabriel Scherer has been studying whether the use of open existential types introduced earlier by Benoît Montagu for first-class modules can be used to simplify the presentation of mixin modules, hoping that they could be given a direct semantics, instead of one by means of elaboration into another language with recursive modules.

6.2.5. Coercion abstraction

Participants: Julien Cretin, Didier Rémy.

Expressive type systems often allow non trivial conversions between types, which may lead to complex, challenging, and sometimes ad hoc type systems. Such examples are the extension of System F with type equalities to model GADT and type families of Haskell, or the extension of System F with explicit contracts. A useful technique to simplify the meta-theoretical studies of such systems is to make type conversions explicit in terms using “coercions”.

We studied $F^\pi$, a language where all type transformations are represented as coercions. This language provides polymorphism as in System F, (upper) bounded polymorphism as in $F_{\leq}$, lower bounded polymorphism as in MLF, and $\eta$-expansion as in $F_\eta$. Hence, $F^\pi$ unifies these four languages in a generic framework.

We showed that $F^\pi$ has a type erasing semantics by bisimulation with the lambda calculus. This means that coercions can be dropped before evaluation without changing the meaning of programs.

This work is described in a paper to be presented at the POPL 2012 conference [21] and in a technical report [33].

6.2.6. Kind-level typing in Haskell

Participants: Julien Cretin, Brent Yorgey [University of Pennsylvania], Stephanie Weirich [University of Pennsylvania], José Pedro Magalhães [Utrecht University], Simon Peyton Jones [Microsoft Research Cambridge], Dimitrios Vytiniotis [Microsoft Research Cambridge].

Haskell is a functional programming language with a rich static type system. Programmers use advanced type features to enforce invariants over data structures. This quickly leads to the need for computation in types. Until now, computation at the type level was untyped in Haskell and therefore prone to errors and hard to debug.

We extended the kind level of Haskell with two features already present at the type level: data types and polymorphism. These features are already well-known at the type level, and should remain easy to understand for programmers at the kind level.

Kind polymorphism is now implemented and used in the core language of the
Glasgow Haskell Compiler (GHC). Promotion of data-types is implemented in a branch of GHC. Both extensions are described in a paper to be presented at the TLDI 2012 workshop [31].

6.3. Software specification and verification

6.3.1. Proved time complexity bounds for program components

Participants: Sylvain Dailler, François Pottier.

During a six-month master internship (M2), Sylvain Dailler extended Arthur Charguéraud’s CFML tool with a notion of “time credit”. This allows CFML to be used to prove not only that an algorithm (or a data structure, or a library) is correct, but also that it meets a desired worst-case asymptotic complexity bound. Because CFML is hosted within Coq, these proofs are machine-checked. Sylvain Dailler was able to establish the functional correctness and the time complexity of a library that implements “bags” as circular doubly-linked lists [35].

6.3.2. Hybrid contract checking via symbolic simplification

Participant: Na Xu.

Program errors are hard to detect or prove absent. Allowing programmers to write formal and precise specifications, especially in the form of contracts, is one popular approach to program verification and error discovery. Na Xu formalized and implemented a hybrid contract checker for a subset of OCaml. The key technique is the use of symbolic simplification, which makes integrating static and dynamic contract checking easy and effective. This technique statically verifies that a function satisfies its contract or blames the function violating the contract. When a contract satisfaction is undecidable, it leaves residual code for dynamic contract checking. A paper describing this result will be presented at the PEPM’2012 conference [30]. A technical report version is also available [34].

6.3.3. Tools for TLA+

Participants: Damien Doligez, Leslie Lamport [Microsoft Research], Stephan Merz [EPI VeriDis], Denis Cousineau [Microsoft Research-INRIA Joint Centre], Markus Kuppe [Microsoft Research-INRIA Joint Centre], Hernán Vanzetto [Microsoft Research-INRIA Joint Centre].

Damien Doligez is head of the “Tools for Proofs” team in the Microsoft-INRIA Joint Centre. The aim of this team is to extend the TLA+ language with a formal language for hierarchical proofs, formalizing the ideas in [45], and to build tools for writing TLA+ specifications and mechanically checking the corresponding formal proofs.

This year, the TLA+ project prepared the release of the third version of the TLA+ tools: the GUI-based TLA Toolbox and the TLA+ Proof System, an environment for writing and checking TLA+ proofs. This new release will add many improvements in terms of efficiency, notably with a system of fingerprints to support incremental development of proofs. It will also bring support for new back-ends based on SMT provers (CVC3, Z3, Yices, VeriT). This extends the range of proof obligations that the system can discharge automatically.

Web site: http://tlaplus.net/.

6.3.4. The Zenon automatic theorem prover

Participant: Damien Doligez.

Damien Doligez continued the development of Zenon, a tableau-based prover for first-order logic with equality and theory-specific extensions. This year, a refactoring of the prover’s architecture was started.

6.4. The Caml language and system

6.4.1. The OCaml system

Participants: Xavier Clerc [team SED], Damien Doligez, Alain Frisch [Lexifi SAS], Jacques Garrigue [University of Nagoya], Fabrice Le Fessant [EPI Asap and OCamlPro start-up company], Jacques Le Normand [Lexifi SAS], Xavier Leroy, Nicolas Pouillard, Pierre Weis [EPI Estime].
This year, we released version 3.12.1 of the OCaml system. This is a minor release that fixes 65 reported bugs and 9 unreported bugs, and introduces 11 small extensions. Damien Doligez acted as release manager for this version.

In parallel, we have been working on the next major release of OCaml. The major innovation is support for generalized algebraic datatypes (GADTs). These non-uniform datatype definitions enable programmers to express some invariants over data structures, and the OCaml type-checker to enforce these invariants. They also support interesting ways of reflecting types into run-time values. GADTs are found in proof assistants such as Coq and in functional languages such as Agda and Haskell. Their integration in OCaml raised delicate issues of partial type inference and principality of inferred types, to which Jacques Garrigue and Jacques Le Normand provided original solutions [43].

Other features in preparation for the next major release include:

- More lightweight first-class modules. Signature annotations over first-class modules can now be omitted when they are determined by the context.
- Better reporting of type errors: shorter but more relevant context is shown; improved tracking of source code locations in modules.
- Improvements in native-code generation, for instance in the case of partial function applications.
- Improvements in the generic hashing primitive and the standard library for hash tables.

### 6.4.2. Customizable unmarshaling for OCaml

**Participants:** Pascal Cuq [CEA LIST], Damien Doligez, Julien Signoles [CEA LIST].

In collaboration with members of the CEA LIST laboratory, Damien Doligez developed a Caml library for treating marshaled data by applying user-specified on-the-fly transformations during the unmarshaling process. This library is used in CEA’s Frama-C software to support marshaling of hash-consed data. The library was presented at the ML workshop [32].

### 6.5. Meta-programming

**Participants:** Nicolas Pouillard, François Pottier.

In an effort to improve meta-programming support (the ability to write programs that manipulate other programs) in programming languages, we have focused first on the issue of binders. Programming with data structures containing binders occurs frequently: from compilers and static analysis tools to theorem provers and code generators, it is necessary to manipulate abstract syntax trees, type expressions, logical formulae, proof terms, etc. All these data structures contain variables and binding constructs.

Nicolas Pouillard, under the supervision of François Pottier, investigated the design of a programming interface for names and binders where the representations of these two types are kept abstract. This interface is sufficiently general to enable a large body of program transformations.

This year, the de Bruijn indices approach has been investigated more in-depth, resulting in a programming interface specialized to safe programming with de Bruijn indices and providing much more precise results than those published in 2010. This work was published at the ICFP 2011 conference [27].

### 6.6. Formal management of package dependencies

**Participants:** Roberto Di Cosmo, Ralf Treinen [University Paris Diderot], Jaap Boender [University Paris Diderot], Pietro Abate [University Paris Diderot], Jerôme Vouillon [University Paris Diderot], Stefano Zacchiroli [University Paris Diderot].

Roberto Di Cosmo’s current main line of research is the study and analysis of large component-based software repositories, in particular GNU/Linux-based distributions. These distributions consists of collections of dozens of thousands of software packages, together with metadata, installation and configuration tools, and a variety of different production processes, involving quality assurance at several levels.
Ensuring quality of software assemblies built using these components is a challenging issue: the simple question of knowing whether a single component can or not be deployed turns out to be NP-complete, and yet industry needs to deploy components all the time.

The research currently conducted within the Mancoosi FP7 european project, coordinated by Roberto Di Cosmo, addresses some of the relevant issues, by elaborating sophisticated deployment algorithms and designing specialised installation and configuration languages targeted at enabling transactional capabilities in the tools used to maintain software assemblies built out of GNU/Linux based distributions.

The results of this project are available at http://www.mancoosi.org/ and include four publications this year: one at the CBSE conference [18], which received an ACM distinguished paper award; one at the FSE conference [23], which received an ACM distinguished artifact award; one in the Science of Computer Programming journal [12]; and one at the workshop on Logics for Component Configuration [22].
3. New Results

3.1. 3D matrix-free $P^1$-exact conservative interpolation

Participants: F. Alauzet [correspondant]

The interpolation stage is a crucial step for time-dependent mesh adaptive simulations. Indeed, if the accuracy of the solution is spoiled during this stage then it is lost for ever. In the past, we have demonstrated the superiority of conservative interpolation for 2D compressible flow simulations. Here, we develop the 3D extension of the method on tetrahedral meshes. The same conclusion arose. The main difficulty was to design a fast, accurate and robust mesh intersection algorithm.

3.2. A changing-topology ALE numerical scheme

Participants: F. Alauzet [correspondant] and G. Olivier

The main difficulty arising in numerical simulations with moving geometries is to handle the displacement of the domain boundaries, i.e., the moving bodies. Only vertices displacement is not sufficient to achieve complex movement such as shear. We proved that the use of edge swapping allows us to achieve such complex displacement. We therefore developed an ALE formulation of this topological mesh modification to preserve the solver accuracy and convergence order [31].

3.3. Advanced boundary layer meshing

Participants: F. Alauzet [correspondant], J. Castelneau, L. Marechal, D. Marcum and A. Loseille

We design a new method to generate structured boundary layer meshes which are mandatory to accurately compute compressible flows a high Reynolds number (several millions). It couple the specification of the optimal boundary layer from the geometry boundary and moving mesh techniques to extrude the boundary layer in an already existing mesh. The main advantage of this approach is its robustness, i.e., at each step of the algorithm we have always a valid mesh.

3.4. Applications du maillage à la cryptographie

Participants: T. Grosges [correspondant], D. Barchiesi, Michael François

3.5. Applications du maillage à l’électromagnétisme et modélisation multi-physiques

Participants: D. Barchiesi [correspondant], T. Grosges, Houman Borouchaki, Laurence Giraud-Moreau, Sameh Kessentini, Anis Chaari

3.6. Automatic decomposition of discretized surfaces for parallel processing

Participants: S.H. Lo, H. Borouchaki [correspondant], P. Laug

Free-form surfaces and industrial surface forms could nowadays be conveniently generated efficiently by laser-based digitizing techniques or from a CAD graphics system. Automatic algorithms are imperative to decompose complex triangulated objects consisting of thousands to millions of nodal points into simpler surface parts for parameterization and parallel processing. Non-manifold complicated discretized objects will be handled and simple closed or open surface parts (manifolds) are retrieved by means of pure topological considerations. Each of the simple surface part, which is topologically equivalent to an open surface, a sphere or a torus will be decomposed by entirely topological operations into n equal pieces based on a specified geometrical criterion such as surface area, Gaussian curvatures or magnitudes of dihedral angles, etc. Cut planes could be conveniently defined normal to the axes of inertia of the object to be decomposed. The cut plane which produces surface parts which best respect the given criterion will be chosen, and the two bisected surfaces will be made as equal as possible by means of some general balancing mechanisms. This procedure could be repeated as often as necessary until sub-surface parts satisfying the given criterion are obtained. Each piece of the decomposed surfaces having an intact topological boundary can then be processed independently in parallel, and all the pieces could be put back together to recover the original object or partially to represent a certain portion of the object [29].

3.7. Construction de maillages de degré 2 – Triangle et tétraèdre P2

Participants: P.L. George [correspondant], H. Borouchaki, P. Laug

There is a need for finite elements of degree 2 or more to solve various P.D.E. problems. This study discusses a method to construct such meshes in the case of triangular element (in the plane or for a surface) or tetrahedral element (in the volume case), restricting at degree 2. This first part considers the planar case and, to begin with, returns to Bézier curves and Bézier triangles of degree 2. In the case of triangles, the relation with Lagrange P2 finite element is shown. Validity conditions are discussed and some invalid elements are shown while proposing a method to correct them. A construction method is then proposed [34].

3.8. Continuous and Discrete Adjoints to the Euler Equations for Fluids

Participants: F. Alauzet [correspondant] and O. Pironneau

Adjoints are used in optimization to speed-up computations, simplify optimality conditions or compute sensitivities. Because time is reversed in adjoint equations with first order time derivatives, boundary conditions and transmission conditions through shocks can be difficult to understand. In this work, we analyzed the adjoint equations that arise in the context of compressible flows governed by the Euler equations of fluid dynamics. We showed that the continuous adjoints and the discrete adjoints computed by automatic differentiation agree numerically; in particular the adjoint is found to be continuous at the shocks and usually discontinuous at contact discontinuities by both [9].

3.9. Goal-oriented anisotropic mesh adaptation for unsteady problems

Participants: F. Alauzet [correspondant], A. Belme and A. Dervieux

We have extended our previous work on goal-oriented mesh adaptation to time dependent simulations. This requires to set up a global fixed point algorithm in which state and adjoint variables problems are solved. The adjoint problem is solved backward in time [24].

3.10. Hessian recovery techniques on isotropic and anisotropic meshes

Participants: M. Picasso, F. Alauzet [correspondant], H. Borouchaki and P.-L. George
Mesh adaptation required the use of second order derivatives, i.e., the Hessian. For second order numerical scheme, the provided numerical solution is only piecewise linear. Consequently, numerical methods are considered to recover second order derivatives, the famous recovery techniques. In this work, we have investigated several methods. Numerical results on 2D and 3D isotropic and anisotropic meshes indicate that the quality of the results is strongly linked to the mesh topology and that no convergence can be insured in general [22].

3.11. High Quality Geometric Meshing of CAD Surfaces

Participants: P. Laug [correspondent], H. Borouchaki

We propose a general scheme of an indirect approach for generating isotropic and anisotropic geometric meshes of a surface constituted by a conformal assembly of parametric patches, based on the concept of metric. The different steps of the scheme are considered and, in particular, the definition of the geometric metric at each point of the surface (internal to a patch, belonging to an interface or boundary curve, or extremity of such a curve) as well as its corresponding induced metric in parametric domains.

Isotropic or anisotropic geometric metrics can locally produce significant size variations (internal to a patch or across interface curves) and can even be discontinuous across the interface curves. The larger the rate of the mesh size variation, the worse is the shape quality of the resulting mesh. To control this size variation, various methodologies based on metric reduction have been proposed in the case of a continuous isotropic metric. We introduce a novel iterative mesh gradation approach for discontinuous metrics. The approach uses a particular metric reduction procedure in order to ensure the convergence of the gradation process. In particular, we show that in the worst case the anisotropic discontinuous geometric metric map is reduced to an isotropic continuous geometric metric map for which the gradation is controlled [27].

3.12. Linéarisation et maillage des surfaces paramétréées

Participants: P. Laug, H. Borouchaki [correspondant], E. Renaut

Nous proposons une méthodologie pour simplifier la paramétrisation des surfaces composées de carreaux paramétrés issues généralement des environnements CAO (conception assistée par ordinateur). Cette nouvelle paramétrisation est définie via la construction d’une triangulation adaptative appelée support pour chaque carreau. L’adaptation est gouvernée par le contrôle de l’écart entre la paramétrisation initiale et celle issue de la triangulation support. Ce support est utilisé pour générer les maillages de ces surfaces selon une approche indirecte, dans laquelle le maillage est généré via les domaines des paramètres. Le support permet de déconnecter le mailleur du système CAO, et en ce sens constitue un outil universel pour le maillage de telles surfaces [19].

3.13. Mesh adaptation for very high-order numerical scheme

Participants: F. Alauzet, A. Loseille [correspondant] and E. Mbinky

In the past, we have demonstrate that multi-scale anisotropic mesh adaptation is a powerful tool to accurately simulate compressible flow problem and to obtain faster convergence to continuous solutions. But, this was limited to second order numerical scheme. Nowadays, numerous teams are working on the development of very high-order numerical scheme (e.g. of third or greater order): Discontinuous Galerkin, Residual Distribution scheme, Spectral method, ...

This work extend interpolation error estimates to higher order numerical solution representation. We have examined the case of third-order accuracy. The first step is to reduce the tri-linear form given by the third order error term into a quadratic form based on the third order derivative. From this local error model, the optimal mesh is exhibited thanks to the continuous mesh framework.

3.14. Méthodes de remaillages adaptatifs pour le formage incrémental de tôles minces

Participants: L. Moreau [correspondant], A. Chrouat, H. Borouchaki
Développement d’une méthode de remaillage adaptatif surfacique 3D permettant de raffiner et déraffiner le maillage localement autour de l’outil sphérique au cours des simulations numériques de formage incrémental.

3.15. Méthodes de remaillages adaptatifs surfacique dans le cadre des simulations numériques d’emboutissage de structure minces

Participants : L. Moreau [correspondant], A. Cherouat, H. Borouchaki
Développement de méthodes de remaillage adaptatif surfacique 3D, développement de méthodes d’interpolation et transfert des champs, interfaçage avec le code EF Abaqus et application sur des exemples concrets de mise en forme de structure métalliques et composites.

3.16. Multi-scale anisotropic mesh adaptation for unsteady problems

Participants : F. Alauzet [correspondant] and G. Olivier
We focused on the extension of the multi-scale anisotropic mesh adaptation to unsteady flows. It leads to the development of a global fixed point mesh adaptation algorithm and space-time error estimates. Moreover, the mesh adaptation methodology has been extended to the case of moving meshes simulations.

3.17. Parallel CAD surface meshing

Participants : P. Laug, H. Borouchaki [correspondant]
A wide range of surfaces can be defined by means of composite parametric surfaces as is the case for most CAD modelers. There are, essentially, two approaches to meshing parametric surfaces: direct and indirect. Popular direct methods include the octree-based method, the advancing-front-based method and the paving-based method working directly in the tridimensional space. The indirect approach consists in meshing the parametric domain and mapping the resulting mesh onto the surface. Using the latter approach, we have proposed a general meshing scheme which consists in discretizing each interface curve and meshing each parametric domain according to the above boundary discretizations. Complex surfaces such as a car engine or a complete aircraft are composed of thousands of patches, and meshing these surfaces using the above sequential scheme can be inefficient. We propose a parallel version of the general meshing scheme while naturally balancing the load to each processor.

3.18. Quelques avancées dans les algorithmes de maillages tétraédriques

Participants : H. Borouchaki, P.-L. George [correspondant], L. Marechal
Le comportement en complexité des algorithmes de triangulation sur les "gros" maillage nous amène à utiliser les algorithmes de renumérotation de type Hilbert qui minimise les défauts de cache. Cette technique est également utilisée comme aide à l’optimisation des "gros" maillages. L’algorithme de renumérotation est multi-cœurs.

Des triangulations de plusieurs dizaines de millions de sommets sont construites en utilisant un "simple" ordinateur. La vitesse d’insertion trole le million de tétraèdre à la seconde.

3.19. Reconstruction de surface 3D à partir d’images numériques 2D

Participants : L. Moreau [correspondant], H. Borouchaki, A. Cherouat
Mise au point d’une méthode d’acquisition de la morphologie du buste féminin, développement d’algorithmes de reconstruction de surface 3D d’un buste féminin à partir de photos numériques dans l’objectif de modéliser le comportement du sein en modes statiques et dynamiques.

3.20. Validité des éléments finis usuels

Participants : H. Borouchaki, P.-L. George [correspondant], P. Laug, L. Marechal
On étudie les conditions assurant la validité géométrique des éléments finis usuels de degré 1 et 2. La formulation éléments finis mme conduisant pas toujours à une conclusion simple, on formule les éléments finis sous leur forme de Bézier. Ceci conduit à exhiber des conditions suffisantes (parfois nécessaires et suffisantes) de validité des éléments, c’est-à-dire de la positivité de leur jacobien. Pour les éléments de degré 2, on donne l’interprétation géométrique de ces conditions. Les éléments étudiés sont le triangle à 3 nœuds, le triangle à 6 nœuds, le quadrilatère à 4 nœuds et les quadrilatères à 8 et 9 nœuds, le tétraèdre à 4 nœuds et le tétraèdre à 10 nœuds puis les hexaèdres à 8, 27 et 20 nœuds.

Le cas du simplexe de dimension quelconque et de degré quelconque est traité.

Quelques remarques sur les maillages de surface de degré 2 indiquent quelques pistes à suivre ou à éviter lors de la construction de tels éléments.

3.21. Visualisation et modification des maillages courbes d’ordre élevé

Participants : J. Castelneau, A. Loseille [correspondant], L. Maréchal
Dans le cadre du projet ILab, des nouveaux algorithmes de visualisation et de modifications interactives des maillages courbes et hybrides ont été développés. En effet, une des principales difficultés dans la génération de maillages courbes reste la visualisation. Il est également nécessaire de disposer d’algorithmes de corrections interactifs car les maillages de surfaces initiaux (de degré 2) sont pour la plupart faux.

4. New Results

4.1. Understanding graph representations

4.1.1. Distributed algorithms without knowledge of global parameters

Participants: Amos Korman, Jean-Sébastien Sereni, Laurent Viennot.

Many fundamental local distributed algorithms are non-uniform, that is, they assume that all nodes know good estimations of one or more global parameters of the network, e.g., the maximum degree $\Delta$ or the number of nodes $n$. In [28], we introduce a rather general technique for transforming a non-uniform algorithm into a uniform one with same asymptotic complexity.

4.1.2. Asymptotic modularity

Participants: Fabien de Montgolfier, Mauricio Soto, Laurent Viennot.

Modularity has been introduced as a quality measure for graph partitioning by Newman and Girvan. It has received considerable attention in several disciplines, especially complex systems. In order to better understand this measure from a graph theoretical point of view, we study in [32], [31] the asymptotic modularity of a variety of graph classes.

4.1.3. Internet Structure

Participants: Fabien de Montgolfier, Mauricio Soto, Laurent Viennot.

In [33], [1], we study the measurement of the Internet according to two graph parameters: treewidth and hyperbolicity.

4.1.4. Multipath Spanners

Participants: Cyril Gavoille, Quentin Godfroy, Laurent Viennot.

Motivated by multipath routing, we introduce in [23], [39] a multi-connected variant of spanners.

4.1.5. $\delta$–hyperbolicity

Participants: Victor Chepoi [CNRS LIF, University of Marseille, France], Feodor Dragan [University of Ohio, USA], Bernard Estrella [CNRS LIF, University of Marseille, France], Michel Habib [CNRS LIAFA, University of Paris Diderot, France], Yann Vaxes [University of Florence, Italy], Yang Xiang [University of Ohio, USA].

$\delta$–Hyperbolic metric spaces have been defined by M. Gromov in 1987 via a simple 4-point condition: for any four points $u, v, w, x$, the two larger of the distance sums $d(u, v) + d(w, x), d(u, w) + d(v, x), d(u, x) + d(v, w)$ differ by at most $2\delta$. They play an important role in geometric group theory, geometry of negatively curved spaces, and have recently become of interest in several domains of computer science, including algorithms and networking. In [5] paper, we study un-weighted $\delta$–hyperbolic graphs. Using the Layering Partition technique, we show that every $n$–vertex $\delta$–hyperbolic graph with $\delta \geq 1/2$ has an additive $O(\delta \log n)$–spanner with at most $O(\delta n)$ edges and provide a simpler, in our opinion, and faster construction of distance approximating trees of $\delta$-hyperbolic graphs with an additive error $O(\delta \log n)$. The construction of our tree takes only linear time in the size of the input graph. As a consequence, we show that the family of $n$–vertex $\delta$–hyperbolic graphs with $\delta \geq 1/2$ admits a routing labeling scheme with $O(\delta \log^2 n)$ bit labels, $O(\delta \log n)$ additive stretch and $O(\log^2 (4\delta))$ time routing protocol, and a distance labeling scheme with $O(\log^2 n)$ bit labels, $O(\delta \log n)$ additive error and constant time distance decoder.
4.1.6. Perfect Phylogeny

4.1.6.1. Perfect Phylogeny Is $NP$–Hard

**Participants:** Michel Habib [CNRS LIAFA, University of Paris Diderot, France], Juraj Stacho [University of Haifa, Israel].

We answer in the affirmative [24], to the question proposed by Mike Steel as a $100$ challenge: “Is the following problem $NP$–hard? Given a ternary phylogenetic $X$-tree $T$ and a collection $Q$ of quartet subtrees on $X$, is $T$ the only tree that displays $Q$?” As a particular consequence of this, we show that the unique chordal sandwich problem is also $NP$–hard.

4.1.6.2. Compatibility of Multi-states Characters

**Participants:** Michel Habib [CNRS LIAFA, University of Paris Diderot, France], Thu-Hien To [CNRS LIAFA, University of Paris Diderot, France].

Perfect phylogeny consisting of determining the compatibility of a set of characters is known to be $NP$–complete. We propose in [25], a conjecture on the necessary and sufficient conditions of compatibility: Given a set $C$ of $r$–states full characters, there exists a function $f(r)$ such that $C$ is compatible if $f$ every set of $f(r)$ characters of $C$ is compatible. According to numerous references, $f(2) = 2$, $f(3) = 3$ and $f(r) \geq r$. Some conjectured that $f(r) = r$ for any $r \geq 2$. In this paper, we present an example showing that $f(4) \geq 5$. Therefore it could be the case that for $r \geq 4$ characters, the problem behavior drastically changes. In a second part, we propose a closure operation for chordal sandwich graphs. The later problem is a common approach of perfect phylogeny.

4.1.7. Graph sandwich

**Participants:** Arnaud Durand [CNRS LIAFA, University of Paris Diderot, France], Michel Habib [CNRS LIAFA, University of Paris Diderot, France].

Graph sandwich problems were introduced by Golumbic et al. (1994) in [12] for DNA physical mapping problems and can be described as follows. Given a property $\Pi$ of graphs and two disjoint sets of edges $E_1$, $E_2$ with $E_1 \subseteq E_2$ on a vertex set $V$, the problem is to find a graph $G$ on $V$ with edge set $E_s$ having property $\Pi$ and such that $E_1 \subseteq E_s \subseteq E_2$. In [8] paper, we exhibit a quasi-linear reduction between the problem of finding an independent set of size $k \geq 2$ in a graph and the problem of finding a sandwich homogeneous set of the same size $k$. Using this reduction, we prove that a number of natural (decision and counting) problems related to sandwich homogeneous sets are hard in general. We then exploit a little further the reduction and show that finding efficient algorithms to compute small sandwich homogeneous sets would imply substantial improvement for computing triangles in graphs.

4.1.8. Diameter of Real-World Undirected Graphs

**Participants:** Pierluigi Crescenzi [University of Florence, Italy], Roberto Grossi [University of Pisa, Italy], Michel Habib [CNRS LIAFA, University of Paris Diderot, France], Lorenzo Lanzi [University of Florence, Italy], Andrea Marino [University of Florence, Italy].

In [16], we propose a new algorithm for computing the diameter of undirected unweighted graphs. Even though, in the worst case, this algorithm has complexity $O(nm)$, where $n$ is the number of nodes and $m$ is the number of edges of the graph, we experimentally show (on almost 200 real-world graphs) that in practice our method works in linear time. Moreover, we show how to extend our algorithm to the case of undirected weighted graphs and, even in this case, we present some preliminary very positive experimental results.

4.1.9. Parsimonious flooding in dynamic graphs

**Participants:** Hervé Baumann [CNRS LIAFA, University of Paris Diderot, France], Pierluigi Crescenzi [University of Florence, Italy], Pierre Fraigniaud [CNRS LIAFA, University of Paris Diderot, France].
An edge-Markovian process with birth-rate \( p \) and death-rate \( q \) generates infinite sequences of graphs \((G_0, G_1, G_2, \ldots)\) with the same node set \([n]\) such that \(G_t\) is obtained from \(G_{t-1}\) as follows: if \( e \not\in E(G_{t-1}) \) then \( e \in E(G_t) \) with probability \( p \), and if \( e \in E(G_{t-1}) \) then \( e \not\in E(G_t) \) with probability \( q \). In \cite{2}, we establish tight bounds on the complexity of flooding in edge-Markovian graphs, where flooding is the basic mechanism in which every node becoming aware of an information at step \( t \) forwards this information to all its neighbors at all forthcoming steps \( t' > t \). These bounds complete previous results obtained by Clementi et al. Moreover, we also show that flooding in dynamic graphs can be implemented in a parsimonious manner, so that to save bandwidth, yet preserving efficiency in term of simplicity and completion time. For a positive integer \( k \), we say that the flooding protocol is \( k \)--active if each node forwards an information only during the \( k \) time steps immediately following the step at which the node receives that information for the first time. We define the reachability threshold for the flooding protocol as the smallest integer \( k \) such that, for any source \( s[n] \), the \( k \)--active flooding protocol from \( s \) completes (i.e., reaches all nodes), and we establish tight bounds for this parameter. We show that, for a large spectrum of parameters \( p \) and \( q \), the reachability threshold is by several orders of magnitude smaller than the flooding time. In particular, we show that it is even constant whenever the ratio \( p/(p + q) \) exceeds \( \log n/n \). Moreover, we also show that being active for a number of steps equal to the reachability threshold (up to a multiplicative constant) allows the flooding protocol to complete in optimal time, i.e., in asymptotically the same number of steps as when being perpetually active. These results demonstrate that flooding can be implemented in a practical and efficient manner in dynamic graphs. The main ingredient in the proofs of our results is a reduction lemma enabling to overcome the time dependencies in edge-Markovian dynamic graphs.

### 4.2. Distributed computational complexities

#### 4.2.1. Local Distributed Decision

**Participants:** Pierre Fraigniaud [CNRS LIAFA, University of Paris Diderot, France], Amos Korman [CNRS LIAFA, University of Paris Diderot, France], David Peleg [Weizmann Institute of Science, Israeli].

Inspired by sequential complexity theory, in \cite{20} we focus on a complexity theory for distributed decision problems. We first study the intriguing question of whether randomization helps in local distributed computing, and to what extent. Our main result provides a sharp threshold for the impact of randomization on decision hereditary problems. In addition, we investigate the impact of non-determinism on local decision, and establish some structural results inspired by classical computational complexity theory. Specifically, we show that non-determinism does help, but that this help is limited, as there exist languages that cannot be decided non-deterministically. Perhaps surprisingly, it turns out that it is the combination of randomization with non-determinism that enables to decide all languages in constant time. Finally, we introduce the notion of local reduction, and establish some completeness results.

#### 4.2.2. Asynchronous Wait-free Decision

**Participants:** Pierre Fraigniaud [CNRS LIAFA, University of Paris Diderot, France], Sergio Rajsbaum [Maths. Institute, University of Mexico, Mexico], Corentin Travers [Technion, Israeli].

In order to capture the core of asynchronous distributed decision model, we address in \cite{22} the \textit{wait-free} model with crash failures. The set of tasks whose input is a pair \((s, t)\) and deciding whether \( t \in \Delta(s) \), i.e. whether \( t \) is a valid output for \( s \), has been proven to be decidable in this model.

#### 4.2.3. Mobile Distributed Decision

**Participants:** Pierre Fraigniaud [CNRS LIAFA, University of Paris Diderot, France], Andrzej Pelc [UQO, University of Quebec, Canada].

In \cite{21}, we partially answer the question of decidability of any language for mobile agents in a 2D environment like telecom networks or robots. It is proven that, for every agent, verifying whether (i) he/she is alone or not and (ii) he/she is able to capture the environment, is associated with the question of pertaining to an equivalence class of a map. A positive answer helps in the non-deterministic decision for any language for mobile agent.
4.2.4. Approximating the Statistics of various Properties in Randomly Weighted Graphs

**Participants:** Yuval Emek [University of Tel Aviv, Israel], Amos Korman [CNRS LIAFA, University of Paris Diderot, France], Yuval Shavitt [University of Tel Aviv, Israel].

In [19], we consider the setting of randomly weighted graphs. Under this setting, weighted graph properties typically become random variables and we are interested in computing their statistical features. Unfortunately, this turns out to be computationally hard for some weighted graph properties albeit the problem of computing the properties per se in the traditional setting of algorithmic graph theory is tractable. For example, there are well known efficient algorithms that compute the diameter of a given weighted graph, yet, computing the expected diameter of a given randomly weighted graph is \#P-hard even if the edge weights are identically distributed. In this paper, we define a family of weighted graph properties and show that for each property in this family, the problem of computing the \( k \)’th moment (and in particular, the expected value) of the corresponding random variable in a given randomly weighted graph \( G \) admits a fully polynomial time randomized approximation scheme (FPRAS) for every fixed \( k \). This family includes fundamental weighted graph properties such as the diameter of \( G \), the radius of \( G \) (with respect to any designated vertex) and the weight of a minimum spanning tree of \( G \).

4.2.5. New bounds for the controller problem

**Participants:** Yuval Emek [University of Tel Aviv, Israel], Amos Korman [CNRS LIAFA, University of Paris Diderot, France].

In [10], we establish two new lower bounds on the message complexity of the controller problem. We first prove a simple lower bound stating that any \((M, W)\)-controller must send \( \Omega(N \log \frac{M}{W+1}) \) messages. Second, for the important case when \( W \) is proportional to \( M \) (this is the common case in most applications), we use a surprising reduction from the (centralized) monotonic labeling problem to show that any \((M, W)\)-controller must send \( \Omega(N \log N) \) messages. In fact, under a long lasting conjecture regarding the complexity of the monotonic labeling problem, this lower bound is improved to a tight \( \Omega(N \log^2 N) \).
In [30], we initiate a systematic study of distributed verification, and give almost tight lower bounds on the running time of distributed verification algorithms for many fundamental problems such as connectivity, spanning connected subgraph, and $s-t$ cut verification. We then show applications of these results in deriving strong unconditional time lower bounds on the hardness of distributed approximation for many classical optimization problems including minimum spanning tree, shortest paths, and minimum cut. Many of these results are the first non-trivial lower bounds for both exact and approximate distributed computation and they resolve previous open questions. Moreover, our unconditional lower bound of approximating minimum spanning tree (MST) subsumes and improves upon the previous hardness of approximation bound of Elkin [STOC 2004] as well as the lower bound for (exact) MST computation of Peleg and Rubinovich [FOCS 1999]. Our result implies that there can be no distributed approximation algorithm for MST that is significantly faster than the current exact algorithm, for any approximation factor. Our lower bound proofs show an interesting connection between communication complexity and distributed computing which turns out to be useful in establishing the time complexity of exact and approximate distributed computation of many problems.

4.3. Peer to Peer Networks Performance

Participants: Fabien Mathieu, François Baccelli.

In [3], we present and discuss possible architectures for P2P systems to manage overlays that try to cope with the underlying network.

In [40], [29], we discuss theoretical performance issues that arise from using “Live Seeding”, a technique that can be employed to leverage the capacity of a P2P/Hybrid Live Streaming Systems by utilizing the capacities of idle peers.

In [38], we propose a new paradigm for P2P networks, where the bandwidth bottleneck is not the access node anymore. This new model is versatile enough to be used in the context of classical networks with congestion control, wireless networks, or semantic networks.

4.4. Fault Tolerance in Distributed Networks

4.4.1. Verification of population protocols

Participants: Hugues Fauconnier, Carole Gallet-Delpo.

In [15], we address the problem of verification by model-checking of the basic population protocol (PP) model of Angluin et al. This problem has received special attention in the last two years and new tools have been proposed to deal with it. We show that the problem can be solved by using the existing model-checking tools, e.g., Spin and Prism. In order to do so, we apply the counter abstraction to get an abstraction of the PP model which can be efficiently verified by the existing model-checking tools. Moreover, this abstraction preserves the correct stabilization property of PP models. To deal with the fairness assumed by the PP models, we provide two new recipes. The first one gives sufficient conditions under which the PP model fairness can be replaced by the weak fairness implemented in Spin. We show that this recipe can be applied to several PP models. In the second recipe, we show how to use probabilistic model-checking and, in particular, Prism to take completely in consideration the fairness of the PP models. The correctness of this recipe is based on existing theorems involving finite discrete Markov chains. An abstract of this paper has been also published in [34].

4.4.2. Failure Detection

Participants: Hugues Fauconnier, Carole Gallet-Delpo.

What does it mean to solve a distributed task? In Paxos, Lamport proposed a definition of solvability in which every process is split into a proposer that submits commands to be executed, an acceptor that takes care of the command execution order, and a learner that receives the outcomes of executed commands. The resulting perspective of computation in which every proposed command can be executed, be its proposer correct or faulty, proved to be very useful when processes take steps on behalf of each other, i.e., in simulations.
Most interesting tasks cannot be solved asynchronously, and failure detectors were proposed to circumvent these impossibilities. Alas, when it comes to solving a task using a failure detector, we cannot leverage simulation-based techniques. A process cannot perform steps of failure detector-based computation on behalf of another process, since it cannot access the remote failure-detector module.

In [17], we propose a new definition of solving a task with a failure detector in which computation processes that propose inputs and provide outputs are treated separately from synchronization processes that coordinate using a failure detector. In the resulting framework, any failure detector is shown to be equivalent to the availability of some $k$-set agreement. As a corollary, we obtain a complete classification of tasks, including ones that evaded comprehensible characterization so far, such as renaming.

Shared objects like atomic register, test-and-set, cmp-and-swap are classical hardware primitives that help to develop fault-tolerant distributed applications. In order to compare shared objects, in [41], we consider their implementations in message passing models. With the minimal failure detector for each object, we get a new hierarchy that has only two levels. This paper summarizes recent works and results on this topic.

In [7], we first define the basic notions of local and non-local tasks for distributed systems. Intuitively, a task is local if, in a system with no failures, each process can compute its output value locally by applying some local function on its own input value (so the output value of each process depends only on the process’ own input value, not on the input values of the other processes); a task is non-local otherwise. All the interesting distributed tasks, including all those that have been investigated in the literature (e.g., consensus, set agreement, renaming, atomic commit, etc.) are non-local.

In this paper we consider non-local tasks and determine the minimum information about failures that is necessary to solve such tasks in message-passing distributed systems. As part of this work, we also introduces weak set agreement—a natural weakening of set agreement—and show that, in some precise sense, it is the weakest non-local task in message-passing systems.

4.4.3. Adversary disagreement and Byzantine agreement

Participants: Hugues Fauconnier, Carole Gallet-Delporte.

At the heart of distributed computing lies the fundamental result that the level of agreement that can be obtained in an asynchronous shared memory model where $t$ processes can crash is exactly $t + 1$. In other words, an adversary that can crash any subset of size at most $t$ can prevent the processes from agreeing on $t$ values. But what about all the other $2^{2^t} - (n + 1)$ adversaries that are not uniform in this sense and might crash certain combination of processes and not others? In [6], we present a precise way to classify all adversaries. We introduce the notion of disagreement power: the biggest integer $k$ for which the adversary can prevent processes from agreeing on $k$ values. We show how to compute the disagreement power of an adversary and derive $n$ equivalence classes of adversaries.

So far, the distributed computing community has either assumed that all the processes of a distributed system have distinct identifiers or, more rarely, that the processes are anonymous and have no identifiers. These are two extremes of the same general model: namely, $n$ processes use $\ell$ different authenticated identifiers, where $1 \leq \ell \leq n$. In [18], we ask how many identifiers are actually needed to reach agreement in a distributed system with $t$ Byzantine processes.

We show that having $3t + 1$ identifiers is necessary and sufficient for agreement in the synchronous case but, more surprisingly, the number of identifiers must be greater than $\frac{n+3t}{2}$ in the partially synchronous case. This demonstrates two differences from the classical model (which has $\ell = n$): there are situations where relaxing synchrony to partial synchrony renders agreement impossible; and, in the partially synchronous case, increasing the number of correct processes can actually make it harder to reach agreement. The impossibility proofs use the fact that a Byzantine process can send multiple messages to the same recipient in a round. We show that removing this ability makes agreement easier: then, $t + 1$ identifiers are sufficient for agreement, even in the partially synchronous model.
4.4.4. Fast and compact self stabilizing verification, computation, and fault detection of an MST

**Participants:** Amos Korman [CNRS LIAFA, University of Paris Diderot, France], Shay Kutten [Technion, Israel], Toshimitsu Masuzawa [Osaka University, Japan].

In [27], we address the impact of optimizing the memory size on the time complexity, and show that this carries at most a small cost in terms of time in the context of MST. Specifically, we present a self stabilizing distributed verification algorithm whose time complexity is $O(\log^2 n)$ in synchronous networks, or $O(\Delta \log^2 n)$ in asynchronous networks, where $\Delta$ denotes the largest degree of a node. More importantly, the memory size at each node remains optimal - $O(\log n)$ bits throughout the execution. This answers an open problem posed by Awerbuch and Varghese (FOCS 1991). We also show that $\Omega(\log n)$ time is necessary if the memory size is restricted to $O(\log n)$ bits, even in synchronous networks. We demonstrate the usefulness of our verification scheme by using it as a module in a new self stabilizing MST construction algorithm. This algorithm has the important property that, if faults occur after the construction ended, they are detected by some nodes within $O(\log^2 n)$ time in synchronous networks, or within $O(\Delta \log^2 n)$ time in asynchronous networks. The rest of the nodes detect within $O(D \log n)$ time, where $D$ denotes the diameter. Moreover, if a constant number of faults occur, then, within the required detection time above, they are detected by some node in the $O(\log n)$ locality of each of the faults. The memory size of the self stabilizing MST construction is $O(\log n)$ bits per node (optimal), and the time complexity is $O(n)$. This time complexity is significantly better than the best time complexity of previous self stabilizing MST algorithms, that was $\Omega(n^2)$ even when using memory of $\Omega(\log^2 n)$ bits, and even without having the above localized fault detection property. The time complexity of previous algorithms that used $O(\log n)$ memory size was $O(n|E|)$.

4.5. Discrete Optimization Algorithms

4.5.1. Estimating Satisfiability

**Participants:** Yacine Boufkhad, Thomas Hugel.

In [4], the problem of estimating the proportion of satisfiable instances of a given CSP (constraint satisfaction problem) can be tackled through weighting. It consists in putting onto each solution a non-negative real value based on its neighborhood in a way that the total weight is at least 1 for each satisfiable instance. We define in this paper a general weighting scheme for the estimation of satisfiability of general CSPs. First we give some sufficient conditions for a weighting system to be correct. Then we show that this scheme allows for an improvement on the upper bound on the existence of non-trivial cores in 3-SAT obtained by Maneva and Sinclair (2008) to 4.419. Another more common way of estimating satisfiability is ordering. This consists in putting a total order on the domain, which induces an orientation between neighboring solutions in a way that prevents circuits from appearing, and then counting only minimal elements. We compare ordering and weighting under various conditions.

4.5.2. Eigenvectors of three term recurrence Toeplitz matrices and Riordan group

**Participant:** Dominique Fortin.

Eigenvalues of tridiagonal (including main) Toeplitz matrices are analytically known under some regular distance to the main diagonal. Any eigenvector may be easily computed then, through a backward process; instead, in [11], we give an analytical form for each component through the reciprocation of the underlied trinomial. More generally, the connection to the Riordan group follows some bilinear iterative process.

4.5.3. Piecewise Convex Maximization problems and algorithms

**Participants:** Dominique Fortin, Ider Tseveendorj.

In [14], we provide a global search algorithm for maximizing a piecewise convex function $F$ over a compact $D$. We propose to iteratively refine the function $F$ at local solution $y$ by a virtual cutting function $p_y(\cdot)$ and to solve
max\{\min \{ F(x) - F(y), p_y(x) \} \mid x \in D \} \text{ instead. We call this function either a patch, when it avoids returning back to the same local solutions, or a pseudo patch, when it possibly yields a better point. It is} \text{ virtual in the sense that the role of cutting constraints is played by additional convex pieces in the objective function. We report some computational results, that represent an improvement on previous linearization based techniques.}

It is well known that maximization of any difference of convex functions could be turned into a convex maximization; in [13], we aim at a piecewise convex maximization problem instead. Despite, it may seem harder, sometimes the dimension may be reduced by 1 and the local search improved by using extreme points of the closure of the convex hull of better points. We show that it is always the case for both binary and permutation problems and give, as such instances, piecewise convex formulations for the maximum clique problem and the quadratic assignment problem.

In [12], we consider mathematical programming problems with the so-called piecewise convex objective functions. A solution method for this interesting and important class of nonconvex problems is presented. This method is based on Newton’s law of universal gravitation, multicriteria optimization and Helly’s theorem on convex bodies. Numerical experiments using well known classes of test problems on piecewise convex maximization, convex maximization as well as the maximum clique problem show the efficiency of the approach.
5. New Results

5.1. New results: geometric control

A first set of new results concerns sub-Riemannian geometry.

- In [3] we continued the study of almost-Riemannian structures, which are rank-varying sub-Riemannian structures locally generated by a number of vector fields equal to the dimension of the ambient manifold. In particular, two-dimensional almost-Riemannian structures are generalized Riemannian structures on surfaces for which local orthonormal frames are Lie bracket generating pair of vector fields that can become collinear. We considered the Carnot–Carathéodory distance canonically associated with an almost-Riemannian structure and studied the problem of Lipschitz equivalence between two such distances on a given compact oriented surface. We analyzed the generic case, allowing in particular for the presence of tangency points, i.e., points where two generators of the distribution and their Lie bracket are linearly dependent. The main result of the paper provides a characterization of the Lipschitz equivalence class of an almost-Riemannian distance in terms of a labeled graph associated with it.

- In [1] we studied nilpotent 2-step, corank 2 sub-Riemannian metrics. Such metrics naturally appear as nilpotent approximations of general sub-Riemannian ones. We exhibited optimal syntheses for these problems. It turns out that in general the cut time is not equal to the first conjugate time but has a simple explicit expression. As a byproduct of this study we proved some smoothness properties of the spherical Hausdorff measure in the case of a generic 6-dimensional, 2-step corank 2 sub-Riemannian metric.

- In [12] we started from the remark that in Carnot–Carathéodory spaces the class of 1-rectifiable sets does not contain smooth non-horizontal curves. We were looking for a new definition of rectifiable sets including non-horizontal curves. We introduced, for any metric space, a new class of curves, called continuously metric differentiable of degree $k$, which are Hölder but not Lipschitz continuous when $k > 1$. Replacing Lipschitz curves by this kind of curves we defined $(\mathcal{H}^k, 1)$-rectifiable sets and showed a density result generalizing the corresponding one in Euclidean geometry. This theorem has been obtained as a consequence of computations of Hausdorff measures along curves, for which we gave an integral formula. In particular, we showed that both spherical and standard Hausdorff measures along curves coincide with a class of dimensioned lengths and are related with an interpolation complexity, for which estimates have already been obtained in Carnot–Carathéodory spaces.

A class of problems for which tracking and motion planning is crucial, is given by the control of unmanned aerial vehicles (UAV). In order to develop improved planning tasks that take into account payload requirements, optimal costs and obstacles avoidance (or no flight zones), it is important to develop reliable and flexible simulators. One such simulator for a UAV ground control station is proposed in [9]. The research focuses on the connection between the UAV trajectories and its sensors. Our proposal includes a module-based description of the architecture of the simulator and is based on a nonlinear model of a fixed wing aircraft.

5.2. New results: quantum control

New results have been obtained for the control of the bilinear Schrödinger equation, with two different approaches.
In [2] we proved an approximate controllability result by finite-dimensional methods, considering the Galerkin approximations. The approach improves the technique that we developed in [40]. The result requires less restrictive non-resonance hypotheses on the spectrum of the uncontrolled Schrödinger operator than those already known. The control operator is not required to be bounded and we are able to extend the controllability result to the density matrices. The proof is based on fine controllability properties of the finite-dimensional Galerkin approximations and allows to get estimates for the $L^1$ norm of the control. The general controllability result is applied to the problem of controlling the rotation of a bipolar rigid molecule confined on a plane by means of two orthogonal external fields.

In [4] we presented a constructive method to control the bilinear Schrödinger equation via two controls. The method is based on adiabatic theory and works if the spectrum of the Hamiltonian admits conical eigenvalue intersections. We provided sharp estimates of the relation between the error and the controllability time. We also showed that for a Hamiltonian of the kind $-\Delta + V_0(x) + u_1 V_1(x) + u_2 V_2(x)$ on a domain of $\mathbb{R}^n$ the eigenvalue intersections are conical generically with respect to $V_0, V_1, V_2$.

5.3. New results: neurophysiology

We gave new contributions to the developing theory of human locomotion modeled through optimal control problems. In this paradigm, the trajectories are assumed to be solutions of an optimal control problem whose cost has to be determined.

- The purpose of [6] has been to analyze the class of optimal control problems defined in this way. We proved strong convergence of their solutions, on the one hand for perturbations of the initial and final points (stability), and on the other hand for perturbations of the cost (robustness).
- In [5] we discussed the modeling of both the dynamical system and the cost to be minimized, and we analyzed the corresponding optimal synthesis. The main results describe the asymptotic behavior of the optimal trajectories as the target point goes to infinity.

In [10] we studied the model of geometry of vision due to Petitot, Citti and Sarti [81]. One of the main features of this model is that the primary visual cortex V1 lifts an image from $\mathbb{R}^2$ to the bundle of directions of the plane. Neurons are grouped into orientation columns, each of them corresponding to a point of this bundle. In this model a corrupted image is reconstructed by minimizing the energy necessary for the activation of the orientation columns corresponding to regions in which the image is corrupted. The minimization process intrinsically defines a hypoelliptic heat equation on the bundle of directions of the plane. In the original model, directions are considered both with and without orientation giving rise respectively to a problem on the group of rototranslations of the plane $SE(2)$ or on the projective tangent bundle of the plane. We provided a mathematical proof of several important facts for this model. We first proved that the model is mathematically consistent only if directions are considered without orientation. We then proved that the convolution of a $L^2(\mathbb{R}^2, \mathbb{R})$ function (e.g. an image) with a 2D Gaussian is generically a Morse function. This fact is important since the lift of Morse functions to the projective tangent bundle of the plane is defined on a smooth manifold. We then provided the explicit expression of the hypoelliptic heat kernel on the projective tangent bundle of the plane in terms of Mathieu functions. Finally, we presented the main ideas of an algorithm which allows to perform image reconstruction on real non-academic images. The algorithm is massively parallelizable and needs no information on where the image is corrupted.

5.4. New results: switched systems

New results on switched systems have been obtained in three directions:

- **Discrete-time systems.** In [14] we dealt with the stability properties of linear discrete-time switched systems with polytopic sets of modes. The most classical and viable way of studying the uniform asymptotic stability of such a system is to check for the existence of a quadratic Lyapunov function. It
is known from the literature that letting the Lyapunov function depend on the time-varying switching parameter improves the chance that a quadratic Lyapunov function exists. The contribution of [14] is twofold. We first proved that under a non-degeneracy assumption the dependence on the switching function can be actually assumed to be linear with no prejudice on the effectiveness of the method. Moreover, we showed that no gain is obtained even if we allow the Lyapunov function to depend on the time. Second, we introduced the notion of eventual accessible sets and we showed that, in the degenerate case, it leads to a relaxation of the LMI conditions to check stability of switched linear systems. As a consequence, equivalence between different notions of quadratic stability can still be established under an additional assumption but, in general, allowing the Lyapunov function to depend on time leads to less conservative LMI conditions, as we explicitly showed through an example. We also discussed the case where the variation of the switching parameter is bounded by a prescribed constant between two subsequent times.

- **Continuous-time systems subject to persistent-excitation.** In [11] we studied linear control systems for which the controlled part can be switched off by a signal subject to a persistent excitation condition. We were interested in the stabilization problem of this system by a linear state feedback and we positively answered a question asked in [41], proving the following: Assume that the class of persistently exciting signals is restricted to those which are \( M \)-Lipschitzian, where \( M > 0 \) is a positive constant. Then, given any \( C > 0 \), there exists a linear state feedback depending on the class of signals under consideration (but not an individual signal) so that the rate of exponential decay of the time-varying system associated with any signal is greater than \( C \).

- **Infinite-dimensional continuous-time systems.** In [13] we partially extended the analysis of finite-dimensional systems subject to persistently exciting signals to the case of systems driven by PDEs. More precisely, we studied the asymptotic stability of a dissipative evolution in a Hilbert space subject to intermittent damping. We observed that, even if the intermittence satisfies a persistent excitation condition, if the Hilbert space is infinite-dimensional then the system needs not being asymptotically stable (not even in the weak sense). Exponential stability is recovered under a generalized observability inequality, allowing for time-domains that are not intervals. Weak asymptotic stability is obtained under a similarly generalized unique continuation principle. Strong asymptotic stability is proved for intermittences that do not necessarily satisfy some persistent excitation condition, evaluating their total contribution to the decay of the trajectories of the damped system. Our results are discussed using the example of the wave equation and the linear Schrödinger equation.
6. New Results

6.1. Mesh Generation and Geometry Processing

6.1.1. Isotropic 2D Quadrangle Meshing with Size and Orientation Control

Participants: Pierre Alliez, Bertrand Pellenard.

In collaboration with Jean-Marie Morvan from University of Lyon.

We propose an approach for automatically generating isotropic 2D quadrangle meshes from arbitrary domains with a fine control over sizing and orientation of the elements. At the heart of our algorithm is an optimization procedure that, from a coarse initial tiling of the 2D domain, enforces each of the desirable mesh quality criteria (size, shape, orientation, degree, regularity) one at a time, in an order designed not to undo previous enhancements. Our experiments demonstrate how well our resulting quadrangle meshes conform to a wide range of input sizing and orientation fields. [31].

Figure 1. The algorithm takes as input a 2D domain, a sizing field and a cross field (not shown). It then operates on a triangle background mesh: The initialization clusters background mesh triangles so that the tiling roughly meets the size and shape criteria; A relaxation then improves the tiling for shape and orientation while preserving size; A conforming relaxation improves the degree of the tiles and the regularity of the tiling; A series of local parameterizations further improves the degrees and regularity; Barycentric subdivision generates a pure quadrangle mesh; Smoothing finally improves the shape of the quadrangles. We depict the conformance both to the sizing and to the cross field.
6.1.2. An Optimal Transport Approach to Robust Reconstruction and Simplification of 2D Shapes

**Participants:** Pierre Alliez, David Cohen-Steiner.

*In collaboration with Fernando de Goes and Mathieu Desbrun from Caltech.*

We propose a robust 2D shape reconstruction and simplification algorithm which takes as input a defect-laden point set with noise and outliers. We introduce an optimal-transport driven approach where the input point set, considered as a sum of Dirac measures, is approximated by a simplicial complex considered as a sum of uniform measures on 0- and 1-simplices. A fine-to-coarse scheme is devised to construct the resulting simplicial complex through greedy decimation of a Delaunay triangulation of the input point set. Our method performs well on a variety of examples ranging from line drawings to grayscale images, with or without noise, features, and boundaries. [25].

![Figure 2. Robustness to noise and outliers. The input shape (3K points) has sharp corners subtending small angles as well as boundaries. Our reconstruction is perfect for a noise-free input (left); as noise is added (middle, 2% and 2.5% of bounding box), the output degrades gracefully, still capturing most of the sharp angles; even after adding 4K or 4.5K outliers and 2% of noise (right), the reconstruction remains of quality, although artifacts start appearing in this regime.](image)

6.1.3. Anisotropic Delaunay Mesh Generation

**Participants:** Jean-Daniel Boissonnat, Mariette Yvinec.

*In collaboration with Camille Wormser from Google.*

Anisotropic meshes are triangulations of a given domain in the plane or in higher dimensions, with elements elongated along prescribed directions. Anisotropic triangulations are known to be well suited for interpolation of functions or solving PDEs. Assuming that the anisotropic shape requirements for mesh elements are given through a metric field varying over the domain, we propose a new approach to anisotropic mesh generation, relying on the notion of anisotropic Delaunay meshes. An anisotropic Delaunay mesh is defined as a mesh in which the star of each vertex $v$ consists of simplices that are Delaunay for the metric associated to vertex $v$. This definition works in any dimension and allows to define a simple refinement algorithm. The algorithm takes as input a domain and a metric field and provides, after completion, an anisotropic mesh whose elements are shaped according to the metric field. [46]

6.1.4. Triangulating Smooth Submanifolds with Light Scaffolding

**Participants:** Jean-Daniel Boissonnat, Arijit Ghosh.
Figure 3. Two examples of anisotropic meshes produced by our algorithm.

We propose an algorithm to sample and mesh a $k$-submanifold $M$ of positive reach embedded in $\mathbb{R}^d$ [45]. The algorithm first constructs a crude sample of $M$. It then refines the sample according to a prescribed parameter $\epsilon$, and builds a mesh that approximates $M$. Differently from most algorithms that have been developed for meshing surfaces of $\mathbb{R}^3$, the refinement phase does not rely on a subdivision of $\mathbb{R}^d$ (such as a grid or a triangulation of the sample points) since the size of such scaffoldings depends exponentially on the ambient dimension $d$. Instead, we only compute local stars consisting of $k$-dimensional simplices around each sample point. By refining the sample, we can ensure that all stars become coherent leading to a $k$-dimensional triangulated manifold $\hat{M}$. The algorithm uses only simple numerical operations. We show that the size of the sample is $O(\epsilon^{-k})$ and that $\hat{M}$ is a good triangulation of $M$. More specifically, we show that $M$ and $\hat{M}$ are isotopic, that their Hausdorff distance is $O(\epsilon^2)$ and that the maximum angle between their tangent bundles is $O(\epsilon)$. The asymptotic complexity of the algorithm is $T(\epsilon) = O(\epsilon^{-k^2-k})$ (for fixed $M$, $d$ and $k$).

6.2. Topological and Geometric Inference

6.2.1. Metric graph reconstruction from noisy data

Participants: Frédéric Chazal, Marc Glisse.

In collaboration with Mridul Aanjaneya, Daniel Chen, Leonidas J. Guibas and Dmitriy Morozov.

Many real-world data sets can be viewed as noisy samples of special types of metric spaces called metric graphs. Building on the notions of correspondence and Gromov-Hausdorff distance in metric geometry, we describe a model for such data sets as an approximation of an underlying metric graph. We present a novel algorithm that takes as an input such a data set, and outputs the underlying metric graph with guarantees. We also implement the algorithm, and evaluate its performance on a variety of real world data sets [26].

6.2.2. Persistence-Based Clustering in Riemannian Manifolds

Participants: Frédéric Chazal, Steve Oudot.

In collaboration with Leonidas J. Guibas and Primoz Skraba.
We introduce a clustering scheme that combines a mode-seeking phase with a cluster merging phase in the corresponding density map. While mode detection is done by a standard graph-based hill-climbing scheme, the novelty of our approach resides in its use of topological persistence to guide the merging of clusters. Our algorithm provides additional feedback in the form of a set of points in the plane, called a persistence diagram (PD), which provably reflects the prominences of the modes of the density. In practice, this feedback enables the user to choose relevant parameter values, so that under mild sampling conditions the algorithm will output the correct number of clusters, a notion that can be made formally sound within persistence theory.

The algorithm only requires rough estimates of the density at the data points, and knowledge of (approximate) pairwise distances between them. It is therefore applicable in any metric space. Meanwhile, its complexity remains practical: although the size of the input distance matrix may be up to quadratic in the number of data points, a careful implementation only uses a linear amount of memory and takes barely more time to run than to read through the input. [29].

6.2.3. Data-driven trajectory smoothing

Participant: Frédéric Chazal.

In collaboration with Daniel Chen, Leonidas J. Guibas, Xiaoye Jiang and Christian Sommer

Motivated by the increasing availability of large collections of noisy GPS traces, we present a new data-driven framework for smoothing trajectory data. The framework, which can be viewed of as a generalization of the classical moving average technique, naturally leads to efficient algorithms for various smoothing objectives. We analyze an algorithm based on this framework and provide connections to previous smoothing techniques. We implement a variation of the algorithm to smooth an entire collection of trajectories and show that it performs well on both synthetic data and massive collections of GPS traces. [28].

6.2.4. A Weighted k-Nearest Neighbor Density Estimate for Geometric Inference

Participants: Frédéric Chazal, David Cohen-Steiner.
Motivated by a broad range of potential applications in topological and geometric inference, we introduce a weighted version of the $k$-nearest neighbor density estimate. Various pointwise consistency results of this estimate are established. We present a general central limit theorem under the lightest possible conditions. In addition, a strong approximation result is obtained and the choice of the optimal set of weights is discussed. In particular, the classical $k$-nearest neighbor estimate is not optimal in a sense described in the manuscript. The proposed method has been implemented to recover level sets in both simulated and real-life data. [12].

6.2.5. Deconvolution for the Wasserstein metric and geometric inference

Participants: Frédéric Chazal, Claire Caillerie.

In collaboration with Jérôme Dedecker and Bertrand Michel

Recently, [17], [13] have defined a distance function to measures to answer geometric inference problems in a probabilistic setting. According to their result, the topological properties of a shape can be recovered by using the distance to a known measure $\nu$, if $\nu$ is close enough to a measure $\mu$ concentrated on this shape. Here, close enough means that the Wasserstein distance $W_2$ between $\mu$ and $\nu$ is sufficiently small. Given a point cloud, a natural candidate for $\nu$ is the empirical measure $\mu_n$. Nevertheless, in many situations the data points are not located on the geometric shape but in the neighborhood of it, and $\mu_n$ can be too far from $\mu$. In a deconvolution framework, we consider a slight modification of the classical kernel deconvolution estimator, and we give a consistency result and rates of convergence for this estimator. Some simulated experiments illustrate the deconvolution method and its application to geometric inference on various shapes and with various noise distributions. [14].

6.2.6. Manifold Reconstruction Using Tangential Delaunay Complexes

Participants: Jean-Daniel Boissonnat, Arijit Ghosh.

We give a new provably correct algorithm to reconstruct a $k$-dimensional manifold embedded in $d$-dimensional Euclidean space [44]. The input to our algorithm is a point sample coming from an unknown manifold. Our approach is based on two main ideas: the notion of tangential Delaunay complex and the technique of sliver removal by weighting the sample points. Differently from previous methods, we do not construct any subdivision of the $d$-dimensional ambient space. As a result, the running time of our algorithm depends only linearly on the extrinsic dimension $d$ while it depends quadratically on the size of the input sample, and exponentially on the intrinsic dimension $k$. This is the first certified algorithm for manifold reconstruction whose complexity depends linearly on the ambient dimension. We also prove that for a dense enough sample the output of our algorithm is ambient isotopic to the manifold and a close geometric approximation of the manifold.

6.2.7. Equating the witness and restricted Delaunay complexes

Participants: Jean-Daniel Boissonnat, Ramsay Dyer, Arijit Ghosh, Steve Oudot.

It is a well-known fact that the restricted Delaunay and witness complexes may differ when the landmark and witness sets are located on submanifolds of Rd of dimension 3 or more. Currently, the only known way of overcoming this issue consists of building some crude superset of the witness complex, and applying a greedy sliver exudation technique on this superset. Unfortunately, the construction time of the superset depends exponentially on the ambient dimension, which makes the witness complex based approach to manifold reconstruction impractical. This work [43] provides an analysis of the reasons why the restricted Delaunay and witness complexes fail to include each other. From this a new set of conditions naturally arises under which the two complexes are equal.

6.2.8. Reconstructing 3D compact sets

Participant: David Cohen-Steiner.

In collaboration with Frédéric Cazals.
Reconstructing a 3D shape from sample points is a central problem faced in medical applications, reverse engineering, natural sciences, cultural heritage projects, etc. While these applications motivated intense research on 3D surface reconstruction, the problem of reconstructing more general shapes hardly received any attention. This paper develops a reconstruction algorithm changing the 3D reconstruction paradigm as follows.

First, the algorithm handles general shapes i.e. compact sets as opposed to surfaces. Under mild assumptions on the sampling of the compact set, the reconstruction is proved to be correct in terms of homotopy type. Second, the algorithm does not output a single reconstruction but a nested sequence of plausible reconstructions. Third, the algorithm accommodates topological persistence so as to select the most stable features only. Finally, in case of reconstruction failure, it allows the identification of under-sampled areas, so as to possibly fix the sampling.

These key features are illustrated by experimental results on challenging datasets (see Figure 5), and should prove instrumental in enhancing the processing of such datasets in the aforementioned applications. [16].

6.3. Data Structures and Robust Geometric Computation

6.3.1. Explicit array-based compact data structures for triangulations

Participant: Olivier Devillers.

In collaboration with Luca Castelli Aleardi (LIX, Palaiseau).

We consider the problem of designing space efficient solutions for representing triangle meshes. Our main result is a new explicit data structure for compactly representing planar triangulations: if one is allowed to permute input vertices, then a triangulation with \( n \) vertices requires at most \( 4n \) references (\( 5n \) references if vertex permutations are not allowed). Our solution combines existing techniques from mesh encoding with a novel use of minimal Schnyder woods. Our approach extends to higher genus triangulations and could be
applied to other families of meshes (such as quadrangular or polygonal meshes). As far as we know, our solution provides the most parsimonious data structures for triangulations, allowing constant time navigation in the worst case. Our data structures require linear construction time, and all space bounds hold in the worst case. We have implemented and tested our results, and experiments confirm the practical interest of compact data structures[47], [35].

6.3.2. Hyperbolic Delaunay triangulations and Voronoi diagrams made practical

**Participants:** Mikhail Bogdanov, Olivier Devillers, Monique Teillaud.

![Figure 6. Hyperbolic Delaunay triangulation and Voronoi diagram in the Poicaré plane.](image)

We show how to compute Delaunay triangulations and Voronoi diagrams of a set of points in hyperbolic space in a very simple way. The algorithm is implemented in an exact and efficient way[34] (see Figure 6).

6.4. Applications

6.4.1. Study of the cosmic web

**Participant:** Monique Teillaud.

*In collaboration with many coauthors: members of the OrbiCG Associate Team (Section 8.3.1.3), Herbert Edelsbrunner (IST Austria, Duke University, and Geomagic Inc.), and others*

We introduce a new descriptor of the weblike pattern in the distribution of galaxies and matter: the scale dependent Betti numbers which formalize the topological information content of the cosmic mass distribution (see Figure 7). While the Betti numbers do not fully quantify topology, they extend the information beyond conventional cosmological studies of topology in terms of genus and Euler characteristic used in earlier analyses of cosmological models. The richer information content of Betti numbers goes along with the availability of fast algorithms to compute them. When measured as a function of scale they provide a “Betti signature” for a point distribution that is a sensitive yet robust discriminator of structure. The signature is highly effective in revealing differences in structure arising in different cosmological models, and is exploited towards distinguishing between different dark energy models and may likewise be used to trace primordial non-Gaussianities. In this study we demonstrate the potential of Betti numbers by studying their behaviour in simulations of cosmologies differing in the nature of their dark energy [48], [41]. This work uses previous results obtained in GEOMETRICA [49], [50].
Figure 7. Four $\alpha$-shapes of a Voronoi filament model realization. It concerns a sample of 200000 particles in a periodic box of 50 $h^3$Mpc size with 8 Voronoi cells. From top left to bottom right:

$\alpha = 0.5 \times 10^4, 1.0 \times 10^4, 2 \times 10^4 and 4.0 \times 10^4$. 
6.5. Software

6.5.1. CGAL

Two major new releases of CGAL, versions 3.8 and 3.9, have been made available in 2011. These releases contain the following new features, involving GEOMETRICA researchers:

- **Generator.** In release 3.8, the package Generator has been extended to provide various point set generators in dimensions higher than 3. It can generate random point sets in/on a sphere, in a cube, and points on a grid [40].

- **Spatial sorting.** Spatial sorting allows to order a set of points to improve the efficiency of incremental randomized algorithms. The spatial sorting package was existing in previous releases, and has been extended to dimensions higher than 3 in release 3.9 [39].

- **3D Mesh Generation.** The mesh generation package was introduced in CGAL 3.5. From release CGAL 3.6, the package offers, after Delaunay refinement, an optional optimization step to either improve the global mesh quality or get rid of slivers. Release CGAL 3.7 includes an interactive demo based on Qt and the code has been optimized for efficiency. Release 3.8 and further [38] offer the possibility to preserve sharp features such as creases and corners when provided in the description of the input domain.

The new release also contains new packages implemented by our CGAL partners and improvements to some existing packages: a detailed list can be found on the CGAL web site.

Two one-week CGAL developers meetings take place each year. The last one, organized in September at INRIA Sophia Antipolis by Mariette Yvinec, gathered 20 participants.
6. New Results

6.1. Multiplicative cascades in real/synthetic oceanographic signals: application to the evaluation of ocean dynamics

Participants: Hussein Yahia, Oriol Pont, Joel Sudre, Véronique Garçon, Claire Pottier [CNES], Antonio Turiel, Christine Provost.

This work is performed during the final year of the HIRESUBCOLOR contract with CNES/NASA. From a fundamental point of view, significant advances have been worked out in the application of complex systems methods for the derivation of new methods for computing ocean dynamics at high spatial resolution (high resolution Sea Surface Temperature, pixel size: 4 x 4 kms). No temporal information is used. Instead, the norms and orientations of low resolution vector fields derived from altimetry and scatterometers are propagated along the scales of turbulent signals. This year, specific study on the propagation of the norm of the vector field has been conducted, resulting in the complete mapping (norm and orientation) of ocean dynamics at the high resolution of Sea Surface Temperature data. Validation is performed by comparison with the output of the ROMS 3D simulation model, with excellent results, and buoy validation is under way. H. Yahia has been invited to the AGU (American Geophysical Union) Fall meeting in San Francisco to make a presentation of HIRESUBCOLOR results (December 5-9 2011) and also to the EGU meeting to be held in Vienna in 2012. In 2011 the complete method for the determination of ocean dynamics has been finalized and it includes:

- the determination of both norm and orientation of the vector fields,
- the propagation along the scale of both geostrophic and ageostrophic dynamics.

These methods are generic, and can be applied to the determination of high resolution information for ocean/atmosphere interaction. For that matter, the Oceanflux proposal has been submitted and accepted, starting November 1, 2011, and a new proposal called MULTICARO will be submitted to CNES-OSTST. Related publications: [28], [21].

6.2. Endocardial potential analysis for cardiac arrhythmias

Participants: Oriol Pont, Hussein Yahia, Harish Kumar Goddabanahalli, Michel Haissaguerre, Nicolas Derval, Méleze Hocini.

Cardiac diseases are the main cause of morbidity and mortality in western countries. Both the pathogenic areas and the evolution of the condition are complex to detect and estimate in the case of arrhythmias, specially in atrial and ventricular fibrillation. In these cases, the dynamics of the cardiac potential behaves chaotically in a highly complex way that challenges its description. Under this context, we are working in the direction of the characterization of the heartbeat dynamics in a model-agnostic way. We have performed analysis of heartbeat dynamics through singularity spectrum, empirical analysis of LPEs for the deart-beat Dynamics, and a novel innovative method to distinguish arrhythmic heartbeat with rhythmic heartbeat has been studied.

Intracardial potential is measured by means of electrode catheters used during the radiofrequency ablation procedure for cases of atrial fibrillation. We have found that in the electric potential signal, a simple fast-changing three-state orientation signal can be sifted from its complex but slow-changing modulation. The fast dynamics experimentally fits a Markovian process which can be described in a simple and compact way and its parameters are robustly estimated. This shows a clear change of signature even with small statistics that can be used to detect transitions in the arrhythmia and identify different regimes in them.

Related publications: [18], [23], [19], [24].
6.3. Phonetic segmentation

Participants: Vahid Khanagha, Joshua Winebarger, Khalid Daoudi, Oriol Pont, Hussein Yahia, Régine André-Obrecht.

Previously we had developed a novel phonetic segmentation method based on Microcanonical Multiscale Formalism (MMF). The algorithm was based on precise computation of Local Predictability Exponents (LPEs) at each point, and then using their integration over time axis (ACC) as a quantitative representative of changes in behavior of distribution of these exponents between neighboring phonemes. The piecewise linear estimation of ACC had provided very good segmentation precision. By performing error analysis of the original algorithm, we proposed a 2-step technique which better exploits LPEs to improve the segmentation accuracy. In the first step, we detect the boundaries of the original signal and of a low-pass filtered version, and we consider the union of all detected boundaries as candidates. In the second step, we use a hypothesis test over the local LPE distribution of the original signal to select the final boundaries. In summary following steps have been taken:

- Detailed error analysis of the original method, which resulted in the realization of the fact that a high-pass filtering can help to detect some of the missed boundaries.
- Development of the hypothesis test method, using the Log Likelihood Ratio Test for final decision over a list of candidates.
- Evaluation of the overall 2-step algorithm on the whole train part of the TIMIT database, to compare with the original method.
- Evaluation on test part of TIMIT database to compare with the state of the art methods.

We continued and improved the adaptation of speaker segmentation methods to develop new (nonlinear) techniques for phonetic segmentation. We succeeded in proposing simple and efficient new algorithms that outperform existing ones. Even with new approaches, our nonlinear approach was still competitive.

6.4. Optimal wavelets, unpredictable points manifold and the emergence of complexity

Participants: Oriol Pont, Hussein Yahia, Suman Maji.

We have found new theoretical developments that link the optimal wavelet description with the information transfer that characterizes the singularity exponents in complex signals. This fact is particularly relevant when there exists a microcanonical cascade as an effective dynamics for the underlying complex system. The implication of this is that under a multiscale hierarchy, the unpredictable set of a signal can be described in terms of its optimal wavelet coefficients and the multiplicative cascade relations between them, easing the information inference or reconstructability between resolution levels.

A new method for the detection of the unpredictable points manifold has been developed, enhancing previous implementations. The algorithm exploits the basic signal symmetries that can be easily verified and has the advantage of not assuming any underlying model. That work is the result of the collaboration between our team and A. Turiel’s team at Institute of Marine Sciences of Barcelona.

Additionally, we have developed a new algorithm that allows for the first time a very robust detection of the optimal wavelet in 2D signals. The main advantage of this new algorithm is that it optimizes the wavelet shape in a totally unconstrained way, therefore not restricting to specific wavelet families.

6.5. Discriminative learning for automatic speaker recognition

Participants: Khalid Daoudi, Reda Jourani, Régine André-Obrecht.
Most of the speaker recognition systems rely on generative learning of Gaussian Mixture Models (GMM). During the last decade, discriminative approaches have been an interesting and valuable alternative to address directly the classification problem. For instance, Support Vector Machines (SVM) combined with GMM supervectors are among state-of-the-art approaches in speaker recognition. Recently a new discriminative approach for multiway classification has been proposed, the Large Margin Gaussian mixture models (LM-GMM). These latter methods have the same advantage as SVM in term of the convexity of the optimization problem to solve. However they differ from SVM because they draw nonlinear class boundaries directly in the input space, and thus no kernel trick is required. We continued our work on investigating simplified versions of LM-GMM for speaker recognition that can handle large scale databases. We developed a new and efficient learning algorithm and evaluated it on NIST-SRE data. The results show that this new algorithm not only outperforms both the original LM-GMM and the traditional GMM, but also outperforms state-of-the-art discriminative methods such as GMM-supervectors SVM.

6.6. A multiscale approach to phase reconstruction for Adaptive Optics

Participants: Suman Kumar Maji, Hussein Yahia, Oriol Pont, Thierry Fusco, Vincent Michau, Joel Sudre.

Atmospheric turbulence in Earth’s atmosphere upper layers plays a fundamental role in limiting the resolution of ground based instruments. These turbulent layers perturbate to a great extent incoming light from outer space. One of the best known solutions to overcome this hurdle is Adapative Optics (AO). It provides real-time compensation by deforming a mirror through a servo-loop, according to phase measurements provided by a wavefront sensor (WFS). We propose and experiment with a new model for phase reconstruction from an acquired subimage of the perturbated phase: instead of reconstructing the phase gradient using conventional methods of AO, we propagate along the scales phase information, from the low resolution of the WFS to higher resolution, using specific wavelet projections that mimic inference along the scales associated to cascading properties of fully developed turbulence.

6.7. Reconstruction of Speech signal from its Unpredictable Points Manifold

Participants: Vahid Khanagha, Khalid Daoudi, Oriol Pont, Hussein Yahia.

Local Predictability Exponents (LPEs) can be used to classify a given signal’s samples according to their predictability. In particular, the Unpredictable Points Manifold, the subset of less predictable points can be formed as the ensemble of points having the least value of singularity exponents. We call these exponents the Local Predictability Exponents since they are computed according to a procedure based on the evaluation of the degree of reconstruction at a given point. We demonstrate in the case of Speech signal that LPEs are key quantities related to predictability in the framework of reconstructible systems: it is possible to reconstruct the whole Speech signal by applying a reconstruction kernel to the UPM. This provides a strong indication of the importance of the UPM, already demonstrated for other types of complex signals. Experiments show that a UPM containing a small number of the points provides very good perceptual reconstruction quality. In summary following steps have been taken:

- Using the LPEs to form the UPM for Speech signal and coping with the implementation issues in particular case of Speech signal.
- Successful reconstruction of Speech signal from the UPM. The performance was measured using objective measures of reconstruction quality.
- Detailed study of geometrical implications of the points in UPM, and proposition of a new multiscale measure, to be used in estimation procedure of exponents, which is more appropriate for speech analysis. In fact, the same quality of reconstruction is achieved with a quite smaller UPM.
- Development of a very simple compression algorithm (8-bit differential nonuniform quantizer) which overperforms the traditional DPCM coding method.

6.8. New upwelling indices from complex system methods

**Participants:** Hussein Yahia, Ayoub Tamim, Khalid Minaoui, Driss Aboutajdine, Véronique Garçon, Joel Sudre.

We started the Volubilis project on the study of upwelling in the Moroccan coast by satellite imaging. A Ph.D. student, Ayoub Tamim, was recruited in January 2011. We organized the kick-off meeting of the project in Rabat from June 6 to June 10 with the presence of all partners (INRIA, LEGOS, FSR and CRTS). A. Tamim implemented a new version of the software CRTS is using to compute an upwelling index. He then joined GEOSTAT (from September 5 to December 15, 2011) where he first constituted a small validation database of SST and Chlorophyll images. He then implemented some algorithms such as Morand index and multiscale entropy. The goal being to define in a first step a coarse segmentation of upwelling regions.

6.9. A detailed analysis of multisensor fusion of moderate resolution imaging spectroradiometer

**Participants:** Harish Kumar Goddabanahalli, Dharmendra Singh, Hussein Yahia.

6. New Results

6.1. Scheduling Strategies and Algorithm Design for Heterogeneous Platforms

6.1.1. Virtual Machine Resource Allocation for Service Hosting on Heterogeneous Distributed Platforms

We proposed algorithms for allocating multiple resources to competing services running in virtual machines on heterogeneous distributed platforms. We developed a theoretical problem formulation, designed algorithms, and compared these algorithms via simulation experiments based in part on workload data supplied by Google. Our main finding is that vector packing approaches proposed in the homogeneous case can be extended to provide high-quality solutions in the heterogeneous case, and combined to provide a single efficient algorithm. We also considered the case when there may be errors in estimates of performance-related resource needs. We provided a resource sharing algorithm and proved that for the single-resource, single-node case, when there is no bound on the error, its performance ratio relative to an omniscient optimal algorithm is \( \frac{2J}{J+1} \), where \( J \) is the number of services. We also provided a heuristic approach for compensating for bounded errors in resource need estimates that performs well in simulation.

6.1.2. Dynamic Fractional Resource Scheduling vs. Batch Scheduling

We finalized this work in which we proposed a novel job scheduling approach for homogeneous cluster computing platforms. Its key feature is the use of virtual machine technology to share fractional node resources in a precise and controlled manner. Other VM-based scheduling approaches have focused primarily on technical issues or extensions to existing batch scheduling systems, while we take a more aggressive approach and seek to find heuristics that maximize an objective metric correlated with job performance. We derived absolute performance bounds and developed algorithms for the online, non-clairvoyant version of our scheduling problem. We further evaluated these algorithms in simulation against both synthetic and real-world HPC workloads and compared our algorithms to standard batch scheduling approaches. We found that our approach improves over batch scheduling by orders of magnitude in terms of job stretch, while leading to comparable or better resource utilization. Our results demonstrated that virtualization technology coupled with lightweight online scheduling strategies can afford dramatic improvements in performance for executing HPC workloads.

6.1.3. Greedy algorithms for energy minimization

This year, we have revisited the well-known greedy algorithm for scheduling independent jobs on parallel processors, with the objective of energy minimization. We have assessed the performance of the online version, as well as the performance of the offline version, which sorts the jobs by non-increasing size before execution. We have derived new approximation factors, as well as examples that show that these factors cannot be improved, thereby completely characterizing the performance of the algorithms.

6.1.4. Energy-aware mappings on chip multiprocessors

This year, in collaboration with Rami Melhem at Pittsburgh University (USA), we have studied the problem of mapping streaming applications that can be modeled by a series-parallel graph, onto a 2-dimensional tiled CMP architecture. The objective of the mapping is to minimize the energy consumption, using dynamic and voltage scaling techniques, while maintaining a given level of performance, reflected by the rate of processing the data streams. This mapping problem turned out to be NP-hard, but we identified simpler instances, whose
optimal solution can be computed by a dynamic programming algorithm in polynomial time. Several heuristics were proposed to tackle the general problem, building upon the theoretical results. Finally, we assessed the performance of the heuristics through comprehensive simulations using the StreamIt workflow suite and various CMP grid sizes.

We are pursuing this work by investigating the routing of communications in chip multiprocessors (CMPs). The goal is to find a valid routing in the sense that the amount of data routed between two neighboring cores does not exceed the maximum link bandwidth while the power dissipated by communications is minimized. Our position is at the system level: we assume that several applications, described as task graphs, are executed on a CMP, and each task is already mapped to a core. Therefore, we consider a set of communications that have to be routed between the cores of the CMP. We consider a classical model, where the power consumed by a communication link is the sum of a static part and a dynamic part, with the dynamic part depending on the frequency of the link. This frequency is scalable and it is proportional to the throughput of the link.

The most natural and widely used algorithm to handle all these communications is XY routing: for each communication, data is first forwarded horizontally, and then vertically, from source to destination. However, if it is allowed to use all Manhattan paths between the source and the destination, the consumed power can be reduced dramatically. Moreover, some solutions may be found while none existed with the XY routing. We have compared XY routing and Manhattan routing, both from a theoretical and from a practical point of view. We considered two variants of Manhattan routing: in single-path routing, only one path can be used for each communication, while multi-paths routing allows to split a communication between different routes. We established the NP-completeness of the problem of finding a Manhattan routing that minimizes the dissipated power, we exhibited the minimum upper bound of the ratio power consumed by an XY routing over power consumed by a Manhattan routing, and finally we performed simulations to assess the performance of Manhattan routing heuristics that we designed.

6.1.5. Power-aware replica placement

We have investigated optimal strategies to place replicas in tree networks, with the double objective to minimize the total cost of the servers, and/or to optimize power consumption. The client requests are known beforehand, and some servers are assumed to pre-exist in the tree. Without power consumption constraints, the total cost is an arbitrary function of the number of existing servers that are reused, and of the number of new servers. Whenever creating and operating a new server has higher cost than reusing an existing one (which is a very natural assumption), cost optimal strategies have to trade-off between reusing resources and load-balancing requests on new servers. We provide an optimal dynamic programming algorithm that returns the optimal cost, thereby extending known results without pre-existing servers. With power consumption constraints, we assume that servers operate under a set of $M$ different modes depending upon the number of requests that they have to process. In practice $M$ is a small number, typically 2 or 3, depending upon the number of allowed voltages. Power consumption includes a static part, proportional to the total number of servers, and a dynamic part, proportional to a constant exponent of the server mode, which depends upon the model for power. The cost function becomes a more complicated function that takes into account reuse and creation as before, but also upgrading or downgrading an existing server from one mode to another. We have shown that with an arbitrary number of modes, the power minimization problem is NP-complete, even without cost constraint, and without static power. Still, we have provided an optimal dynamic programming algorithm that returns the minimal power, given a threshold value on the total cost; it has exponential complexity in the number of modes $M$, and its practical usefulness is limited to small values of $M$. Still, experiments conducted with this algorithm showed that it can process large trees in reasonable time, despite its worst-case complexity.

6.1.6. Reclaiming the energy of a schedule

In this work, we consider a task graph to be executed on a set of processors. We assume that the mapping is given, say by an ordered list of tasks to execute on each processor, and we aim at optimizing the energy consumption while enforcing a prescribed bound on the execution time. While it is not possible to change the allocation of a task, it is possible to change its speed. Rather than using a local approach such as backfilling, we have considered the problem as a whole and studied the impact of several speed variation models on its
complexity. For continuous speeds, we gave a closed-form formula for trees and series-parallel graphs, and we cast the problem into a geometric programming problem for general directed acyclic graphs. We showed that the classical dynamic voltage and frequency scaling (DVFS) model with discrete modes leads to a NP-complete problem, even if the modes are regularly distributed (an important particular case in practice, which we analyzed as the incremental model). On the contrary, the VDD-hopping model leads to a polynomial solution. Finally, we provided an approximation algorithm for the incremental model, which we extended for the general DVFS model.

6.1.7. Workload balancing and throughput optimization
We have investigated the problem of optimizing the throughput of streaming applications for heterogeneous platforms subject to failures. The applications are linear graphs of tasks (pipelines), and a type is associated to each task. The challenge is to map tasks onto the machines of a target platform, but machines must be specialized to process only one task type, in order to avoid costly context or setup changes. The objective is to maximize the throughput, i.e., the rate at which jobs can be processed when accounting for failures. For identical machines, we have proved that an optimal solution can be computed in polynomial time. However, the problem becomes NP-hard when two machines can compute the same task type at different speeds. Several polynomial time heuristics have been designed, and simulation results have demonstrated their efficiency.

6.1.8. Comparing archival policies for BlueWaters
In this work, we focus on the archive system which will be used in the BlueWaters supercomputer. We have introduced two new tape archival policies that can improve tape archive performance in certain regimes, compared to the classical RAIT (Redundant Array of Independent Tapes) policy. The first policy, PARALLEL, still requires as many parallel tape drives as RAIT but pre-computes large data stripes that are written contiguously on tapes to increase write/read performance. The second policy, VERTICAL, writes contiguous data into a single tape, while updating error correcting information on the fly and delaying its archival until enough data has been archived. This second approach reduces the number of tape drives used for every user request to one. The performance of the three RAIT, PARALLEL and VERTICAL policies have been assessed through extensive simulations, using a hardware configuration and a distribution of I/O requests similar to these expected on the BlueWaters system. These simulations have shown that VERTICAL is the most suitable policy for small files, whereas PARALLEL must be used for files larger than 1 GB. We have also demonstrated that RAIT never outperforms both proposed policies, and that a heterogeneous policy mixing VERTICAL and PARALLEL performs 10 times better than any other policy.

6.1.9. Using Virtualization and Job Folding for Batch Scheduling
In this work we study the problem of batch scheduling within a homogeneous cluster. In this context, the problem is that the more processors the job requires the more difficult it is to find an idle slot to run it on. As a consequence the resources are often inefficiently used as some of them remain unallocated in the final schedule. To address this issue we propose a technique called job folding that uses virtualization to reduce the number of processors allocated to a parallel job and thus allows to execute it earlier. Our goal is to optimize the resource use. We propose several heuristics based on job folding and we compare their performance with classical on-line scheduling algorithms as FCFS or backfilling. The contributions of this work are both the design of the job folding algorithms and their performance analysis.

6.1.10. A Genetic Algorithm with Communication Costs to Schedule Workflows on a SOA-Grid
We propose in this work to study the problem of scheduling a collection of workflows, identical or not, on a SOA (Service Oriented Architecture) grid. A workflow (job) is represented by a directed acyclic graph (DAG) with typed tasks. All of the grid hosts are able to process a set of typed tasks with unrelated processing costs and are able to transmit files through communication links for which the communication times are not negligible. The goal of our study is to minimize the maximum completion time (makespan) of the workflows. To solve this problem we propose a genetic approach. The contributions of this paper are both the design of a Genetic Algorithm taking the communication costs into account and its performance analysis.
6.1.11. Checkpointing policies for post-petascale supercomputers

In this work, we provided an analysis of checkpointing strategies for minimizing expected job execution times in an environment that is subject to processor failures. In the case of both sequential and parallel jobs, we gave the optimal solution for exponentially distributed failure inter-arrival times, which, to the best of our knowledge, is the first rigorous proof that periodic checkpointing is optimal. For non-exponentially distributed failures, we developed a dynamic programming algorithm to maximize the amount of work completed before the next failure, which provides a good heuristic for minimizing the expected execution time. Our work considers various models of job parallelism and of parallel checkpointing overhead. We first performed extensive simulation experiments assuming that failures follow Exponential or Weibull distributions, the latter being more representative of real-world systems. The obtained results not only corroborate our theoretical findings, but also show that our dynamic programming algorithm significantly outperforms previously proposed solutions in the case of Weibull failures. We then performed simulation experiments that use failure logs from production clusters. These results confirmed that our dynamic programming algorithm significantly outperforms existing solutions for real-world clusters.

We have also showed an unexpected result: in some cases, when (i) the platform is sufficiently large, and (ii) the checkpointing costs are sufficiently expensive, or the failures are frequent enough, then one should limit the application parallelism and duplicate tasks, rather than fully parallelize the application on the whole platform. In other words, the expectation of the job duration is smaller with fewer processors! To establish this result we have derived and analyzed several scheduling heuristics.

6.1.12. Scheduling parallel iterative applications on volatile resources

In this work we study the efficient execution of iterative applications onto volatile resources. We studied a master-worker scheduling scheme that trades-off between the speed and the (expected) reliability and availability of enrolled workers. A key feature of this approach is that it uses a realistic communication model that bounds the capacity of the master to serve the workers, which requires the design of sophisticated resource selection strategies. The contribution of this work is twofold. On the theoretical side, we assess the complexity of the problem in its off-line version, i.e., when processor availability behaviors are known in advance. Even with this knowledge, the problem is NP-hard. On the pragmatic side, we proposed several on-line heuristics that were evaluated in simulation while a Markovian model of processor availabilities.

We have started this study with the simple case of iterations composed of independent tasks that can execute asynchronously. Then we have investigated a much more challenging scenario, that of a tightly-coupled application whose tasks steadily communicate throughout the iteration. In this latter scenario, if one processor computing some task fails, all the work executed for current iteration is lost, and the computation of all tasks has to be restarted. Similarly, if one processor of the current configuration is preempted, the computation of all tasks is interrupted. Changing the configuration within an iteration becomes a much riskier decision than with independent tasks.

6.1.13. Tiled QR factorization algorithms

In this work, we have revisited existing algorithms for the QR factorization of rectangular matrices composed of $p \times q$ tiles, where $p \geq q$. We target a shared-memory multi-core processor. Within this framework, we study the critical paths and performance of algorithms such as FIBONACCI and GREEDY, and those found within PLASMA. Although neither is optimal, both are shown to be asymptotically optimal for all matrices of size $p = q^2 f(q)$, where $f$ is any function such that $\lim_{q \to \infty} f = 0$. This novel and important complexity result applies to all matrices where $p$ and $q$ are proportional, $p = \lambda q$, with $\lambda \geq 1$, thereby encompassing many important situations in practice (least squares). We provide an extensive set of experiments that show the superiority of the new algorithms for tall matrices.

We have then extended this work to a distributed-memory environment, that corresponds to clusters of multicore processors. These platforms make the present and the foreseeable future of high-performance computing. In the context of a cluster of multicores, in order to minimize the number of inter-processor communications (aka, “communication-avoiding” algorithm), it is natural to consider two-level hierarchical reduction trees
composed of an “inter-node” tree which acts on top of “intra-node” trees. At the intra-node level, we propose a hierarchical tree made of three levels: (0) “TS level” for cache-friendliness, (1) “low level” for decoupled highly parallel inter-node reductions, (2) “coupling level” to efficiently resolve interactions between local reductions and global reductions. Our hierarchical algorithm and its implementation are flexible and modular, and can accommodate several kernel types, different distribution layouts, and a variety of reduction trees at all levels, both inter-cluster and intra-cluster. Numerical experiments on a cluster of multicore nodes (1) confirm that each of the four levels of our hierarchical tree contributes to build up performance and (2) build insights on how these levels influence performance and interact within each other. Our implementation of the new algorithm with the Dague scheduling tool significantly outperforms currently available QR factorization softwares for all matrix shapes, thereby bringing a new advance in numerical linear algebra for petascale and exascale platforms.

### 6.1.14. Scheduling malleable tasks and minimizing total weighted flow

Malleable tasks are jobs that can be scheduled with preemptions on a varying number of resources. In this work, we have focused on the special case of work-preserving malleable tasks, for which the area of the allocated resources does not depend on the allocation and is equal to the sequential processing time. Moreover, we have assumed that the number of resources allocated to each task at each time instant is bounded. Although this study concerns malleable task scheduling, we have shown that this is equivalent to the problem of minimizing the makespan of independent tasks distributed among processors, when the data corresponding to tasks is sent using network flows sharing the same bandwidth.

We have considered both the clairvoyant and non-clairvoyant cases, and we have focused on minimizing the weighted sum of completion times. In the weighted non-clairvoyant case, we have proposed an approximation algorithm whose ratio (2) is the same as in the unweighted non-clairvoyant case. In the clairvoyant case, we have provided a normal form for the schedule of such malleable tasks, and proved that any valid schedule can be turned into this normal form, based only on the completion times of the tasks. We have shown that in these normal form schedules, the number of preemptions per task is bounded by 3 on average. At last, we have analyzed the performance of greedy schedules, and proved that optimal schedules are greedy for a special case of homogeneous instances. We conjecture that there exists an optimal greedy schedule for all instances, which would greatly simplify the study of this problem.

### 6.1.15. Parallelizing the construction of the ProDom database

ProDom is a protein domain family database automatically built from a comprehensive analysis of all known protein sequences. ProDom development is headed by Daniel Kahn (INRIA project-team BAMBOO, formerly HELIX). With the protein sequence databases increasing in size at an exponential pace, the parallelization of MkDom2, the algorithm used to build ProDom, has become mandatory (the original sequential version of MkDom2 took 15 months to build the 2006 version of ProDom).

When protein domain families and protein families are built independently, the result may be inconsistent. In order to solve this inconsistency problem, we designed a new algorithm, MPI_MkDom3, that simultaneously builds a clustering in protein domain families and one in protein families. This algorithm mixes the principles of MP_MkDom2 and that of the building of Hogenom. As a proof of concept, we successfully processed all the sequences included in the April 2010 version of the UniProt database, namely 6 118 869 sequences and 2 194 382 846 amino-acids.

### 6.2. Algorithms and Software Architectures for Service Oriented Platforms

**Participants:** Daniel Balouek, Nicolas Bard, Julien Bigot, Yves Caniou, Eddy Caron, Florent Chuffart, Simon Delamare, Frédéric Desprez, Gilles Fedak, Sylvain Gault, Haiwu He, Cristian Klein, Georges Markmanolis, Adrian Muresan, Christian Pérez, Vincent Pichon, Jonathan Rouzaud-Cornabas, Anthony Simonet, José Saray, Bing Tang.
6.2.1. Parallel constraint-based local search

Constraint Programming emerged in the late 1980’s as a successful paradigm to tackle complex combinatorial problems in a declarative manner. It is somehow at the crossroads of combinatorial optimization, constraint satisfaction problems (CSP), declarative programming language and SAT problems (boolean constraint solvers and verification tools). Up to now, the only parallel method to solve optimization problems being deployed at large scale is the classical branch and bound, because it does not require much information to be communicated between parallel processes (basically: the current bound).

Adaptive Search was proposed by [86], [87] as a generic, domain-independent constraint-based local search method. This meta-heuristic takes advantage of the structure of the problem in terms of constraints and variables and can guide the search more precisely than a single global cost function to optimize, such as for instance the number of violated constraints. A parallelization of this algorithm based on threads realized on IBM BladeCenter with 16 Cell/BE cores show nearly ideal linear speed-ups for a variety of classical CSP benchmarks (magic squares, all-interval series, perfect square packing, etc.).

We parallelized the algorithm using the multi-start approach and realized experiments on the HA8000 machine, an Hitachi supercomputer with a maximum of nearly 16000 cores installed at University of Tokyo, and on the Grid’5000 infrastructure, the French national Grid for the research, which contains 8612 cores deployed on 11 sites distributed in France. Results show that speedups may surprisingly be architecture and problem dependant. Work in progress considers communications between each computing resource, and a new problem (costa) has been tested for its capability to have an exponential distribution of its time to complete on a sequential resolution.

6.2.2. Service Discovery in Peer-to-Peer environments

In 2010 we experimentally validated the scalability of the Spades Based Middleware (SBAM). SBAM is an auto-stabilized P2P middleware designed for the service discovery. The context of this development is the ANR SPADES project (see Section 7.2.2). In 2011, we wanted to guaranty truthfulness of information exchanged between SBAM-agents. In this context, the implementation of an efficient mechanism ensuring quality of large scale service discovery became a challenge. In collaboration with LIP6 team we developed a self stabilized model called CoPIF and we implemented it in SBAM using synchronous message exchange between agents. Indeed, when a node has to read its neighbor states, it sends a message to each and wait all response. Despite the fact that this kind of implementation is expensive, especially on a large distributed data structure, experiment shown that our model implementation stay efficient, even on a huge prefix tree. We use this broadcast mechanism not only to check the truthfulness of the distributed data structure but also to propagate activation of services on the entire SPADES platform. For the end of 2011 and the beginning of 2012 we plan to work on experimental evaluation of a self-stabilization inspired fault tolerance mechanism. We do this through a collaboration with Myriads team at Rennes.

Moreover, in the occasion of demonstration session of IEEE P2P’2011, we introduced the feasibility of multisite resources aggregation, thanks to SBAM, we ran SBAM on up to 200 peers (we generated machine volatility in order to show the self-stabilization) on 50 physical nodes of Grid’5000 to demonstrate the scalability of multi sites, self-stabilization good performance of our P2P middleware SBAM.

6.2.3. Décrypthon

In 2011, The DIET WebBoard (a web interface to manage the Décrypthon Grid through the DIET middleware) only received bugfixes and a few new features: the possibility to use a totally customized command to call the DIET client, improved support for multiprocessor tasks, and a basic support for replication of tasks (possibility to launch “clones” of an important task, in order to increase the probability of having a successful result). We deployed the new versions of the DIET Webboard on the Décrypthon university grid whenever we made changes to it.

In 2011, we started to port the Rhénovia application (a neuron simulation program in Java and python) on the Décrypthon grid.
The “Help cure muscular dystrophy, phase 2” program that we submitted to the world community grid was still in progress, we received large amounts of result files every day. We had to do the sorting of these files, checking, compressing and moving them to a long term storage space on a regular basis. We also made statistics for the internet users: http://graal.ens-lyon.fr/~nbard/WCGStats/. The last update was on 2011 June 27th: 76.67%.

6.2.4. Scheduling Applications with a Complex Structure

Non-predictably evolving applications are applications that change their resource requirements during execution. These applications exist, for example, as a result of using adaptive numeric methods, such as adaptive mesh refinement and adaptive particle methods. Increasing interest is being shown to have such applications acquire resources on the fly. However, current HPC Resource Management Systems (RMSs) only allow a static allocation of resources, which cannot be changed after it started. Therefore, non-predictably evolving applications cannot make efficient use of HPC resources, being forced to make an allocation based on their maximum expected requirements.

In 2011, we have revisited CoORM, an RMS targeting moldable application, and extended it to CoORMv2, an RMS which supports efficient scheduling of non-predictably evolving applications. An application can make “pre-allocations” to specify its peak resource usage. The application can then dynamically allocate resources as long as the pre-allocation is not outgrown. Resources which are pre-allocated but not used, can be filled by other applications. Results show that the approach is feasible and leads to a more efficient resource usage while guaranteeing that resource allocations are always satisfied.

As future work, we plan to extend CoORMv2 for non-homogeneous clusters, for example, for supercomputers that feature a non-homogeneous network. Moreover, we would like to apply the concepts proposed by CoORMv2 to large scale resource managers such as XtreemOS.

6.2.5. High Level Component Model

Most software component models focus on the reuse of existing pieces of code called primitive components. There are however many other elements that can be reused in component-based applications. Partial assemblies of components, well defined interactions between components and existing composition patterns (a.k.a. software skeletons) are examples of such reusable elements. It turns out that such elements of reuse are important for parallel and distributed applications. Therefore, we have designed High Level Component Model (HLCM), a software component model that supports the reuse of these elements thanks to the concepts of hierarchy, genericity and connectors—and in particular the novel concepts of open connection.

In 2011, we have developed two specific implementations of HLCM: L2C for for C++, MPI and CORBA based applications and GLUON++ for CHARM++ based applications in collaboration with Prof. Kale’s team at the University of Illinois at Urbana-Champaign. L2C was used to study how HLCM may simplify the development of domain decomposition applications. GLUON++ was in particular used to study the performance portability of FFT library on various kind of machines. Moreover, on going work includes the study of the benefit of HLCM for MapReduce applications.

6.2.6. Simplifying Code-Coupling in the SALOME platform

The SALOME platform is a generic platform for pre- and post-processing for numerical simulations. It is made of modules which are themselves a set of components. YACS is the module responsible for coupling applications, based on spatial and temporal relationships. The coupling of domain decomposition code, such as the coupling of several instances of Code_Aster, a thermomechanical calculation code from EDF R&D, turns out to be a complex task because of the lack of abstraction of current SALOME model.

In 2011, we have proposed and implemented some extensions to the SALOME model and platform to remove this limitation. The main extension is the ability to express the cloning of a service, which generates also the cloning of connections. The actual semantic of the cloning operation has been specified in function of the nature of the service (sequential, parallel) and of the ports (data or control flow). It has greatly simplified the expression of the coupling of several instances of Code_Aster without generating any measurable overhead at runtime: no more recompilation is needed when varying the number of coupled instances.
6.2.7. Towards Data Desktop Grid

Desktop Grids use the computing, network and storage resources from idle desktop PC's distributed over multiple-LAN’s or the Internet to compute a large variety of resource-demanding distributed applications. While these applications need to access, compute, store and circulate large volumes of data, little attention has been paid to data management in such large-scale, dynamic, heterogeneous, volatile and highly distributed Grids. In most cases, data management relies on ad-hoc solutions, and providing a general approach is still a challenging issue.

We have proposed the BITDEW framework which addresses the issue of how to design a programmable environment for automatic and transparent data management on computational Desktop Grids. BITDEW relies on a specific set of meta-data to drive key data management operations, namely life cycle, distribution, placement, replication and fault-tolerance with a high level of abstraction.

Since July 2010, in collaboration with the University of Sfax, we are developing a data-aware and parallel version of Magik, an application for arabic writing recognition using the BITDEW middleware. We are targeting digital libraries, which require distributed computing infrastructure to store the large number of digitalized books as raw images and at the same time to perform automatic processing of these documents such as OCR, translation, indexing, searching, etc.

In 2011, we have surveyed P2P strategies (replication, erasure code, replica repair, hybrid storage), which provides reliable and durable storage on top of hybrid distributed infrastructures composed of volatile and stable storage. Following this simulation studies, we are implementing a prototype of the Amazon S3 storage on top of BitDew, which will provide reliable storage by using both Desktop free disk space and volunteered remote Cloud storage.

6.2.8. MapReduce programming model for Desktop Grid

MapReduce is an emerging programming model for data-intense application proposed by Google, which has recently attracted a lot of attention. MapReduce borrows from functional programming, where programmer defines Map and Reduce tasks executed on large sets of distributed data. In 2010, we have developed an implementation of the MapReduce programming model based on the BitDew middleware. Our prototype features several optimizations which make our approach suitable for large scale and loosely connected Internet Desktop Grid: massive fault tolerance, replica management, barriers-free execution, latency-hiding optimization as well as distributed result checking. We have presented performance evaluations of the prototype both against micro-benchmarks and real MapReduce applications. The scalability test shows that we achieve linear speedup on the classical WordCount benchmark. Several scenarios involving lagger hosts and host crashes demonstrate that the prototype is able to cope with an experimental context similar to real-world Internet.

In collaboration with the Huazhong University of Science & Technology, we have developed an emulation framework to assess MapReduce on Internet Desktop Grid. We have made extensive comparison on BitDew-MapReduce and Hadoop using Grid5000 which show that our approach has all the properties desirable to cope with an Internet deployment, whereas Hadoop fails on several tests.

In collaboration with the Babes-Bolyai University of Cluj-Napoca, we have proposed a distributed result checker based on the Majority Voting approach. We evaluated the efficiency of our algorithm by computing the aggregated probability with which a MapReduce computation produces an erroneous result.

We have published two chapters in collective books around Cloud and Desktop Grid technologies. The first one, in collaboration with University of Madrid is an introduction to MapReduce and Hadoop, the second one, in collaboration with Virginia Tech is a presentation of two alternative implementations of MapReduce for Desktop Grids: Moon and Bitdew.

6.2.9. SpeQuloS: Providing Quality-of-Service to Desktop Grids using Cloud resources

EDGI is an FP7 European project, following the successful FP7 EDGEs project, whose goal is to build a Grid infrastructure composed of "Desktop Grids", such as BOINC or XtremWeb, where computing resources are
provided by Internet volunteers, and "Service Grids", where computing resources are provided by institutional
Grid such as EGEE, gLite, Unicore and "Clouds systems" such as OpenNebula and Eucalyptus, where
resources are provided on-demand. The goal of the EDGI project is to provide an infrastructure where Service
Grids are extended with public and institutional Desktop Grids and Clouds.

The main limitation with the current infrastructure is that it cannot give any QoS support for applications
running in the Desktop Grid (DG) part of the infrastructure. For example, a public DG system enables clients
to return work-unit results in the range of weeks. Although there are EGEE applications (e.g. the fusion
community’s applications) that can tolerate such a long latency most of the user communities want much
smaller latencies.

In 2011, we have developed the SpeQuloS middleware to solve this critical problem. Providing QoS features
even in Service Grids is hard and not solved yet satisfactorily. It is even more difficult in an environment where
there are no guaranteed resources. In DG systems, resources can leave the system at any time for a long time
or forever even after taking several work-units with the promise of computing them. Our approach is based on
the extension of DG systems with Cloud resources. For such critical work-units the SpeQuloS system is able
to dynamically deploy fast and trustable clients from some Clouds that are available to support the EDGI DG
systems. It takes the right decision about assigning the necessary number of trusted clients and Cloud clients for
the QoS applications. At this stage, the prototype is fully developed and validated. It supports the XtremWeb
and BOINC Desktop Grid and OpenNebula, StratusLab, OpenStack and Amazon EC2 Clouds. The first
versions have been delivered to the EDGI production infrastructure. We have conducted extensive simulations
to evaluate various strategies of Cloud resources provisioning. Results show that SpeQuloS improve the QoS
of BoTs on three aspects: it reduces the makespan by removing the tail effect, it improves the execution
stability and it allows to accurately predicts the BoT completion time.

6.2.10. Performance evaluation and modeling

Simulation is a popular approach to obtain objective performance indicators of platforms that are not at one’s
disposal. It may for example help the dimensioning of compute clusters in large computing centers. In many
cases, the execution of a distributed application does not behave as expected, it is thus necessary to understand
what causes this strange behavior. Simulation provides the possibility to reproduce experiments under similar
conditions. This is a suitable method for experimental validation of a parallel or distributed application.

The tracing instrumentation of a profiling tool is the ability to save all the information about the execution
of an application at run-time. Every scientific application executed computes instructions. The originality of
our approach is that we measure the completed instructions of the application and not its execution time. This
means that if a distributed application is executed on N cores and we execute it again by mapping two processes
per core then we need N/2 cores and more time for the execution time of the application. An execution trace of
an instrumented application can be transformed into a corresponding list of actions. These actions can then be
simulated by SimGrid. Moreover the SimGrid execution traces will contain almost the same data because the
only change is the use of half cores but the same number of processes. This does not affect the number of the
completed instructions so the simulation time does not get increased because of the overhead. The Grid'5000
platform is used for this work and the NAS Parallel Benchmarks are used to measure the performance of the
clusters.

Our main contribution is to propose of a new execution log format that is time-independent. This means
that we decouple the acquisition of the traces from the replay. Furthermore we implemented a trace replay
tool which relies on top of fast, scalable and validated simulation kernel of SimGrid. We proved that this
framework applies for some of the NAS Parallel Benchmarks and we can predict their performance with a
good accuracy. Moreover we are working on further improvements for solving some performance issues with
the rest benchmarks. We plan to apply some new techniques about the instrumentation of the benchmarks
which we have already discussed with people from the performance analysis community and also improve
the trace replay tool in order to improve its accuracy. Finally we did a survey on many different tracing tools
with regards to the requirements of our methodology which includes all the latest provided tools from the
community.
6.2.11. Elastic Scheduling for Functional Workflows

Non-DAG (or functional) workflows are sets of task-graph workflows with non-deterministic transitions between them, that are determined at runtime by special nodes that control the execution flow. In a current work we are focusing on formalizing and evaluating an allocation and scheduling strategy for on-line non-DAG workflows. The goal of this work is to target real-world non-DAG applications and use cloud platforms to perform elastic allocations while keeping cost and stretch fairness constraints.

To address the previous problem we consider each non-DAG workflow as a set of DAG sub-workflows with non-deterministic transitions between them. Whenever an event occurs (a sub-workflow’s execution is completed, a new workflow arrives in the system, a workflow is canceled, etc.) we need to do a rescheduling. The rescheduling strategy considers the currently-running tasks as fixed. Given that the number of events increases proportional to the number of workflows in the system, there is the risk of spending too much time on the scheduling problem and not enough on the workflows themselves. As a result, the scheduling strategy that we will adopt will be a computational inexpensive one, which will give us more room for the number of possible workflows in the system.

This work is currently in the validation step through experimentation with synthetic data. In the near future we will validate against traces of real-world applications that use non-DAG workflows.

6.2.12. Self Adaptive Middleware Deployment

A computer application can be considered as a system of components that exchange information. Each component type has its specific constraints. The application, as a whole, has also its constraints. Deploying an application on a distributed system consist, among other things, to make a mapping between application components and system resources to meet each component constraints, the application constraints, and possibly those set by the the user. Previous work exists on the deployment of middleware, including DIET (with two finished PhD). However, few take into account the issue of redeployment in the event of variation (availability, load, number) of resources. We study this problem of self adaptive deployment of middleware. It consist of achieving an initial deployment, then scrutinizing some changes in the environment, and automatically adjust the deployment (if beneficial) in case of detecting a variation that degrades the performance expected. To do this, we have surveyed the fields of autonomic computing, self adaptive systems and we have defined the different problems that must be solved to achieve this goal. From this, we first define a resource model to represent the physical system, we are to define a model of middleware-based software components, have started the implementation of the resource model to achieve a simulator.

6.2.13. Virtual Machine Placement with Security Requirements

With the number of services using virtualization and clouds growing faster and faster, it is common to mutualize thousands of virtual machines (VMs) within one distributed system. Consequently, the virtualized services, pieces of software and hardware, and infrastructures share the same physical resources. This has given rise to important challenges regarding the security of VMs and the importance of enforcing non-interference between them. Indeed, cross-VM attacks are an important and real world threat. The problem is even worse in the case of adversary users hosted on the same hardware (multi-tenancy). Therefore, the isolation facility within clouds needs to be strong. Furthermore, each user has different adversaries and the placement and scheduling processes need to take these adversaries into account.

First, we have worked on resource model to describe distributed system and application model to describe the composition of virtual machine. Then we have formalize isolation requirements between users, between applications and between virtual machines. We also formalized the redundancy requirement. We have created a simulator that can load our resource model and application model. Using it, we have described the Grid'5000 infrastructure and a Virtual Cluster application. We have formalized and implemented an algorithm that takes into account the requirements and place the application. Work in progress considers using Constraint Satisfaction Problems (CSP) and SAT problems to improve the quality of placement. Moreover, we study the trade-off between performance, security requirements and infrastructure consolidation. This works is part of a project on Cloud Security with Alcatel-Lucent Bell Labs and ENSI de Bourges.
6.2.14. Scheduling for MapReduce Based Applications

After a study of the state of the art regarding scheduling, especially scheduling on grid and clouds and MapReduce application scheduling, experiments were performed over the Grid’5000 and Google/IBM Hadoop platforms. We are now working on improving a previous work by Berlinska and Drozdowski which aims at providing a good static schedule of the Map and Reduce phases. A visualization tool has been developed which draws Gantt charts resulting from Berlinska and Drozdowski’s algorithms as well as from our own scheduling heuristics.

A BlobSeer model is also developed in collaboration with the Kerdata research team that will be used for our next developments.

6.3. Parallel Sparse Direct Solvers and Combinatorial Scientific Computing

Participants: Maurice Brémond, Guillaume Joslin, Johannes Langguth, Jean-Yves L’Excellent, Mohamed Sid-Lakhdar, Bora Uçar.

6.3.1. Parallel computation of entries of the inverse of a sparse matrix

Following last year’s work on computing entries of the inverse of a sparse matrix in a serial, in-core or out-of-core environment, and that was implemented in MUMPS, we have pursued work to address this issue in a parallel environment. In such this case, it has been shown that minimizing the number of operations (or the number of accesses to the factors) and balancing the work between the processors are contradictory objectives. Several ideas have been investigated and implemented in order to deal with this issue and to reach high speed-ups. Experimental results are promising and show good speed-ups on relatively small number of processors (up to 16) when dealing with large blocks of sparse right-hand sides, while we used to experience speed-downs before.

6.3.2. Multithreaded parallelism for the MUMPS solver

Apart from using message-passing, we have in the past only exploited multicore parallelism through threaded libraries (e.g. BLAS: Basic Linear Algebra Subroutines), and a few OpenMP directives. We are currently investigating the combination of this fork-join model with threaded parallelism resulting from the task graph, which, in our context, is a tree. To do so, and in order to also target NUMA architectures, we apply ideas from distributed-memory environments to multithreaded environments. Simulations based on benchmarks followed by a first prototype implementation have validated this approach for some classes of matrices on small numbers of cores. We are currently revisiting this implementation and plan to pursue experiments on larger numbers of cores with larger classes of matrices. This starting work was done in the context of a master thesis and is the object of a starting PhD thesis. In a distributed-memory environments, it will be combined with parallelism based on message passing, where the scalability of the existing communication schemes should also be addressed. Both directions will be followed in order to face the multicore (r)evolution.

6.3.3. Low-rank approximations

Low-rank approximations are commonly used to compress the representation of data structures. The loss of information induced is often negligible and can be controlled. Although the dense internal datastructures involved in a multifrontal method, the so-called frontal matrices or fronts, are full-rank, they can be represented by a set of low-rank matrices. Applying to our context the notion of geometric clustering used by Bebendorf to define hierarchical matrices, we have shown that the efficiency of this representation to reduce the complexity of both the factorization and solve phases strongly depends on how variables are grouped. The proposed approach can be used either to accelerate the factorization and solution phases or to build a preconditioner. The ultimate goal of this work is to extend the features of the MUMPS solver to exploit low-rank properties.

This work, and the work described in the two previous paragraphs are in the context of a collaboration with ENSEEIHT-IRIT and with the partners involved in the MUMPS project (see Section 5.2).
6.3.4. On partitioning problems with complex objectives

Hypergraph and graph partitioning tools are used to partition work for efficient parallelization of many sparse matrix computations. Most of the time, the objective function that is reduced by these tools relates to reducing the communication requirements, and the balancing constraints satisfied by these tools relate to balancing the work or memory requirements. Sometimes, the objective sought for having balance is a complex function of a partition. We mention some important class of parallel sparse matrix computations that have such balance objectives. For these cases, the current state of the art partitioning tools fall short of being adequate. To the best of our knowledge, there is only a single algorithmic framework in the literature to address such balance objectives. We propose another algorithmic framework to tackle complex objectives and experimentally investigate the proposed framework.

6.3.5. On the Use of Cluster-Based Partial Message Logging to Improve Fault Tolerance for MPI HPC Applications

Fault tolerance is becoming a major concern in HPC systems. The two traditional approaches for message passing applications, coordinated checkpointing and message logging, have severe scalability issues. Coordinated checkpointing protocols make all processes roll back after a failure. Message logging protocols log a huge amount of data and can induce an overhead on communication performance. Hierarchical rollback-recovery protocols based on the combination of coordinated checkpointing and message logging are an alternative. These partial message logging protocols are based on process clustering: only messages between clusters are logged to limit the consequence of a failure to one cluster. These protocols would work efficiently only if one can find clusters of processes in the applications such that the ratio of logged messages is very low. We study the communication patterns of message passing HPC applications to show that partial message logging is suitable in most cases. We propose a partitioning algorithm to find suitable clusters of processes given the communication pattern of an application. Finally, we evaluate the efficiency of partial message logging using two state of the art protocols on a set of representative applications.

6.3.6. Integrated data placement and task assignment for scientific workflows in clouds

We consider the problem of optimizing the execution of data-intensive scientific workflows in the Cloud. We address the problem under the following scenario. The tasks of the workflows communicate through files; the output of a task is used by another task as an input file and if these tasks are assigned on different execution sites, a file transfer is necessary. The output files are to be stored at a site. Each execution site is to be assigned a certain percentage of the files and tasks. These percentages, called target weights, are pre-determined and reflect either user preferences or the storage capacity and computing power of the sites. The aim is to place the data files into and assign the tasks to the execution sites so as to reduce the cost associated with the file transfers, while complying with the target weights. To do this, we model the workflow as a hypergraph and with a hypergraph-partitioning-based formulation, we propose a heuristic which generates data placement and task assignment schemes simultaneously. We report simulation results on a number of real-life and synthetically generated scientific workflows. Our results show that the proposed heuristic is fast, and can find mappings and assignments which reduce file transfers, while respecting the target weights.

6.3.7. UMPa: A Multi-objective, multi-level partitioner for communication minimization

We propose a directed hypergraph model and a refinement heuristic to distribute communicating tasks among the processing units in a distributed memory setting. The aim is to achieve load balance and minimize the maximum data sent by a processing unit. We also take two other communication metrics into account with a tie-breaking scheme. With this approach, task distributions causing an excessive use of network or a bottleneck processor which participates to almost all of the communication are avoided. We show on a large number of problem instances that our model improves the maximum data sent by a processor up to 34% for parallel environments with 4, 16, 64 and 256 processing units compared to the state of the art which only minimizes the total communication volume.
6.3.8. A Divisive clustering technique for maximizing the modularity

We present a new graph clustering algorithm aimed at obtaining clusterings of high modularity. The algorithm pursues a divisive clustering approach and uses established graph partitioning algorithms and techniques to compute recursive bipartitions of the input as well as to refine clusters. Experimental evaluation shows that the modularity scores obtained compare favorably to many previous approaches. In the majority of test cases, the algorithm outperformed the best known alternatives. In particular, among 13 problem instances common in the literature, the proposed algorithm improves the best known modularity in 9 cases.

6.3.9. Constructing elimination trees for sparse unsymmetric matrices

The elimination tree model for sparse unsymmetric matrices and an algorithm for constructing it have been recently proposed [Eisenstat and Liu, SIAM J. Matrix Anal. Appl., 26 (2005) and 29 (2008)]. The construction algorithm has a worst case time complexity $O(mn)$ for an $n \times n$ unsymmetric matrix having $m$ nonzeros. We propose another algorithm that has a worst case time complexity of $O(m \log n)$.

6.3.10. Multithreaded clustering for multi-level hypergraph partitioning

Requirements for efficient parallelization of many complex and irregular applications can be cast as a hypergraph partitioning problem. The current-state-of-the art software libraries that provide tool support for the hypergraph partitioning problem are designed and implemented before the game-changing advancements in multi-core computing. Hence, analyzing the structure of those tools for designing multithreaded versions of the algorithms is a crucial task. The most successful partitioning tools are based on the multi-level approach. In this approach, a given hypergraph is coarsened to a much smaller one, a partition is obtained on the the smallest hypergraph, and that partition is projected to the original hypergraph while refining it on the intermediate hypergraphs. The coarsening operation corresponds to clustering the vertices of a hypergraph and is the most time consuming task in a multi-level partitioning tool. We present three efficient multithreaded clustering algorithms which are very suited for multi-level partitioners. We compare their performance with that of the ones currently used in today’s hypergraph partitioners. We show on a large number of real life hypergraphs that our implementations, integrated into a commonly used partitioning library PaToH, achieve good speedups without reducing the clustering quality.

6.3.11. Partitioning, ordering, and load balancing in a hierarchically parallel hybrid linear solver

PDSLin is a general-purpose algebraic parallel hybrid (direct/iterative) linear solver based on the Schur complement method. The most challenging step of the solver is the computation of a preconditioner based on an approximate global Schur complement. We investigate two combinatorial problems to enhance PDSLin’s performance at this step. The first is a multi-constraint partitioning problem to balance the workload while computing the preconditioner in parallel. For this, we describe and evaluate a number of graph and hypergraph partitioning algorithms to satisfy our particular objective and constraints. The second problem is to reorder the sparse right-hand side vectors to improve the data access locality during the parallel solution of a sparse triangular system with multiple right-hand sides. This is needed to eliminate the unknowns associated with the interface in PDSLin. We study two reordering techniques: one based on a postordering of the elimination tree and the other based on a hypergraph partitioning. To demonstrate the effect of these techniques on the performance of PDSLin, we present the numerical results of solving large-scale linear systems arising from numerical simulations of modeling accelerator cavities and of modeling fusion devices.

6.3.12. Experiments on push-relabel-based maximum cardinality matching algorithms for bipartite graphs

We report on careful implementations of several push-relabel-based algorithms for solving the problem of finding a maximum cardinality matching in a bipartite graph and compare them with fast augmenting-path-based algorithms. We analyze the algorithms using a common base for all implementations and compare their relative performance and stability on a wide range of graphs. The effect of a set of known initialization heuristics on the performance of matching algorithms is also investigated. Our results identify a variant of
the push-relabel algorithm and a variant of the augmenting-path-based algorithm as the fastest with proper initialization heuristics, while the push-relabel based one having a better worst case performance.

6.3.13. Towards a scalable hybrid linear solver based on combinatorial algorithms

The availability of large-scale computing platforms comprised of tens of thousands of multicore processors motivates the need for the next generation of highly scalable sparse linear system solvers. These solvers must optimize parallel performance, processor (serial) performance, as well as memory requirements, while being robust across broad classes of applications and systems. In this study, we present a hybrid parallel solver that combines the desirable characteristics of direct methods (robustness) and effective iterative solvers (low computational cost), while alleviating their drawbacks (memory requirements, lack of robustness). We discuss several combinatorial problems that arise in the design of this hybrid solver, present algorithms to solve these combinatorial problems, and demonstrate their impact on a large-scale three-dimensional PDE-constrained optimization problem.
GRAND-LARGE Project-Team

6. New Results

6.1. Communication avoiding algorithms for linear algebra

Participants: Laura Grigori, Simplice Donfack, Amal Khabou, Mathias Jacquelin, Sophie Moufawad.

The focus of this research is on the design of efficient parallel algorithms for solving problems in numerical linear algebra, as solving very large sets of linear equations and large least squares problems, often with millions of rows and columns. These problems arise in many numerical simulations, and solving them is very time consuming.

This research focuses on developing new algorithms for linear algebra problems, that minimize the required communication, in terms of both latency and bandwidth. We have introduced in 2008 two communication avoiding algorithms for computing the LU and QR factorizations, that we refer to as CALU and CAQR (joint work with J. Demmel and M. Hoemmen from U.C. Berkeley, J. Langou from C.U. Denver, and H. Xiang then at INRIA) [6], [9]. Since then, we have also designed a communication avoiding algorithm for rank revealing QR. In addition, we have also extended theoretical lower bounds to sparse Cholesky factorization and identified algorithms that attain these bounds and so minimize communication. The communication avoiding algorithms are now studied by several other groups, including groups at INRIA, and they start being implemented and being available in public libraries as ScaLAPACK.

During 2011, our research has focused on a study of the stability of communication avoiding LU factorization and on its implementation on multicore machines. In [20] we focus on numerical properties of CALU. To decrease the communication required in the LU factorization, CALU uses a new pivoting strategy, referred to as tournament pivoting, that may lead to a different row permutation than the classic LU factorization with partial pivoting. We have further investigated the numerical stability of CALU. The reason to consider CALU is that it does an optimal amount of communication, and asymptotically less than Gaussian elimination with partial pivoting (GEPP), and so will be much faster on platforms where communication is expensive, as shown in previous work. We show that the Schur complement obtained after each step of performing CALU on a matrix A is the same as the Schur complement obtained after performing GEPP on a larger matrix whose entries are the same as the entries of A (sometimes slightly perturbed) and zeros. More generally, the entire CALU process is equivalent to GEPP on a large, but very sparse matrix, formed by entries of A and zeros. Hence we expect that CALU will behave as GEPP and it will be also very stable in practice. In addition, extensive experiments on random matrices and a set of special matrices show that CALU is stable in practice. The upper bound on the growth factor of CALU is worse than of GEPP. However, there are Wilkinson like-matrices for which GEPP has exponential growth factor, but not CALU, and vice-versa.

We present experimental results for random matrices and for a set of special matrices, including sparse matrices, for binary tree based and flat-tree-based CALU. We discuss both the stability of the LU factorization and of the linear solver, in terms of pivot growth and backward errors. The results show that in practice CALU is stable. We present the backward errors measured three ways: by $\|PA - LU\|/\|A\|$, by the normwise backward error $\|Ax - b\|/\|A\|\|x\| + \|b\|$, and by the componentwise backward error (after iterative refinement in working precision). For random matrices, all CALU’s backward errors were at most 1.9 times larger than GEPP’s backward errors. We also tested "special" matrices, including known difficult examples: (1) The ratios of $\|PA - LU\|/\|A\|$ were at most 1 in over 69% of cases (i.e. CALU was at least as stable as GEPP), and always 1.5 or smaller, except for one ratio of 4.3, in which case both backward errors were much smaller than $2^{-53}$ = machine epsilon. (2) The ratios of normwise backward errors were at most 1 in over 53% of cases, and always 1.5 or smaller, except for 5 ratios ranging up to 26, in which cases all backward errors were less than 4x machine epsilon. (3) The ratios of componentwise backward errors were at most 1 in over 52% of cases, and always 3.2 or smaller, except for one ratio of 8.3.
In [30] we design a scheduling algorithm for efficiently executing CALU on multicore architectures. We focus on a tunable scheduling strategy that maintains load balance across cores while also maintaining data locality and low dequeue overhead. To achieve this, we use a strategy that combines static and dynamic scheduling. This approach was shown to be successful on regular mesh computations by V. Kale and B. Gropp. This tunable scheduling strategy allows us to flexibly control the percentage of tasks that can be scheduled dynamically; this gives a knob to control load balancing so that it occurs only at the point in computation when the benefits it provides outweigh the costs it induces. On NUMA machines where remote memory access is costly, the percentage of work scheduled dynamically should be small enough to avoid excessive cache misses, but large enough to keep the cores busy during idle times in the static part.

In this work, we show the effectiveness of this method in the context of already highly-optimized dense matrix factorizations. Our prior work on multi-threaded CALU was based on dynamic scheduling. The algorithm performed well on tall and skinny matrices, but became less scalable on square matrices with increasing numbers of processors. We show that the usage of this scheduling in communication avoiding dense factorization leads to significant performance gains. On a 48 core AMD Opteron NUMA machine, our experiments show that we can achieve up to 64% improvement over a version of CALU that uses fully dynamic scheduling, and up to 30% improvement over the version of CALU that uses fully static scheduling. On a 16-core Intel Xeon machine, our hybrid static/dynamic scheduling approach is up to 8% faster than the version of CALU that uses a fully static scheduling or fully dynamic scheduling. Our algorithm leads to speedups over the corresponding routines for computing LU factorization in well known libraries. On the 48 core AMD NUMA machine, our best implementation is up to 110% faster than MKL, while on the 16 core Intel Xeon machine, it is up to 82% faster than MKL. Our approach also shows significant speedups compared with PLASMA on both of these systems.

6.2. Preconditioning techniques for solving large systems of equations

Participants: Laura Grigori, Riadh Fezzanni, Sophie Moufawad.

A different direction of research is related to preconditioning large sparse linear systems of equations. This research is performed in the context of ANR PETALh project (2011-2012), which follows the ANR PETAL project (2008-2009). It is conducted in collaboration with Frederic Nataf from University Paris 6.

Several highly used preconditioners are for example the incomplete LU factorizations and Schwarz based approaches as used in domain decomposition. Most of these preconditioners are known to have scalability problems. The number of iterations can increase significantly when the size of the problem increases or when the number of independent domains is increased. This is often due to the presence of several low frequency modes that hinder the convergence of the iterative method. To address this problem, we study a different class of preconditioners, called direction preserving or filtering preconditioners. These preconditioners have the property of being identical to the input matrix on a given filtering vector. A judicious choice of the vector allows to alleviate the effect of low frequency modes on the convergence.

We consider in particular two classes of preconditioners. The first preconditioner is an incomplete decomposition that satisfies the filtering property [11]. The nested preconditioner has the same property for a specific vector of all ones. However the construction is different and takes advantage of a nested structure of the input matrix. The previous research on these methods considered only matrices arising from the discretization of PDEs on structured grids, where the matrix has a block tridiagonal structure. This structure imposes a sequential computation of the preconditioner and it is not suitable for the more general case of unstructured grids. Hence, while very efficient, the usage of these preconditioners was very limited. At the beginning of this research we have obtained several theoretical results for these methods that demonstrate their numerical behavior and convergence properties for cases arising from the discretization of PDEs on structured grids [11]. But the main result is the development of a generalized method [48], [46] that has two important properties: it allows the filtering property to be satisfied for any input matrix; the matrix can be reordered such that its computation is highly parallel. Experimental results show that the method is very efficient for certain classes of matrices, and shows good scalability results in terms of both problem size and number of processors.
6.3. Microwave Data Analysis for petaScale computers

Participants: Laura Grigori, Mikolaj Szydlarski, Meisam Shariffy.

In [47] we describe a scalable algorithm for computing an inverse spherical harmonic transform suitable for cluster of multiple CPU-GPUs. We base our implementation on hybrid programming combining MPI and CUDA. We focus our attention on the two major sequential steps involved in the transforms computation, retaining the efficient parallel framework of the original code. We detail optimization techniques used to enhance the performance of the OpenMP/CUDA-based code and compare them with those implemented in the public domain parallel package, S2HAT.

We also present performance comparisons of the multi GPU version and a hybrid, MPI/OpenMP version of the same transform. We find that one NVIDIA Tesla S1070 can accelerate overall execution time of the SHT by as much as 3 times with respect to the MPI/OpenMP version executed on one quad-core processor (Intel Nehalem 2.93 GHz) and, owing to very good scalability of both versions, 128 Tesla cards perform as good as 256 twelve-core processor (AMD Opteron 2.1 GHz).

The work presented here has been performed in the context of the Cosmic Microwave Background simulations and analysis. However, we expect that the developed software will be of more general interest and applicability.

6.4. Innovative linear system solvers for hybrid multicore/GPU architectures

Participant: Marc Baboulin.

The advent of new processor architectures (e.g. multicore, GPUs) requires the rethinking of most of the scientific applications and innovative methods must be proposed in order to take full advantage of current supercomputers [12].

To accelerate linear algebra solvers on current parallel machines, we introduced in public domain libraries a class of solvers based on statistical techniques. A first application concerns the solution of a square linear systems $Ax = b$. We study a random transformation of $A$ that enables us to avoid pivoting and then to reduce the amount of communication [54]. Numerical experiments show that this randomization can be performed at a very affordable computational price while providing us with a satisfying accuracy when compared to partial pivoting. This random transformation called Partial Random Butterfly Transformation (PRBT) is optimized in terms of data storage and flops count. In the solver that we developed, PRBT combined with LU factorization with no pivoting take advantage of the latest generation of hybrid multicore/GPU machines and outperform existing factorization routines from current parallel library MAGMA.

A second application is related to solving symmetric indefinite systems via $LDLT^T$ factorization for which there was no existing parallel implementation in the dense library ScaLAPACK. We developed an efficient and innovative parallel tiled algorithm for solving symmetric indefinite systems on multicore architectures [59] & [1]. This solver avoids pivoting by using a multiplicative preconditioning based on symmetric randomization. This randomization prevents the communication overhead due to pivoting, is computationally inexpensive and requires very little storage. Following randomization, a tiled LDLT factorization is used that reduces synchronization by using static or dynamic scheduling. We compare Gflop/s performance of our solver with other types of factorizations on a current multicore machine and we provide tests on accuracy using LAPACK test cases.

6.5. MILEPOST GCC: machine learning enabled self-tuning compiler

Participant: Grigori Fursin [correspondant].

Tuning compiler optimizations for rapidly evolving hardware makes porting and extending an optimizing compiler for each new platform extremely challenging. Iterative optimization is a popular approach to adapting programs to a new architecture automatically using feedback-directed compilation. However, the large number of evaluations required for each program has prevented iterative compilation from widespread take-up in production compilers. Machine learning has been proposed to tune optimizations across programs systematically but is currently limited to a few transformations, long training phases and critically lacks publicly released, stable tools.
Our approach is to develop a modular, extensible, self-tuning optimization infrastructure to automatically learn the best optimizations across multiple programs and architectures based on the correlation between program features, run-time behavior and optimizations. In this paper we describe MILEPOST GCC, the first publicly-available open-source machine learning-based compiler. It consists of an Interactive Compilation Interface (ICI) and plugins to extract program features and exchange optimization data with the cTuning.org open public repository. It automatically adapts the internal optimization heuristic at function-level granularity to improve execution time, code size and compilation time of a new program on a given architecture. Part of the MILEPOST technology together with low-level ICI-inspired plugin framework is now included in the mainline GCC.

We developed machine learning plugins based on probabilistic and transductive approaches to predict good combinations of optimizations. Our preliminary experimental results show that it is possible to automatically reduce the execution time of individual MiBench programs on various machines from GRID5000, some by more than a factor of 2, while also improving compilation time and code size. We also present a realistic multi-objective optimization scenario for Berkeley DB library using MILEPOST GCC and improve execution time by approximately 17%, while reducing compilation time and code size by 12% and 7% respectively on Intel Xeon processor.

6.6. Loop Transformations: Convexity, Pruning and Optimization

Participant: Cédric Bastoul.

High-level loop transformations are a key instrument in mapping computational kernels to effectively exploit resources in modern processor architectures. However, determining appropriate compositions of loop transformations to achieve this remains a significantly challenging task; current compilers may achieve significantly lower performance than hand-optimized programs. To address this fundamental challenge, we first present a convex characterization of all distinct, semantics-preserving, multidimensional affine transformations. We then bring together algebraic, algorithmic, and performance analysis results to design a tractable optimization algorithm over this highly expressive space. The framework has been implemented and validated experimentally on a representative set of benchmarks run on state-of-the-art multi-core platforms.

6.7. Exact algorithm for the l1-compressive sensing problem using a modified Dantzig-Wolfe method

Participants: Alexandre Borghi, Jerome Darbon, Sylvain Peyronnet.

In this work, we consider the l1-Compressive Sensing problem and presents an efficient algorithm that computes an exact solution. The idea consists in reformulating the problem such that it yields a modified Dantzig-Wolfe decomposition that allows to efficiently apply all standard simplex pivoting rules. Experimental results show the superiority of our approach compared to standard linear programming methods.

6.8. Supple: a flexible probabilistic data dissemination protocol for wireless sensor networks

Participants: Aline Carneiro Viana, Thomas Hérault, Thomas LArgillier, Sylvain Peyronnet, Fatiha Zaidi.

We propose a flexible proactive data dissemination approach for data gathering in self-organized Wireless Sensor Networks (WSN). Our protocol Supple, effectively distributes and stores monitored data in WSNs such that it can be later sent to or retrieved by a sink. Supple empowers sensors with the ability to make on the fly forwarding and data storing decisions and relies on flexible and self-organizing selection criteria, which can follow any predefined distribution law. Using formal analysis and simulation, we show that Supple is effective in selecting storing nodes that respect the predefined distribution criterion with low overhead and limited network knowledge.
6.9. Non-self-stabilizing and self-stabilizing gathering in networks of mobile agents— the notion of speed

Participants: Joffroy Beauquier, Janna Burman, Julien Clément, Shay Kutten.

In the population protocol model, each agent is represented by a finite state machine. Agents are anonymous and supposed to move in an asynchronous way. When two agents come into range of each other (“meet”), they can exchange information. One of the vast variety of motivating examples to the population protocols model is ZebraNet. ZebraNet is a habitat monitoring application where sensors are attached to zebras and collect biometric data (e.g. heart rate, body temperature) and information about their behavior and migration patterns (via GPS). The population protocol model is, in some sense, related to cloud computing and to networks characterized by asynchrony, large scale, the possibility of failures, in the agents as well as in the communications, with the constraint that each agent is resource limited.
